x_4 &=& .4 & 1 & 4 & \boxed{2} & 4 & \ldots \\
x_5 &=& .0 & 1 & 0 & 1 & \boxed{3} & \ldots \\
 & \vdots & & & & & &
\end{array}$$

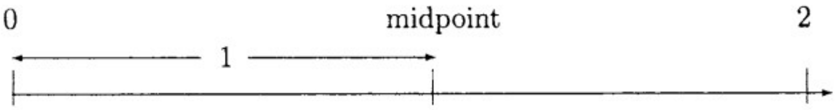
Then

$$x = .2\ 0\ 0\ 3\ 4\ \cdots.$$

The first decimal of x is 2 because the first decimal of x_1 is 1.
The second decimal of x is 0 because the second decimal of x_2 is 9.
The second decimal of x is 0 because the third decimal of x_3 is 9.
The fourth decimal of x is 3 because the fourth decimal of x_4 is 2.
The fifth decimal of x is 4 because the fifth decimal of x_5 is 3.

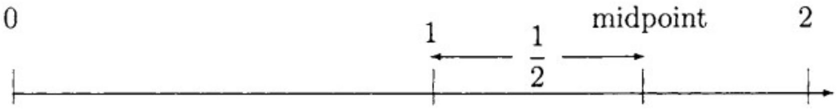
The comparisons of x to the numbers on our implied list are obvious.
$x \neq x_1$ because they differ in decimal place 1,
$x \neq x_2$ because they differ in decimal place 2,
$x \neq x_3$ because they differ in decimal place 3.
These comparisons continue indefinitely. In this way we show that x is not on the implied list $x_1, x_2, x_3, \ldots$.

There is a person at the Hotel who haunts the Lobby. Each day he tries to walk a 2 meter long straight line across the Lobby floor. He starts at one end of the line and wants to get to the other end, but he has a peculiar way of walking. His next step is always half the length of his previous step. He starts with a step of one meter. One meter remains to be crossed.



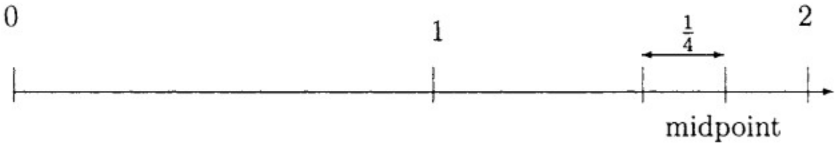
0
midpoint
2
1

He follows this with a $\frac{1}{2}$ meter step. Half a meter remains.



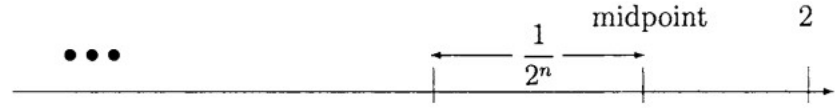
0
1
$\frac{1}{2}$
midpoint
2

Then he steps off a $\frac{1}{4} = \frac{1}{2^2}$ meter step. A $\frac{1}{4}$ meter remains.



0
1
$\frac{1}{4}$
2
midpoint

Continuing on, on his nth step he moves $\frac{1}{2^n}$ meters, and that leaves $\frac{1}{2^n}$ meters left to be covered. The scale is magnified.



• • •
$\frac{1}{2^n}$
midpoint
2

He continues on indefinitely. Upon completion there are 0 meters left to cover and so he has crossed

$$2 = 1 + \frac{1}{2} + \frac{1}{4} + \ldots + \frac{1}{2^n} + \ldots$$

meters. He has walked the entire 2 meter length.

Each of the rooms at Hilbert's Infinite Hotel has to be cleaned and there is one and only one cleaning lady to do the job. Her name is Mary. (Hilbert's mother needed a job.) Her routine is to clean the rooms in order. She begins in the morning with room 1, followed by room 2, and then room 3, and on inductively. She is an industrious woman who picks up momentum as her day progresses so she cleans the first room in 1 hour, the second room in $\frac{1}{2}$ hour, the next in $\frac{1}{2^2}$ hour, and so on, cleaning room n in $\frac{1}{2^n}$ hours. When she has cleaned each room she is done. Thus she works

$$1 + \frac{1}{2} + \frac{1}{4} + \ldots + \frac{1}{2^n} + \ldots = 2$$

hours a day. She certainly has a good job. She only has a 2 hour work day. But something else is wrong here. Where is she at the end of her day? There is no last room for her to clean because the Hotel has *infinitely many rooms*. However, we can be assured that each of the rooms is spotless. We will learn the fate of the cleaning lady when we finish our discussion of ordinals on page 184.

3.3 Equivalent Sets and Cardinality

In this section we will define the equivalence of cardinalities.

Definition 3.3.1 *Sets A and B are said to be* equivalent *if there is a bijection $f : A \longrightarrow B$.*

Theorem 3.3.2 *A and B are equivalent exactly when* $\mathrm{card}(A) = \mathrm{card}(B)$.

If we look at the different steps in Hilbert's Infinite Hotel we see that in making space for the lone stranger Hilbert used the fact that the function

$$f : \{1, 2, 3, \ldots\} \longrightarrow \{2, 3, 4, \ldots\}$$

defined by

$$f(n) = n + 1$$

The puzzle of pi

Squaring the Circle

PRIMES ARE AN OLD IDEA, but circles are even older. Circles led to a great problem that took more than 2000 years to solve. It is one of several related geometric problems that have come down to us from antiquity. The central character in the story is the number π (Greek 'pi') which we meet at school in connection with circles and spheres. Numerically it is 3.14159 and a bit; often the approximation 22/7 is used. The digits of π never stop, and they never repeat the same sequence over and over again. The current record for calculating digits of π is 10 trillion digits, by Alexander Yee and Chigeru Kondo in October 2011.[14] Computations like this are significant as ways to test fast computers, or to inspire and test new methods to calculate π, but very little hinges on the numerical results. The reason for being interested in π is not to calculate the circumference of a circle. The same strange number appears all over mathematics, not just in formulas related to circles and spheres, and it leads into very deep waters indeed. The school formulas are important, even so, and they reflect π's origins in Greek geometry.

There, one of the great problems was the unsolved task of squaring the circle. This phrase is often employed colloquially to indicate a wrong-headed approach to something, rather like trying to fit a square peg into a round hole. Like many common phrases extracted from science, this one's meaning has changed over the centuries.[15] In Greek times, trying to square the circle was a perfectly reasonable idea. The difference in the two shapes – straight or curved – is totally irrelevant:

similar problems have valid solutions.[16] However, it eventually turned out that this particular problem cannot be solved using the specified methods. The proof is ingenious and technical, but its general nature is comprehensible.

In mathematics, squaring the circle means constructing a square whose *area* is the same as that of a given circle, using the traditional methods of Euclid. Greek geometry actually permitted other methods, so one aspect of the problem is to pin down which methods are to be used. The impossibility of solving the problem is then a statement about the limitations of those methods; it doesn't imply that we can't work out the area of a circle. We just have to find another approach. The impossibility proof explains why the Greek geometers and their successors failed to find a construction of the required kind: there isn't one. In retrospect, that explains why they had to introduce more esoteric methods. So the solution, despite being negative, clears up what would otherwise be a big historical puzzle. It also stops people wasting time in a continuing search for a construction that doesn't exist – except for a few hardy souls who regrettably seem unable to get the message, no matter how carefully it is explained.[17]

In Euclid's *Elements* the traditional methods for constructing geometric figures are idealised versions of two mathematical instruments: the ruler and the compass. To be pedantic, compass*es*, for the same reason that you cut paper with scissor*s*, not with a scissor – but I will follow common parlance and avoid the plural. These instruments are used to 'draw' diagrams on a notional sheet of paper, the Euclidean plane.

Their form determines what they can draw. A compass comprises two rigid rods, hinged together. One has a sharp point, the other holds a sharp pencil. The instrument is used to draw a circle, or part of one, with a specific centre and a specific radius. A ruler is simpler: it has a straight edge, and is used to draw a straight line. Unlike the rulers you buy in stationery shops, Euclid's rulers have no marks on them, and this is an important restriction for the mathematical analysis of what they can create.

The sense in which the geometer's ruler and compass are idealisations is straightforward: they are assumed to draw infinitely thin lines. Moreover, the straight lines are exactly straight and the circles are perfectly round. The paper is perfectly flat and even. The other key ingredient of Euclid's geometry is the notion of a point, another ideal. A point is a dot on the paper, but it is a physical impossibility: it has no size. 'A point', said Euclid, in the first sentence of the *Elements*, 'is that which has no part.' This sounds a bit like an atom, or if you're clued into modern physics, a subatomic particle, but compared to a geometric point, those are gigantic. From an everyday human perspective, however, Euclid's ideal point, an atom, and a pencil dot on a sheet of paper, are similar enough for the purposes of geometry.

These ideals are not attainable in the real world, however carefully you make the instruments and sharpen the pencil, and however smooth you make the paper. But idealism can be a virtue, because these requirements make the mathematics much simpler. For instance, two pencil lines cross in a small fuzzy region shaped like a parallelogram, but mathematical lines meet at a single point. Insights gained from ideal circles and lines can often be transferred to real, imperfect ones. This is how mathematics works its magic.

Two points determine a (straight) line, the unique line that passes through them. To construct the line, place your ideal ruler so that it passes through the two points, and run your ideal pencil along it. Two points also determine a circle: choose one as the centre, and place the compass point there; then adjust it so that the tip of the pencil lies on the other point. Now swing the pencil round in an arc, keeping the central point fixed. Two lines determine a unique point, where they cross, unless they are parallel, in which case they don't cross, but a Pandora's box of logical issues yawns wide. A line and a circle determine two points, if they cross; one point, if the line cuts the circle at a tangent; nothing at all if the circle is too small to meet the line. Similarly two circles either meet in two points, one, or none.

Distance is a fundamental concept in the modern treatment of Euclidean geometry. The distance between any two points is measured along the line that joins them. Euclid managed to get his geometry working without an explicit concept of distance, by finding a way to say that two line segments have the *same* length without defining length itself. In fact, this is easy: just stretch a compass between the ends of one segment, transfer it to the second, and see if the ends fit. If they do, the lengths are equal; if they don't, they're not. At no stage do you measure an actual length.

From these basic ingredients, geometers can build up more interesting shapes and configurations. Three points determine a triangle unless they all lie on the same line. When two lines cross, they form an angle. A right angle is especially significant; a straight line corresponds to two right angles joined together. And so on, and so on, and so on. Euclid's *Elements* consists of 13 books, delving ever deeper into the consequences of these simple beginnings.

The bulk of the *Elements* consists of theorems – valid features of geometry. But Euclid also explains how to solve geometric problems, using 'constructions' based on ruler and compass. Given two points joined by a segment of a line, construct their midpoint. Or trisect the segment: construct a point exactly one third of the way along it. Given an angle, construct one that bisects it – is half the size. But some simple constructions proved elusive. Given an angle, construct one that trisects it – is one third the size. You can do that for line segments, but no one could find a method for angles. Approximations, as close as you wish, yes. Exact constructions using only an unmarked ruler and a compass: no. However, no one really needs to trisect angles exactly anyway, so this particular issue didn't cause much trouble.

More embarrassing was a construction that could not be ignored: given a circle, construct a square that has the same area. This is the problem of squaring the circle. From the Greek point of view, if you couldn't solve that, you weren't entitled to claim that a circle *had* an area. Even though it visibly encloses a well-defined space, and intuitively the area is *how much* space. Euclid and his successors, notably Archimedes, settled for a pragmatic solution: assume circles have areas, but don't expect to be able to construct squares with the same area. You can still say a lot; for instance, you can prove, in full logical rigour, that the area of a circle is proportional to the square of its diameter. What you can't do, without squaring the circle, is to construct a line whose length is the constant of proportionality.

The Greeks couldn't square the circle using ruler and compass, so they settled for other methods. One used a curve called a quadratrix.[18] The importance they attached to using only ruler and compass was exaggerated by some later commentators, and it's not even clear that the Greeks considered squaring the circle to be a vital issue. By the nineteenth century, however, the problem was becoming a major nuisance. Mathematics that was unable to answer such a straightforward question was like a cordon bleu cook who didn't know how to boil an egg.

Squaring the circle sounds like a problem in geometry. That's because it is a problem in geometry. But its solution turned out to lie not in geometry at all, but in algebra. Making unexpected connections between apparently unrelated areas of mathematics often lies at the heart of solving a great problem. Here, the connection was not entirely unprecedented, but its link to squaring the circle was not at first appreciated. Even when it was, there was a technical difficulty, and dealing with that required yet another area of mathematics: analysis, the rigorous version of calculus. Ironically, the first breakthrough came from a fourth area: number theory. And it solved a geometric problem that the Greeks would never in their wildest dreams have believed to possess a solution, and as far as we can tell never thought about: how to construct, with ruler and compass, a regular polygon with 17 sides.

It sounds mad, especially if I add that no such construction exists for regular polygons with 7, 9, 11, 13, or 14 sides, but one does for 3, 4, 5, 6, 8, 10, and 12. However, there is method behind the madness, and it is the method that enriched mathematics.

First: what is a regular polygon? A polygon is a shape bounded by straight lines. It is regular if those lines have equal length and meet at equal angles. The most familiar example is the square: all four sides have the same length and all four angles are right angles. There are other shapes with four equal sides or four equal angles: the rhombus and rectangle respectively. Only a square has both features. A regular 3-sided polygon is an equilateral triangle, a regular 5-sided polygon is a regular pentagon, and so on, Figure 4. Euclid provides ruler-and-compass constructions for regular polygons with 3, 4, and 5 sides. The Greeks also knew how to repeatedly double the number of sides, giving 6, 8, 10, 12, 16, 20, and so on. By combining the constructions for 3- and 5-sided regular polygons they could obtain a 15-sided one. But there, their knowledge stopped. And for about 2000 years that's how it remained. No one imagined that any other numbers were feasible.

They didn't even ask, it just seemed obvious that nothing more could be done.

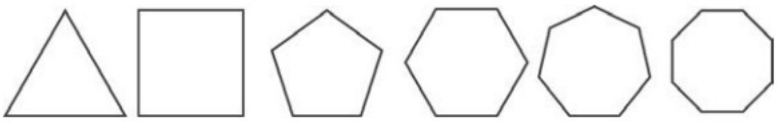

Fig 4 The first few regular polygons. *From left to right*: equilateral triangle, square, pentagon, hexagon, heptagon, octagon.

It took one of the greatest mathematicians who have ever lived to think the unthinkable, ask the unaskable, and discover a truly astonishing answer. Namely, Gauss Carl Friedrich. Gauss was born into a poor, working-class family in the city of Braunschweig (Brunswick) in Germany. His mother Dorothea could not read or write, and failed to write down the date of his birth, but she did remember that it was on a Wednesday, eight days before the feast of the ascension, in 1777. Gauss later worked out the exact date from a mathematical formula he devised for the date of Easter. His father Gebhard came from a farming family, but made a living in a series of low-level jobs: gardener, canal labourer, street butcher, funeral parlour accountant. Their son was a child prodigy who is reputed to have corrected his father's arithmetic at the age of three, and his abilities, which extended to languages as well as mathematics, led the Duke of Braunschweig to fund his university studies at the Collegium Carolinum. While an undergraduate Gauss independently rediscovered several important mathematical theorems that had been proved by illustrious people such as Euler. But his theorem about the regular 17-sided polygon came as a bolt from the blue.

By then, the close link between geometry and algebra had been understood for 140 years. In an appendix to *Discours de la Méthode* ('Discourse on the method') René Descartes formalised an idea that had been floating around in rudimentary form for some time: the notion of a coordinate system. In effect, this takes Euclid's barren plane, a blank sheet of paper, and turns it into paper ruled into squares, which engineers and scientists call graph paper. Draw two straight lines on the paper, one horizontal, the other vertical: these are

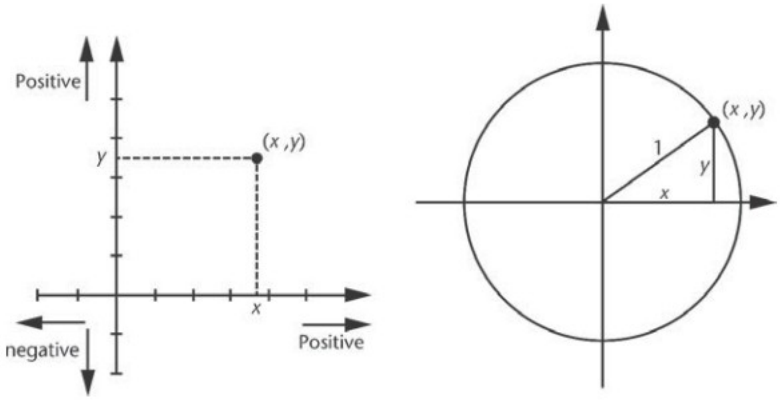

Fig 5 *Left*: Coordinates in the plane. *Right*: How to derive the equation for the unit circle.

called axes. Now you can pin down the location of any point of the plane by asking how far it lies in the direction along the horizontal axis, and how far up the vertical axis, Figure 5 (left). These two numbers, which may be positive or negative, provide a complete description of the point, and they are called its coordinates.

All geometric properties of points, lines, circles, and so on can be translated into algebraic statements about the corresponding coordinates. It's very difficult to talk meaningfully about these connections without using some actual algebra – just as it's hard to talk sensibly about football without mentioning the word 'goal'. So the next few pages will include some formulas. They are there to ensure that the main players in the drama have names and the relationship between them is clear. 'Romeo' is so much simpler to follow than 'the son of an Italian patriarch who falls in love with his father's sworn enemy's beautiful daughter'. Our Romeo will bear the prosaic name x, and his Juliet will be y.

As an example of how geometry converts into algebra, Figure 5 (right) shows how to find the equation for a circle of unit radius centred at the origin, where the two axes cross. The marked point has coordinates (x, y), so the right-angled triangle in the figure has horizontal side of length x and vertical side of length y. The longest side of the triangle is the radius of the circle, which is 1. Pythagoras's theorem now tells us that the sum of the squares of the two coordinates is 1. In symbols, a point with coordinates x and y lies on the circle if (and only if) it satisfies the condition $x^2 + y^2 = 1$. This symbolic characterisation of the circle is brief and precise, and it shows that we really are talking algebra. Conversely, any algebraic property of pairs of numbers, any equation involving x and y, can be reinterpreted as a geometric statement about points, lines, circles, or more elaborate curves.[19]

The basic equations of algebra involve polynomials, combinations of powers of an unknown quantity x, where each power is multiplied by some number, called a coefficient. The largest power of x that occurs is the degree of the polynomial. For example, the equation

$$x^4 - 3x^3 - 3x^2 + 15x - 10 = 0$$

involves a polynomial starting with x^4, so its degree is 4. The coefficients are 1, -3, -3, 15, and -10. There are four distinct solutions: $x = 1, 2, \sqrt{5}$, and $\sqrt{5}$. For these numbers the left-hand side of the equation is equal to zero – the right-hand side. Polynomials of degree 1, like $7x + 2$, are said to be linear, and they involve only the first power of the unknown. Equations of degree 2, like $x^2 - 3x + 2$, are said to be quadratic, and they involve the second power – the square. The equation for a circle involves a second variable, y. However, if we know a second equation relating x and y, for example the equation defining some straight line, then we can solve for y in terms of x and reduce the equation for a circle to one that involves only x. This new equation tells us where the line meets the circle. In this case the new equation is quadratic, with two solutions; this is how the algebra reflects the geometry, in which a line meets the circle at two distinct points.

This feature of the algebra has an important implication for ruler-and-compass constructions. Such a construction, however complicated, breaks up into a sequence of simple steps. Each step produces new points at places where two lines, two circles, or a line and a circle, meet. Those lines and circles are determined by previously constructed points. By translating geometry into algebra, it can be proved that the algebraic equation that corresponds to the intersection of two lines is always linear, while that for a line and a circle, or two circles, is quadratic. Ultimately this happens because the equation for a circle involves x^2 but no higher power of x. So every individual step in a construction corresponds to solving an equation of degree 1 or 2 only.

More complex constructions are sequences of these basic operations, and a certain amount of algebraic technique lets us deduce that each coordinate of any point that can be constructed by ruler and compass is a solution of a polynomial equation, with integer coefficients, whose degree is a power of 2. That is, the degree has to be one of the numbers 1, 2, 4, 8, 16, and so on.[20] This condition is necessary for a construction to exist, but it can be beefed up into a precise characterisation of which regular polygons are constructible. Suddenly a tidy algebraic condition emerges from a complicated geometric muddle – and it applies to *any construction whatsoever.* You don't even need to know what the construction is: just that it uses only ruler and compass.

Gauss was aware of this elegant idea. He also knew (indeed, any competent mathematician would quickly realise) that the question of which regular polygons can be constructed by ruler and compass boils down to a special case, when the polygon has a prime number of sides. To see why, think of a composite number like 15, which is 3×5. Any hypothetical construction of a 15-sided regular polygon automatically yields a 3-sided one (consider every fifth vertex) and a 5-sided one (consider every third vertex), Figure 6. With a bit more effort you can combine constructions for a 3-gon and a 5-gon to get a 15-gon.[21] The numbers 3 and 5 are prime, and the same idea applies in general. So Gauss focused on polygons with a prime number of sides, and asked what the relevant equation looked like. The answer was surprisingly neat. Constructing a regular 5-sided polygon, for example, is equivalent to solving the equation $x^5 - 1 = 0$. Replace 5 by any other prime, and the corresponding statement is true.

The degree of this polynomial is 5, which is *not* one of the powers of 2 that I listed; even so, a construction exists. Gauss quickly figured out why: the equation splits into two pieces, one of degree 1 and the other of degree 4. Both 1 and 4 are powers of 2, and it turns out that the degree-4 equation is the crucial one. To see why, we need to connect the equation to the geometry. That involves a new kind of number, one that is largely ignored in school mathematics but is indispensable for

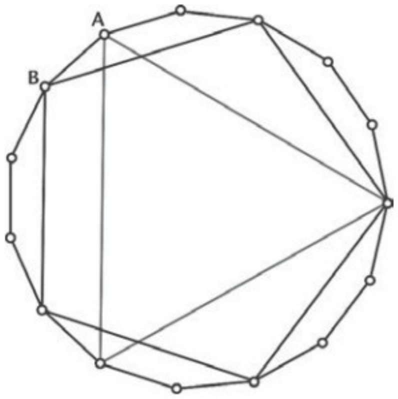

Fig 6 Constructing an equilateral triangle and a regular pentagon from a regular 15-gon. For the reverse, observe that A and B are consecutive points on the regular 15-gon.

anything beyond that. They are called complex numbers, and their defining feature is that in the complex number system −1 has a square root.[22]

An ordinary 'real' number is either positive or negative, and either way, its square is positive, so −1 can't be the square of any real number. This is such a nuisance that mathematicians invented a new kind of 'imaginary' number whose square is −1. They needed a new symbol for it, so they called it i (for 'imaginary'). The usual operations of algebra – adding, subtracting, multiplying, dividing – lead to combinations of real and imaginary numbers such as $3 + 2i$. These are said to be complex, which doesn't mean 'complicated', but indicates that they come in two parts: 3 and 2i. Real numbers lie on the famous number line, like the numbers on a ruler. Complex numbers lie in a number plane, in which an imaginary ruler is placed at right angles to a real one, and the two together form a system of coordinates, Figure 7 (left).

For the last 200 years, mathematicians have considered complex numbers to be fundamental to their subject. We now recognise that logically they are on the same footing as the more familiar 'real' numbers – which, like all mathematical structures, are abstract concepts, not real physical things. Complex numbers were in widespread use before the time of Gauss, but their status was still

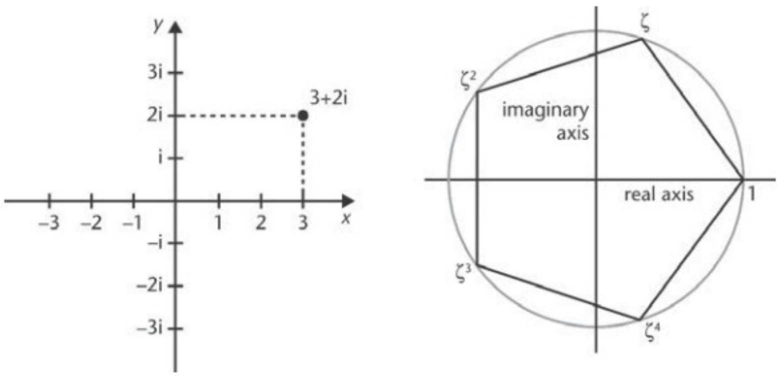

Fig 7 *Left*: The complex plane. *Right:* The complex fifth roots of unity.

mysterious until Gauss and several others demystified them. The source of their attraction was paradoxical: despite the mystery surrounding their meaning, complex numbers were much better behaved than real numbers. They supplied a missing ingredient that the real numbers lacked. They provided a complete set of solutions for an algebraic equation.

Quadratic equations are the simplest example. Some quadratics have two real solutions, while others have none. For example $x^2 - 1 = 0$ has the solutions 1 and -1, but $x^2 + 1 = 0$ has no solutions. In between is $x^2 = 0$, whose sole solution is 0, but there is a sense in which this is the same solution 'repeated twice'.[23] If we allow complex solutions, however, then $x^2 + 1 = 0$ also has two solutions: i and –i. Gauss had no qualms about using complex numbers; in fact, his doctoral thesis provided the first logically sound proof of the fundamental theorem of algebra: the number of complex solutions to any polynomial equation (with multiplicities counted correctly) is equal to the degree of the equation. So quadratics (degree 2) always have two complex solutions, cubics (degree 3) always have three complex solutions, and so on.

The equation $x^5 - 1 = 0$, which I claimed defines a regular pentagon, has degree 5. Therefore it has five complex solutions. There is just one real solution: $x = 1$. What about the other four? They provide four vertexes of a perfect regular pentagon in the complex plane, with $x = 1$ being the fifth, Figure 7 (right). This correspondence is an example of mathematical beauty: an elegant geometric shape becomes an elegant equation.

Now, the equation whose solutions are these five points has degree 5, which is not a power of 2. But, as mentioned earlier, the degree-5 equation splits into two pieces with degrees 1 and 4, called its irreducible factors:

$$x^5 - 1 = (x-1)\left(x^4 + x^3 + x^2 + x + 1\right)$$

('Irreducible' means that no further factors exist, just like prime numbers.) The first factor yields the real solution $x = 1$. The other factor yields the four complex solutions and the other four vertexes of the pentagon. So everything makes much more sense, and is far more elegant, when we use complex numbers.

It is often difficult to reconstruct how the mathematicians of the past arrived at new discoveries, because they had a habit of presenting only the final outcome of their deliberations, not the many false steps they took along the way. This problem is often compounded, because the natural thought patterns in past ages were different from today's. Gauss in particular was notorious for covering his tracks and publishing only his final, highly polished, analysis. But when it comes to Gauss's research on the 17-sided polygon, we are on fairly safe ground; the analysis that he eventually published provides several useful clues.

His starting-point was not new. Several earlier mathematicians were well aware that the above analysis of regular pentagons works in complete generality. Constructing a polygon with any number n of sides is equivalent to solving the equation $x^n - 1 = 0$ in complex numbers. Moreover, this polynomial factorises as

$$(x-1)\left(x^{n-1} + x^{n-2} + \cdots + x^2 + x + 1\right)$$

Again the first factor gives the real solution $x = 1$ and the remaining $n - 1$ solutions come from the second factor. When n is odd, these are all complex; when n is even, one of them is a second real solution $x = -1$.

What Gauss noticed, and everyone else had missed, is that sometimes the second factor can be expressed using a series of quadratic equations. Not by representing it as a product of simpler factors, because that's not possible, but by using equations whose coefficients solve other equations. The key fact here – the weak point in the problem – is an elegant property of algebraic equations, which arises when we solve several of them in turn in this manner. The calculation is always equivalent to solving a single equation, but the degree generally gets bigger. So the price we pay for having fewer equations is an increase in the degree. It can be messy, but there is one feature that we can predict: how big the degree becomes. Just multiply together the degrees of the successive polynomials.

If they are all quadratics, the result is $2 \times 2 \times \cdots \times 2$, a power of 2. So $n - 1$ must be a power of 2 if a construction exists. However, this condition is not always sufficient. When $n = 9$, $n - 1 = 8$, which is a power of 2. But Gauss discovered that no construction exists for the regular 9-gon. The reason is that 9 is not prime.[24] What about the next case, in which we solve a series of four quadratic equations? Now the degree $n - 1$ of the corresponding single equation is $2 \times 2 \times 2 \times 2 = 16$. So $n = 17$, and this is prime.

By this point Gauss must have known he was on to something, but there is a further technical point, possibly fatal. Gauss had convinced himself that in order for construction for a regular pentagon with a prime number of sides to exist, that prime must be a power of 2, plus 1. So this condition is necessary for a construction to exist: if it fails, there is no such construction. However, the condition might not be sufficient: in fact there are plenty of equations of degree 16 that do not reduce to a series of four quadratics.

There was a reason to be optimistic, however: the Greek constructions. Which primes occurred there? Only three: 2, 3, and 5. These are all 1 more than a power of 2, namely $2^0 + 1$, $2^1 + 1$, and $2^2 + 1$. The algebra associated with the pentagon provides further clues. Thinking it all through, Gauss proved that the degree-16 polynomial associated with the 17-sided polygon can indeed be reduced to a series of quadratics. Therefore a ruler-and-compass construction must exist. A similar method proved that the same is true whenever the number of sides is a prime that is 1 greater than some power of 2. The ideas are a tribute to Gauss's ability to understand mathematical patterns. At their heart are some general theorems in number theory, which I won't go into here. The point is, none of this was accidental. There were solid structural reasons for it to work. You just had to be a Gauss to notice them.

Gauss didn't provide an explicit construction, but he did give a formula for the solutions of the degree-16 equation that can be turned into such a construction if you really want one.[25] When he wrote down his ideas in the *Disquisitiones Arithmeticae*, he omitted quite a few of the details, but he did assert that he possessed complete proofs. His epic discovery convinced him that he should devote his life to mathematics rather than languages. The Duke continued to support Gauss financially, but Gauss wanted something more permanent and reliable. When the astronomer Giuseppe Piazzi discovered the first asteroid, Ceres, only a few observations could be made before this new world became invisible against the glare of the Sun. Astronomers were worried that they wouldn't be able to find it again. In a *tour de force* that involved new techniques for calculating orbits, Gauss predicted where it would reappear – and he was right. This led to him being appointed Professor of Astronomy and Director of the Göttingen Observatory. He continued to hold the post for the rest of his life.

It turns out that 17 is not the only new number of this kind. Two more are known: $2^8 + 1 = 257$ and $2^{16} + 1 = 65,537$. (A bit of algebra shows that the power of 2 that occurs must itself be a power of 2; if not, then the number cannot be prime.) However, the pattern stops at that point, because $2^{32} + 1 = 4,294,967,297$ is equal to $641 \times 6,700,417$, hence is not prime. The so-called Fermat numbers $2^{2^n} + 1$ are known not to be prime for $n = 5, 6, 7, \ldots$ up to 32. Many larger Fermat numbers are also known not to be prime. No further prime Fermat numbers have been found, but their existence is by no means impossible.[26] A construction for the 257-sided polygon is known. One mathematician devoted many years to the 65,537-sided polygon, a somewhat pointless task, and his results contain errors anyway.[27]

The upshot of Gauss's analysis is that a regular polygon can be constructed with ruler and compass if and only if the number of sides is a product of a power of 2 and *distinct* odd prime Fermat numbers. In particular, a regular 9-sided polygon cannot be constructed in this manner. This immediately implies that at least one angle cannot be trisected, because the angle in an equilateral triangle is 60 degrees, and one third of that is 20 degrees. Given this angle, it is easy to construct a regular 9-sided polygon. Since that is impossible, there is no general ruler-and-compass construction to trisect an angle.

Gauss omitted many details of the proofs when he wrote up his results, and mathematicians couldn't simply take his word for it. In 1837 the French mathematician Pierre Wantzel published a complete proof of Gauss's characterisation of constructible regular polygons, and deduced the impossibility of trisecting a general angle by ruler-and-compass construction. He also proved that it is impossible to construct a cube whose volume is twice that of a given cube, another ancient Greek problem known as 'duplicating the cube'.

Both angle-trisection and cube-duplication turn out to be impossible because the lengths involved satisfy irreducible *cubic* equations – degree 3. Since 3 is not a power of 2, this knocks the question on the head. However, this method didn't seem to work for the problem of squaring the circle, for interesting reasons. A circle of unit radius has area π, and square of that area has side $\sqrt{\pi}$. Geometric constructions for square roots exist, and so do constructions for squares, so squaring the circle boils down to starting with a line of length 1 and constructing one of length π. If π happened to satisfy an irreducible cubic equation – or any irreducible equation whose degree is not a power of 2 – then Wantzel's methods would prove that it's impossible to square the circle.

However, no one knew any algebraic equation that was satisfied exactly by π, let alone one whose degree is not a power of 2. The school value 22/7 satisfies $7x - 22 = 0$, but that's just an approximation to π, a tiny bit too large, so it doesn't help. If it could be proved that no such equation exists – and many suspected this on the grounds that it would have been found if it did – the impossibility of squaring the circle would follow. Unfortunately, no one could prove that there is no such equation. The algebraic status of π was in limbo. The eventual solution employed methods that did not just go beyond geometry: they went beyond algebra as well.

To appreciate the main issue here, we need to start with a simpler idea. There is an important distinction in mathematics between numbers that can be expressed as exact fractions p/q, where p and q

are whole numbers, and those that can't be so expressed. The former are said to be rational (they are ratios of whole numbers), and the latter are irrational. The approximation 22/7 to π is rational, for example. There are better approximations; a famous one is 355/113, correct to six decimal places. However, it is known that no fraction can represent π exactly: it is irrational. This long-suspected property was first proved by the Swiss mathematician Johann Heinrich Lambert in 1768. His proof is based on a clever formula for the tangent function in trigonometry, which he expressed as a continued fraction: an infinite stack of ordinary fractions.[28] In 1873 Charles Hermite found a simpler proof, based on formulas in calculus, which went further: it proved that π^2 is irrational. Therefore π is not the square root of a rational number either.

Lambert suspected something much stronger. In the article that proved π to be irrational, he conjectured that π is transcendental; that is, π does not satisfy any polynomial equation with integer coefficients. It transcends algebraic expression. Subsequent discoveries proved him right. The breakthrough came in two stages. Hermite's new method for proving irrationality set the scene by hinting that calculus – more precisely, its rigorous version, analysis – might be a useful strategy. By pushing that idea further, Hermite found a wonderful proof that the other famous curious number in mathematics, the base e of natural logarithms, is transcendental. Numerically, e is roughly 2.71828, and if anything it is even more important than π. Hermite's transcendence proof is magical, a rabbit extracted with a flourish from the top hat of analysis. The rabbit is a complicated formula related to a hypothetical algebraic equation that e is assumed to satisfy. Using algebra, Hermite proves that this formula is equal to some nonzero integer. Using analysis, he proves that it must lie between $-\frac{1}{2}$ and $\frac{1}{2}$. Since the only integer in this range is zero, these results are contradictory. Therefore the assumption that e satisfies an algebraic equation must be false, so e is transcendental.

In 1882 Ferdinand Lindemann added some bells and whistles to Hermite's method, and proved that if a nonzero number satisfies an algebraic equation, then e raised to the power of that number does not satisfy an algebraic equation. He then took advantage of a relationship that was known to Euler involving π, e, and the imaginary number i: the famous formula $e^{i\pi} = -1$. Suppose that π satisfies some algebraic equation. Then so does $i\pi$, and Lindemann's theorem implies that -1 does *not* satisfy an algebraic equation. However, it visibly does: it is the solution of $x + 1 = 0$. The only way out of this logical contradiction is that π does not satisfy an algebraic equation; that is, it is transcendental. And that means you can't square the circle.

It was a long and indirect journey from Euclid's geometry to Lindemann's proof, and it took more than 2000 years, but mathematicians finally got there. The story doesn't just tell us that the circle can't be squared. It is an object lesson in how great mathematical problems get solved. It required mathematicians to formulate carefully what they meant by 'geometric construction'. They had to pin down general features of such constructions that might place limits on what they could achieve. Finding those features required making connections with another area of mathematics: algebra. Solving the algebraic problem, even in simpler cases such as the construction of regular polygons, also involved number theory. Dealing with the difficult case of π required further innovations, and the problem had to be transported into yet another area of mathematics: analysis.

None of these steps was simple or obvious. It took about a century to complete the proof, even when the main ideas were in place. The mathematicians involved were among the best of their age, and at least one was among the best of *any* age. Solving great problems requires a deep understanding of mathematics, plus persistence and ingenuity. It can involve years of concentrated effort, most of it apparently fruitless. But imagine how it must feel when your persistence pays off, and you crack wide open something that has baffled the rest of humanity for centuries. As President John F. Kennedy said in 1962 when announcing the Moon landing project: 'We choose to ... do [these] ... things, not because they are easy, but because they are hard.'

Few stories in mathematics end, and π is no exception. Every so often, amazing new discoveries about π appear. In 1997 Fabrice Bellard announced that the trillionth digit of π, in binary notation, is 1.[29] What made the statement remarkable was not the answer. The amazing feature was that he didn't calculate any of the earlier digits. He just plucked one particular digit from the air.

The calculation was made possible by a curious formula for π discovered by David Bailey, Peter Borwein, and Simon Plouffe in 1996. It may seem a bit complicated, but let's take a look anyway:

$$\pi = \sum_{n=0}^{\infty} \frac{1}{2^{4n}} \left(\frac{4}{8n+1} - \frac{2}{8n+4} - \frac{1}{8n+5} - \frac{1}{8n+6} \right)$$

The big Σ means 'add up', over the range specified. Here n runs from 0 to infinity (∞). Bellard actually used a formula that he had derived using similar methods, which is marginally faster for computations:

$$\pi = \frac{1}{64} \sum_{n=0}^{\infty} \frac{(-1)^n}{2^{10n}} \left(-\frac{32}{4n+1} - \frac{1}{4n+3} + \frac{256}{10n+1} - \frac{64}{10n+3} \right.$$
$$\left. - \frac{4}{10n+5} - \frac{4}{10n+7} + \frac{1}{10n+9} \right)$$

The key point is that many of the numbers that occur here – 1, 4, 32, 64, 256, and also 2^{4n} and 2^{10n} – are powers of 2, which of course are very simple in the binary system used for the internal workings of computers. This discovery stimulated a flood of new formulas for π, and for several other interesting numbers. The record for finding a single binary digit of π is broken regularly: in 2010 Yahoo's Nicholas Sze computed the two-quadrillionth binary digit of π, which turns out to be 0.

The same formulas can be used to find isolated digits of π in arithmetic to the bases 4, 8, and 16. Nothing of the kind is known for any other base; in particular, we can't compute decimal digits in isolation. Do such formulas exist? Until the Bailey-Borwein-Plouffe formula was found, no one imagined it could be done in binary.

whole numbers, you now allow yourself to replace any multiple of 12 by zero. For example, $5 \times 5 = 25$, but 24 is twice 12, so subtracting 24 we obtain $5 \times 5 = 1$ to the modulus 12. Modular arithmetic is very pretty, because nearly all of the usual rules of arithmetic still work. The main difference is that you can't always divide one number by another, even when it's not zero. Modular arithmetic is also useful, because it provides a tidy way to deal with questions about divisibility: which numbers are divisible by the chosen modulus, and what is the remainder when they're not? Gauss introduced modular arithmetic in the *Disquisitiones Arithmeticae*, and today it is widely used in computer science, physics, and engineering, as well as mathematics.

Fermat's theorem states that if we choose a prime modulus p, and take any number a that is not a multiple of p, then the $(p-1)$ th power of a is equal to 1 in arithmetic to the modulus p. Suppose, for example, that $p = 17$ and $a = 3$. Then the theorem predicts that when we divide 3^{16} by 17, the remainder is 1. As a check,

$$3^{16} = 43,046,721 = 2,532,160 \times 17 + 1$$

No one in their right mind would want to do the sums that way for, say, 100-digit primes. Fortunately, there is a clever, quick way to carry out this kind of calculation. The point is that if the answer is not equal to 1 then the modulus we started with is composite. So Fermat's theorem forms the basis of an efficient test that provides a necessary condition for a number to be prime.

Unfortunately, the test is not sufficient. Many composite numbers, known as Carmichael numbers, pass the test. The smallest is 561, and in 2003 Red Alford, Andrew Granville, and Carl Pomerance proved, to general amazement, that there are infinitely many. The amazement was because they found a proof; the actual result was less of a surprise. In fact, they showed that there are at least $x^{2/7}$ Carmichael numbers less than or equal to x if x is large enough.

However, more sophisticated variants of Fermat's theorem can be turned into genuine tests for primality, such as one published in 1976 by Gary Miller. Unfortunately, the proof of the validity of Miller's test depends on an unsolved great problem, the generalised Riemann hypothesis, chapter 9. In 1980 Michael Rabin turned Miller's test into a probabilistic one, a test that might occasionally give the wrong answer. The exceptions, if they exist, are very rare, but they can't be ruled out altogether. The most efficient deterministic (that is, guaranteed correct) test to date is the Adleman-Pomerance-Rumely test, named for Leonard Adleman, Pomerance, and Robert Rumely. It uses ideas from number theory that are more sophisticated than Fermat's theorem, but in a similar spirit.

I still vividly recall a letter from one hopeful amateur, who proposed a variant of trial division. Try all possible divisors, but start at the square root and work *downwards*. This method sometimes gets the answer more quickly than doing things in the usual order, but as the numbers get bigger it runs into the same kind of trouble as the usual method. If you try it on my example above, the 22-digit number 1,080,813,321,843,836,712,253, then the square root is about 32,875,725,419. You have to try 794,582,971 prime divisors before you find one that works. This is *worse* than searching in the usual direction.

In 1956 The famous logician Kurt Gödel, writing to John von Neumann, echoed Gauss's plea. He asked whether trial division could be improved, and if so, by how much. Von Neumann didn't pursue the question, but over the years others answered Gödel by discovering practical methods for finding primes with up to 100 digits, sometimes more. These methods, of which the best known is called the quadratic sieve, have been known since about 1980. However, nearly all of them are either probabilistic, or they are inefficient in the following sense.

How does the running time of a computer algorithm grow as the input size increases? For primality testing, the input size is not the number concerned, but how many digits it has. The core distinction in such questions is between two classes of algorithms called P and not-P. If the running time grows like some fixed power of the input size, then the algorithm is class P; otherwise, it's not-P. Roughly speaking, class P algorithms are useful, whereas not-P algorithms are impractical, but there's a stretch of no-man's-land in between where other considerations come into play. Here P stands for 'polynomial time', a fancy way to talk about powers, and we return to the topic of efficient algorithms in chapter 11.

By the class P standard, trial division performs very badly. It's all right in the classroom, where the numbers that occur have two or three digits, but it's completely hopeless for 100-digit numbers. Trial division is firmly in the not-P class. In fact, the running time is roughly $10^{n/2}$ for an n-digit number, which grows faster than any fixed power of n. This type of growth, called exponential, is *really* bad, computational cloud-cuckoo-land.

Until the 1980s all known algorithms for primality testing, excluding probabilistic ones or those whose validity was unproved, had exponential growth rate. However, in 1983 an algorithm was found that lies tantalisingly in the no-man's-land adjacent to P territory: the aforementioned Adleman-Pomerance-Rumely test. An improved version by Henri Cohen and Hendrik Lenstra has running time n raised to the power log log n, where log denotes the logarithm. Technically, log log n can be as large as we wish, so this algorithm is not in class P. But that doesn't prevent it being practical: if n is a googolplex, 1 followed by 10^{100} zeros, then log log n is about 230. An old joke goes: 'It has been proved that log log n tends to infinity, but it has never been observed doing it.'

The first primality test in class P was discovered in 2002 by Manindra Agrawal and his students Neeraj Kayal and Nitin Saxena, who were undergraduates at the time. I've put some details in the Notes.[10] They proved that their algorithm has running time proportional to at most n^{12}; this was quickly improved to $n^{7.5}$. However, even though their algorithm is class P, hence classed as 'efficient', its advantages don't show up until the number n becomes very large indeed. It should beat the Adleman-Pomerance-Rumely test when the number of *digits* in n is about 10^{1000}. There isn't room to fit a number that big into a computer's memory, or, indeed, into the known universe. However, now that we *know* that a class P algorithm for primality testing exists, it becomes worthwhile to look for better ones. Lenstra and Pomerance reduced the power from 7.5 to 6. If various other conjectures about primes are true, then the power can be reduced to 3, which starts to look practical.

The most exciting aspect of the Agrawal-Kayal-Saxena algorithm, however, is not the result, but the method. It is simple – to mathematicians, anyway – and novel. The underlying idea is a variant of Fermat's theorem, but instead of working with numbers, Agrawal's team used a polynomial. This is a combination of powers of a variable x, such as $5x^3 + 4x - 1$. You can add, subtract, and multiply polynomials, and the usual algebraic laws remain valid. Chapter 3 explains polynomials in more detail.

This is a truly lovely idea: expand the domain of discourse and transport the problem into a new realm of thought. It is one of those ideas that are so simple you have to be a genius to spot them. It developed from a 1999 paper by Agrawal and his PhD supervisor Somenath Biswas, giving a probabilistic primality test based on an analogue of Fermat's theorem in the world of polynomials. Agrawal was convinced that the probabilistic element could be removed. In 2001 his students came up with a crucial, rather technical, observation. Pursuing that led the team into deep number-theoretic waters, but eventually everything was reduced to a single obstacle, the existence of a prime p such that $p - 1$ has a sufficiently large prime divisor. A bit of asking around and searching the Internet led to a theorem proved by Etienne Fouvry in 1985 using deep and technical methods. This was exactly what they needed to prove that their algorithm worked, and the final piece of the jigsaw slotted neatly into place.

In the days when number theory was safely tucked away inside its own little ivory tower, none of this would have mattered to the rest of the world. But over the last 20 years, prime numbers have become important in cryptography, the science of secret codes. Codes aren't just important for military use; commercial companies have secrets too. In this Internet age, we all do: we don't want criminals to gain access to our bank accounts, credit card numbers, or, with the growth of identity theft, the name of our cat. But the Internet is such a convenient way to pay bills, insure cars, and book holidays, that we have to accept some risk that our sensitive, private information might fall into the wrong hands.

Computer manufacturers and Internet service providers try to reduce that risk by making various encryption systems available. The involvement of computers has changed both cryptography and cryptanalysis, the dark art of code-breaking. Many novel codes have been devised, and one of the most famous, invented by Ron Rivest, Adi Shamir, and Leonard Adleman in 1978, uses prime numbers. Big ones, about a hundred digits long. The Rivest-Shamir-Adleman system is employed in many computer operating systems, is built into the main protocols for secure Internet communication, and is widely used by governments, corporations, and universities. That doesn't mean that every new result about primes is significant for the security of your Internet bank account, but it adds a definite frisson of excitement to any discovery that relates primes to computation. The Agrawal-Kayal-Saxena test is a case in point. Mathematically, it is elegant and important, but it has no direct practical significance.

It does, however, cast the general issue of Rivest-Shamir-Adleman cryptography in a new and slightly disturbing light. There is still no class P algorithm to solve Gauss's second problem, factorisation. Most experts think nothing of the kind exists, but they're not quite as sure as they used to be. Since new discoveries like the Agrawal-Kayal-Saxena test can lurk unsuspected in the wings, based on such simple ideas as polynomial versions of Fermat's theorem, cryptosystems based on prime factorisation might not be quite as secure as we fondly imagine. Don't reveal your cat's name on the Internet just yet.

Even the basic mathematics of primes quickly leads to more advanced concepts. The mystery becomes even deeper when we ask subtler questions. Euclid proved that the primes go on for ever, so we can't just list them all and stop. Neither can we give a simple, useful algebraic formula for successive primes, in the way that x^2 specifies squares. (There do exist simple formulas, but they 'cheat' by building the primes into the formula in disguise, and don't tell us anything new.[11]) To grasp the nature of these elusive, erratic numbers, we can carry out experiments, look for hints of structure, and try to prove that these apparent patterns persist no matter how large the primes become. For instance, we can ask how the primes are distributed among all whole numbers. Tables of primes strongly suggest that they tend to thin out as they get bigger. Table 1 shows how many primes there are in various ranges of 1000 consecutive numbers.

The numbers in the second column mostly decrease as we move down the rows, though sometimes there are brief periods when they go the other way: 114 is followed by 117, for instance. This is a symptom of the irregularity of the primes, but despite that, there is a clear general tendency for primes to become rarer as their size increases. The

range	number of primes
1–1000	168
1001–2000	135
2001–3000	127
3001–4000	119
4001–5000	118
5001–6000	114
6001–7000	117
7001–8000	106
8001–9000	110
9001–10,000	111

Table 1 The number of primes in successive intervals of 1000 numbers.

reason is not far to seek: the bigger a number becomes, the more potential factors there are. Primes have to avoid all of these factors. It's like fishing for non-primes with a net: the finer the net becomes, the fewer primes slip through.

The 'net' even has a name: the sieve of Eratosthenes. Eratosthenes of Cyrene was an ancient Greek mathematician who lived around 250 BC. He was also an athlete with interests in poetry, geography, astronomy, and music. He made the first reasonable estimate of the size of the Earth by observing the position of the Sun at noon in two different locations, Alexandria and Syene – present-day Aswan. At noon, the Sun was directly overhead at Syene, but about 7 degrees from the vertical at Alexandria. Since this angle is one fiftieth of a circle, the Earth's circumference must be 50 times the distance from Alexandria to Syene. Eratosthenes couldn't measure that distance directly, so he asked traders how long it took to make the journey by camel, and estimated how far a camel typically went in a day. He gave an explicit figure in a unit known as a *stadium*, but we don't know how long that unit was. Historians generally think that Eratosthenes's estimate was reasonably accurate.

His sieve is an algorithm to find all primes by successively eliminating all multiples of numbers already known to be prime. Figure 2 illustrates the method on the numbers up to 102, arranged to

Important:

For surfaces ($n=2$) the answer to the above question is known.

The best Riemannian structures on a given compact surface M are those of constant curvature.

In dimension 2 there is only one notion of curvature, namely the Gauss curvature, which is a function $K: M \to \mathbb{R}$. If M is embedded in $\mathbb{R}^3$

to the *compact* case. If one looks on Einstein manifolds as critical points of the U functional (see 0.12 or Chapter 4) then it is reasonable to hope for an existence result in the compact case (even if this approach is disappointing in the end, see 4.1). The non-compact case remains interesting nevertheless (see Chapter 15).

0.5. For surfaces ($n = 2$) the answer to the above question is known. The best Riemannian structures on a given compact surface M are those of *constant curvature*. In dimension 2, there is only one notion of curvature, namely the Gauss curvature, which is a function $K\colon M \to \mathbb{R}$. If M is embedded in $\mathbb{R}^3$ with the induced natural Riemannian metric, the Gauss curvature is the product of the principal curvatures, or the inverse of the product of the principal radii of curvature. There exists at least one Riemannian metric of constant curvature on any compact surface and the constant can be normalized by scaling to $+1, 0, -1$. Moreover, on a given M, the Riemannian structures of constant given curvature 1, 0 or -1 form a nice finite dimensional submanifold—with singularities—of $\mathscr{M}/\mathfrak{D}$, the so-called *Moduli Space*. For example, on S^2 (the 2-dimensional sphere) and on $\mathbb{R}P^2$ (the real projective plane) there exists exactly one Riemannian structure of constant curvature equal to 1. On a compact surface M, orientable or not, with Euler characteristic $\chi(M) < 0$, the Riemannian structures with constant curvature -1 depend on $-3\chi(M)$ real parameters. For example, $6\gamma - 6$ parameters when M is orientable and of genus γ. For more detail, see 12.B.

0.6. What would a natural generalization of the concept of constant curvature be, for a Riemannian manifold, when the dimension is greater than 2? We claim that a good generalization would be the notion of *constant Ricci curvature*.

0.7. For Ricci curvature the reader can refer to Chapter 1. Here we shall simply say this. The Ricci curvature of a Riemannian manifold (M, g) is a quadratic differential form (alias a bilinear symmetric form), *denoted by* r (or r_g if the metric needs to be specified). By diagonal restriction r defines a function (still denoted by r) on the unit tangent bundle UM of M. This function r is the trace of the curvature endomorphism defined as follows by the curvature 4-tensor R: $r(x) = \operatorname{trace}(z \mapsto R(x, z)x)$. Equivalently, for x in UM, the value $r(x)$ is the sum $\sum_{i=2}^{n} K(x, x_i)$ of the sectional curvatures $K(x, x_i)$ for any completion of x to an orthonormal basis $(x, x_2, \ldots, x_n)$.

0.8. A Riemannian manifold has three main notions of curvature. i) The Riemann *curvature tensor* R (equivalent to the *sectional curvature* function, K, defined on tangent planes) which is a biquadratic form giving complete information, at the curvature level, on g. ii) The Ricci curvature above, r, the trace of R with respect to g. iii) Finally, the scalar curvature, s, a scalar function on M, which is the trace $s = \operatorname{trace}_g r$ with respect to g of the quadractic form r. Note first that when $n = 2$ the three curvatures are equivalent. When $n = 3$ the Ricci curvature contains as much information as the Riemann curvature tensor. This is the main reason why our book is devoted to manifolds of dimension greater than or equal to 4.

1.61 Definitions. Let (M, g) be a Riemannian manifold.

(a) Given a piecewise smooth curve $c\colon [a, b] \to M$, the *length* of c is

$$L(c) = \int_a^b \sqrt{g(\dot{c}, \dot{c})}\, dt.$$

(b) For each pair of points x and y in M, we *denote* by $d(x, y)$ the infimum of the lengths of all piecewise smooth curves starting from x and ending at y.

Note that in (a), if c is a geodesic, then $g(\dot{c}, \dot{c})$ is constant and $L(c) = (b - a)\sqrt{g(\dot{c}, \dot{c})}$; in (b), the infimum $d(x, y)$ may or may not be realized by a curve.

1.62 Theorem. *Given a Riemannian manifold (M, g), the function d is a distance on M, and the topology of the metric space (M, d) is the same as the manifold topology of M.*

A corollary of the Gauss Lemma 1.46 is that the distance is realized (at least locally) by geodesics. More precisely

1.63 Theorem. *For each x in M, there is a neighborhood U_x in M such that, for any y in U_x, the distance $d(x, y)$ is the length of the unique geodesic from x to y in U_x.*

1.64 Corollary. *Any geodesic minimizes the length between any pair of sufficiently near points on it; conversely, any curve having this property is (up to reparameterization) a geodesic.*

Also there is a notion of completeness of a metric space. Fortunately, these notions are as compatible as they can be. This is the content of the following theorem.

1.65 Theorem (H. Hopf-W. Rinow). *For a Riemannian manifold (M, g), the following conditions are equivalent.*

a) *(M, g) is complete for the Levi-Civita connection;*

b) *(M, d) is a complete metric space;*

c) *the bounded subsets of M are relatively compact.*

And these properties imply that

d) *for any two points x, y in M, there exists at least a geodesic starting at x and ending at y.*

Note however that there may be many more than one geodesic connecting x and y and that property d) does not imply the completeness of (M, g).

1.66 Corollary. *A compact Riemannian manifold is complete.*

(This need not be true for pseudo-Riemannian manifolds, even in the homogeneous case, see Chapter 7).

Note that a geodesic connecting two points does not necessarily realize the component of the fixed point set of the isometry group generated by reflection of $\mathbb{R}$ about t and reflections of S^2 about great circles through p. The vector field $\frac{\partial}{\partial t}$ is a Jacobi field along $\gamma_{(t,p)}$ and hence

$$K\left(\frac{\partial}{\partial t} \wedge \frac{\partial}{\partial \rho}\right) = \left\langle D^2_{\partial/\partial\rho}\frac{\partial}{\partial t}, \frac{\partial}{\partial t}\right\rangle \Big/ \left\|\frac{\partial}{\partial t} \wedge \frac{\partial}{\partial \rho}\right\|^2 = F''/F. \tag{3.35a}$$

Similarly, for each unit vector x tangent to S^2, $\partial/\partial\theta$ is a Jacobi field along γ, where θ is the angular coordinate on the great circle S^1 in S^2 generated by x, and hence

$$K\left(\frac{\partial}{\partial \rho} \wedge x\right) = \left\langle D^2_{\partial/\partial\rho}\frac{\partial}{\partial \theta}, \frac{\partial}{\partial \theta}\right\rangle \Big/ \left\|\frac{\partial}{\partial \theta} \wedge \frac{\partial}{\partial \rho}\right\|^2 = G''/G. \tag{3.35b}$$

In other words, we have computed the curvature of 2-dimensional totally geodesic subspaces in Gaussian coordinates.

We can obtain the rest of the relevant sectional curvatures by observing that on each $\rho =$ constant hypersurface $\mathbb{R} \times \{\rho\} \times S^2$ the induced metric is the product metric

$$g_\rho = F^2(\rho)\,dt^2 - G^2(\rho)\,d\sigma^2$$

and the second fundamental form of this hypersurface with respect to the unit normal vector field $\frac{\partial}{\partial \rho}$ is given by $\left(\frac{D}{\partial \rho} g_\rho\right)(x, y) = -2g_\rho(S \cdot x, y)$, hence

$$S = \begin{pmatrix} -FF' & 0 \\ 0 & -GG'h \end{pmatrix},$$

where $h = d\sigma^2$. Hence, by the Gauss equation,

$$K\left(\frac{\partial}{\partial t} \wedge x\right) = \frac{F'}{F}\cdot\frac{G'}{G}, \tag{3.35c}$$

whenever x is tangent to S^2, and

$$K(x \wedge y) = -\frac{1}{G^2} + \left(\frac{G'}{G}\right)^2, \tag{3.35d}$$

whenever both x and y are tangent to S^2.

3.36. It follows that the eigenvalues of the Ricci tensor are

$$r_t = \frac{F''}{F} + 2\frac{F'}{F}\cdot\frac{G'}{G}, \tag{3.36a}$$

$$r_\rho = \frac{F''}{F} + 2\frac{G''}{G}, \tag{3.36b}$$

and

$$r_x = \frac{G''}{G} + \frac{F'}{F}\cdot\frac{G'}{G} - \frac{1}{G^2} + \left(\frac{G'}{G}\right)^2 \qquad \text{(repeated)}. \tag{3.36c}$$

(B % '' 5 ! .

See [Koo] or [Laf 3] for further study of the equation $s_g'^* \cdot f = 0$. It is not difficult to see that the preceding proposition does not give the best possible result. Indeed, for the standard product metric on $S^2 \times S^3$, $s/4$ is an eigenvalue of the Laplacian, but $\operatorname{Ker} s_g'^* = 0$. Anyway, the condition that $s_g/(n-1)$ does not belong to the spectrum will appear again as an important property in the next paragraph.

4.38 Lemma (see [Ka-Wa 2] for the proof). *If* $\dim M \geqslant 2$ *and if* $f \in C^0(M)$, *then an* L^p*-function belongs to the* L^p*-closure of the set* $\{f \circ \varphi, \varphi \in \mathfrak{D}\}$ *if and only if* $\inf f \leqslant f_1(x) \leqslant \sup f$ *almost everywhere.*

4.39 Lemma. *Let* $f_0 \in \mathscr{C}M$ *be the scalar curvature of some metric. If* $f_1 \in \mathscr{C}M$ *is such that, for a positive real number* λ, *the inclusion* $\lambda(\operatorname{Im}(f_0)) \subset \operatorname{Im}(f_1)$ *holds, then* f_1 *is also the scalar curvature of some metric.*

Proof of the lemma. After a homothetic change of metrics, we may suppose that $\lambda = 1$. If $f_0 = s_{g_0}$ and $\operatorname{Ker} s_{g_0}'^* = 0$, apply the inverse function theorem 4.36 to g_0, and take φ in $\mathfrak{D}$ such that $\|f - f_1 \circ \varphi\|_p < \varepsilon$. If $\operatorname{Ker} s_{g_0}'^* \neq 0$ (which by 4.37 implies that s_{g_0} is constant), we can find a metric g_2 such that $\operatorname{Im}(s_{g_2}) \subset \operatorname{Im}(f_1)$ still holds (take g_2 close enough to g_0), but s_{g_2} is no longer a constant. Then apply the preceding argument to g_2.

4.40. *End of the proof of Theorem* 4.35. If M carries a metric whose scalar curvature is non-negative everywhere, but not identically zero, from 4.32 ii), there are also on M metrics with constant positive, constant negative and zero scalar curvatures. Using Lemma 4.39 with those constant functions as functions f_0, we get that any function is a scalar curvature. The other cases follow just in the same way. That $s_g = 0$ implies $r_g = 0$ in case (B) will be proved in 4.49. □

4.41 Remarks. i) If $\dim M = 2$, using the same technique and only replacing Theorem 4.32 by the conformal representation theorem, one gets the following converse to the Gauss-Bonnet theorem ([Ka-Wa 1]): if $\chi(M) > 0$ (resp. $\chi(M) = 0$, resp. $\chi(M) < 0$) a function f on M is the gaussian curvature of some metric if and only if f is positive somewhere (resp. is identically zero or takes both signs, resp. is negative somewhere).

ii) The use of Sobolev spaces L_k^p (and not only L_k^2 as in most discussions of linear elliptic theory) was crucial: some L^p-norm is needed for the approximation lemma 4.38, which is trivially false for the uniform norm. Then the use of the inverse function theorem in 4.36 makes it necessary to take $p > \dim M$.

F. The Manifold of Metrics with Constant Scalar Curvature[1])

4.42. Since the manifold $\mathscr{M}$ of Riemannian metrics and its submanifolds are Fréchet manifolds modelled on $\mathscr{S}^2M$, the usual inverse function theorem cannot be applied to them. This difficulty is taken care of by the technique of ILH-manifolds, developed

---

[1]) This section may be skipped on first reading.

If $R_{XYZU} \neq 0$, the coefficient matrix satisfies the cofactor relations $(\lambda - \xi)(\lambda + \xi - \mu - \nu) = (\nu - \lambda)(\nu + \lambda - \mu - \xi) = (\lambda - \mu)(\lambda + \mu - \nu - \xi) = 0$, which easily imply that λ is equal to one of μ, ν, ξ. Therefore, evaluating R_x on four eigenvectors of B_x yields zero if more than two eigenspaces are involved. Hence $R_{XY}Z = 0$ if λ, μ, ν are mutually distinct. On the other hand, if $\lambda = \mu \neq \nu$, (16.16) gives $0 = B(R^G_{XY}Z + R^G_{YZ}X + R^G_{ZX}Y) = R_{XY}(BZ) + R_{YZ}(BX) + R_{ZX}(BY) = (\nu - \lambda)R_{XY}Z$, which completes the proof. ☐

16.17 Corollary (J.P. Bourguignon, [Bou 9]). *Let b be a Codazzi tensor on a Riemannian manifold (M, g). Then*

(i) *b commutes with r, $\mathring{R}(b)$ and with $Dd(\mathrm{tr}_g b) + \delta Db$.*

(ii) *The endomorphisms R, $g \owedge r$* and *W* of *$\bigwedge^2 TM$* commute with *$g \owedge b$.*

Proof. By 16.14, $r(X, Y) = \mathring{R}(b)(X, Y) = 0$ for eigenvectors X, Y of b corresponding to distinct eigenvalues, so that r and $\mathring{R}(b)$ commute with b. Hence (i) follows from Formula (16.9) (which also directly implies that r and b commute). Since $\bigwedge^2 T_xM$ is spanned by the subspaces $V_\lambda(x) \wedge V_\mu(x)$ and $(g \owedge b)_x$ restricted to such a subspace is $\lambda + \mu$ times the identity, (ii) is immediate from 16.14. ☐

16.18. An orthonormal basis $(X_1, \ldots, X_n)$ of a Euclidean space E is said to *diagonalize* an algebraic curvature tensor $R \in \mathscr{C}E$ if all exterior products $X_i \wedge X_j$, $i < j$, are eigenvectors of R (viewed as an endomorphism of $\bigwedge^2 E$), i.e., if $R(X_i, X_j)X_k = 0$ whenever i, j, k are mutually distinct. Following H. Maillot ([Mai 1], [Mai 2]) we shall call $R \in \mathscr{C}E$ *pure* if it is diagonalized by some orthonormal basis of E. A Riemannian manifold (M, g) will be said to have *pure curvature operator* (resp., *pure Weyl tensor*) if for any $x \in M$, R_x (resp., W_x) is pure. If $n = \dim E = 2$, every orthonormal basis of E diagonalizes any $R \in \mathscr{C}E$, while, for $n \geqslant 3$, such a basis diagonalizes R if and only if it diagonalizes $W(R)$ and $c(R)$. Thus, each of the following conditions implies that the Riemannian manifold (M, g) has pure curvature operator:

(i) $\dim M = 2$, or $W = 0$ (e.g., $\dim M = 3$, cf. 1.119);

(ii) (M, g) is a hypersurface in a space of constant curvature (cf. the Gauss equation (1.72c));

(iii) (M, g) is a Riemannian product of manifolds with pure curvature operators.

Moreover, it is obvious that

(iv) the property of having pure Weyl tensor is conformally invariant.

16.19. If $R \in \mathscr{C}E$ has pure Weyl component $W = W(R)$ (e.g., if R is pure), then all the Pontryagin forms $p_i(R) \in \bigwedge^{4i} E^*$, $i \geqslant 1$, are zero (see [Mai 1]). In fact, it is easy to see (cf. [Gre]) that $p_i(R) = p_i(W)$ and the subalgebra $p(R) = p(W)$ of $\bigwedge E^*$ generated by the $p_i(W)$ has another system of generators $\Omega_i \in \bigwedge^{4i} E^*$, Ω_i being obtained by alternating the map $(Y_1, \ldots, Y_{4i}) \to \mathrm{tr}[W(Y_1 \wedge Y_2) \circ \cdots \circ W(Y_{4i-1} \wedge Y_{4i})]$. However, if an orthonormal basis $(X_1, \ldots, X_n)$ diagonalizes W, then $W(X_i \wedge X_j) \circ W(X_k \wedge X_l) = 0$ for mutually distinct i, j, k, l, which implies $p(W) = \bigwedge^0 E^* = \mathbb{R}$.

16.20 Lemma. *Let E be an oriented 4-dimensional Euclidean space and let $W \in \mathscr{W}(E)$*

it may be useful to point out that they are both optimal and easy to discover. To see this, for example with $l = 0$, let $\varphi \in C_0^\infty(|x| < 1)$, $\varphi \not\equiv 0$, and let $f_\lambda(x) = \varphi(\lambda x) \in C_0^\infty(|x| < 1)$ for $\lambda \geqslant 1$. Applying (8) to the f_λ and doing a brief computation, one obtains

$$\|\varphi\|_{L^q} \leqslant c\lambda^{k+n(1/q-1/p)}\|\varphi\|_{p,k}.$$

Letting $\lambda \to \infty$ there is a contradiction unless (7) holds. This example uses the conformal map $x \to \lambda x$; it leads one to suspect that conformal defomations of metrics lead one to the limiting case of the Sobolev inequality. This suspicion is verified in Chapter 4.

D. Differential Operators

Here and below we will use the notation $F(x, \partial^k u)$, $a(x, \partial^k u)$, etc. to represent any (possibly nonlinear) differential operator of order k. We use local coordinates on $\mathbb{R}^n$ and consider a differential operator on vector valued functions u:

$$F(x, \partial^k u) = \sum_{|\alpha|=k} a_\alpha(x, \partial^l u)\partial^\alpha u + f(x, \partial^l u),$$

where α is a multi-index and $l \leqslant k$. The equation $F(x, \partial^k u) = 0$ is *linear* if the coefficients a_α—which may be complex matrices—and f do not depend on u or its derivatives, while it is *quasilinear* if a_α and f depend only on the derivatives $\partial^\beta u$ of at most order $k - 1$, so $l \leqslant k - 1$. In this case, F is linear in its highest order derivatives. The usual formulas for the various curvatures of a Riemannian manifold are examples of second order quasilinear differential operators in the metric g. Other examples are the minimal surface equation—as well as all Euler-Lagrange equations for variational problems. On the other hand, the Gaussian curvature, K, of a surface $u\colon \mathbb{R}^2 \to \mathbb{R}$ in $\mathbb{R}^3$ (in the notation $u_x = \partial u/\partial x$ etc) satisfies

$$u_{xx}u_{yy} - u_{xy}^2 - K(x, y)(1 + u_x^2 + u_y^2)^2 = 0, \tag{12}$$

which is not quasilinear, it is fully nonlinear. Another fully nonlinear equation is the Monge-Ampère equation for Kähler-Einstein metrics [it is customary to refer to nonlinear equations involving the determinant of the hessian as "Monge-Ampère equations"].

One often meets second order quasilinear equations in *divergence form*

$$\operatorname{div} A(x, u, Du) = f(x, u, Du),$$

where A is a vector field. For example, on $\mathbb{R}^n$ this equation is

$$-\sum_i \frac{\partial}{\partial x^i} A^i(x, u, Du) = f(x, u, Du).$$

Clearly, if $u \in C^2$ is a solution of this in an open set $\Omega \subset \mathbb{R}^n$, then for any $\varphi \in L_1^2$ with support in Ω we have

$$\int \sum_i A^i(x, u, Du) \frac{\partial \varphi}{\partial x^i} \mu_g = \int f(x, u, Du) \varphi \mu_g. \tag{13}$$

In many circumstances, this last formula makes sense even for $u \in L_1^2(\Omega)$, rather than $C^2(\Omega)$ (the model is where $A(x, u, Du) = \operatorname{grad} u$). Then we say that $u \in L_1^2(\Omega)$ is a *weak solution* of the original equation if (13) holds for all $\varphi \in L_1^2$ with support in Ω. Caution: there are several other useful, but not equivalent, definitions of "weak solution".

The main application of these notions is to calculus of variations problems, where one seeks a critical point of

$$J(u) = \int F(x, u, Du) \mu_g.$$

Then the Euler-Lagrange equation is automatically in divergence form, so one may think of (13) as a weak form of an Euler-Lagrange equation.

The virtue of enlarging the class of admissible solutions to allow weak solutions is that this may make it much easier to prove the existence of a solution of the equation. On the other hand, one is then faced with the often difficult regularity problem of determining to what extent this weak solution is actually smooth.

E. Adjoint

If E and F are smooth hermitian vector bundles over M and if $P: C^\infty(E) \to C^\infty(F)$ is a *linear* differential operator, then one can use the L^2 inner product to define the *formal adjoint*, P^*, by the usual rule

$$\langle Pu, v \rangle_F = \langle u, P^* v \rangle_E$$

for all smooth sections $u \in C^\infty(E)$, $v \in C^\infty(F)$. Since the supports of u and v can be assumed to be in a coordinate patch, one can compute P^* locally using integration by parts. For example if $u: \mathbb{R} \to \mathbb{R}^N$ and if $Pu = Du$ (where here $D = d/dx$), then $P^* v = -Dv$, while if

$$Pu = A(x) D^2 u, \quad \text{then} \quad P^* v = D^2(A^*(x) v),$$

where A^* is the adjoint of the matrix A. We use the term "formal adjoint" to avoid confusion with the strict Hilbert space adjoint of an unbounded operator.

F. Principal Symbol

To a linear differential operator $P: C^\infty(E) \to C^\infty(F)$ of order k, at every point $x \in M$ and for every $\xi \in T_x^* M$ one can associate an algebraic object, the *principal symbol* $\sigma_\xi(P; x)$, often written simply $\sigma_\xi(P)$. If, in local coordinates, With the induced natural Riemannian metric the Gauss curvature is the product of the principal curvatures, or the inverse of the product of the principal radii (radii) of curvature. ...

Pag. 36(47) 1.62 Theorem

Given a Riemannian manifold (M, g), the function d is a distance on M, and the topology of the metric space (M, d) is the same as the manifold topology of M.

→ A corollary of the Gauss Lemma 1.46 is that the distance is realized (at least locally) by geodesics. More precisely.

Pag. 103(114)

In other words, we have computed the curvature of 2-dimensional totally geodesic subspaces in Gaussian coordinates.

We can obtain the rest of the relevant sectional curvatures by observing that on each

$\rho =$ constant hypersurface

(%B/

$\mathbb{R} \times \{p\} \times S^2$ the induced metric is the product metric

$$g_p = f^2(p)\,dt^2 - G^2(p)\,d\sigma^2$$

. . .

Pag. 126(137) – 4.41 Remarks

If dim $M = 2$

a function f on M is the gaussian curvature of some metric if and only if f is positive somewhere (resp. is identically zero or takes both signs, resp. is negative somewhere).

F. The Manifold of Metric with Constant Scalar Curvature:

Pag. 439(450) – 16.18

Thus, each of the following conditions implies that the Riemannian manifold (M, g) has pure curvature operator:

(i) dim $M = 2$, or $W = 0$ (e.g., dim $M = 3$, cf. 1.119);

(ii) (M, g) is a hypersurface in a space of constant curvature (cf. the Gauss equation (1.72c));

Quantum Relativity – A Synthesis
of the Ideas of Einstein and
Heisenberg

Pág. 241(256) – $\Delta P \gg \frac{\hbar}{a}$, $\Delta Q \gg a$,
the coherent states are practically orthogonal.

-256- - -* ! - 6 ! 5 ! A 3 2 3
&" ! = ! " : D 1 !) : " D //B 1"
(' $B ! 4 !

where the functions $P(t)$ and $Q(t)$ are just the time-dependent coordinates of an classical free particle with initial position and momentum

$$Q(0) = Q, \quad P(0) = P\,. \tag{5}$$

Coherent states are not orthogonal, and so there is no variable having the coherent states $|Q, P\rangle$ as its eigenvectors and the parameters P (or Q) as corresponding eigenvalues. The parameters P and Q are not eigenvalues of any quantum variables. They cannot be identified with the results of exact measurements.

On the other hand, coherent states can be nearly orthogonal. The inner product between distinct coherent states $|P + \Delta P, Q + \Delta Q\rangle$ and $|Q, P\rangle$ is called the *form factor* for these coherent states and is given by

$$\langle P + \Delta P, Q + \Delta Q|P, Q\rangle = \frac{1}{\sqrt{2\pi}} e^{-(\Delta P^2 + \Delta Q^2)/2} = f(\Delta P, \Delta Q) \tag{6}$$

in units with $a = 1$. This falls off rapidly with the differences $\Delta P, \Delta Q$, so that for macroscopic position and momentum differences,

$$\Delta P \gg \frac{\hbar}{a}, \quad \Delta Q \gg a\,, \tag{7}$$

the coherent states are practically orthogonal.

The wave functions of coherent states $|Q, P\rangle$ in the q frame of basis vectors $|q\rangle$ are harmonically modulated Gaussian wave packets

$$\langle q|P, Q\rangle \sim \exp\left[-\tfrac{1}{2}(q - Q)^2 + iPq\right] \tag{8}$$

P is the modulating wavenumber and Q is the center. In the p frame the wave function has center P and modulating wavenumber $-Q$.

The main point is that the P, Q parameters of the coherent state change according to the classical equations of motion when the mode develops according to Schrödinger's equation. For the harmonic oscilator this is exact. In the general case, one settles for equality up to higher order terms in $\hbar$, which are regarded as negligible for high quantum numbers and large action.

The term "coherent state" is apropriate even though quantum systems do not have states, because the quantum modes called coherent provide a quantum origin for classical statelike behavior. To be sure, an initial vector for one quantum is not a state in a classical sense; but in practice we apply coherent states to such large populations of quanta that we can determine a one-quantum ket from a small part which we then discard, hardly changing the whole.

We now examine how coherent states aid us to understand the classical limit.

path tensor by taking the diagonal elements in one frame, specifically a spacetime frame.

A determination of the quantum path is complementary to a determination of the Hamiltonian of the quantum, and so to its mass and other couplings. We may ask the path that a quantum takes, but then we cannot know what kind of quantum takes that path.

12.5.3 Hamiltonian and Lagrangian Theories

Quantum dynamics was historically discovered in canonical coordinates and expressed as Hamiltonian equations of motion. The Hamiltonian quantum theory looks for the propagator G. It expresses the propagator for infinitesimal time interval δt in units with $\hbar = 1$ in the form

$$G = e^{-iH\delta t} \tag{1}$$

with Hamiltonian $H = H(q, p)$. The propagator for finite intervals x'', x' is found by decomposing the interval into N subintervals, using (1) for each, multiplying in chronological order, and taking the limit $N \to \infty$. This finite propagator is also called the time-ordered product integral of the infinitesimal propagator (1).

This is not a relativistic theory. It inherits this flaw from classical Hamiltonian mechanics. To be sure, a Lorentz transformation is a canonical transformation, so that the form of the classical equations of motion was relativistically invariant. But the main concepts entering into the Hamiltonian equations, the Hamiltonian H and the time derivative d/dt, are not relativistic objects, in that they do not have LORENTZ transformation laws.

Since the differential action $dS = L\,dt$ is a LORENTZ scalar and the Hamiltonian is not, it was natural to found a relativistic quantum theory on an action principle, expressed like the classical action principle in terms of relativistic entities, instead of a Hamiltonian. Dirac posed and partly solved the problem of formulating a quantum action principle. He regarded the Lagrangian $L(x, \dot{x})$ as a matrix element $L = (x'|x)$ relating two positions x, x' at times t, $t' = t + dt$ separated by a differential time dt, and showed, schematically speaking, that the propagator may be expressed equivalently as an exponential in the action and as the matrix element of an exponential in the Hamiltonian. More fully:

Suppose that L and H are of the form

$$L = \tfrac{1}{2}m\dot{x}^2 - V(x) =: K - V\,, \tag{2}$$

$$p = \frac{\partial L}{\partial \dot{x}}\,,$$

$$H(p, x) = p\dot{x} - L = \frac{1}{2m}p^2 + V(x) = K + V\,.$$

Then for infinitesimal $\delta t = t'' - t'$, the propagator (1) may be expressed in terms of the Lagrangian by

$$\langle x''|G|x'\rangle := [x'']e^{-iH\delta t}[x'] = \text{const}\, e^{iL(x,\dot{x})\delta t} + \mathrm{O}(\delta t^{3/2})\,. \tag{3}$$

Here const is a normalization constant whose magnitude is fixed so that (3) defines a unitary G; and the arguments of the Lagrangian function L in (3) are defined by

$$x = \frac{x' + x''}{2} \tag{4}$$

$$\dot{x} = \frac{x'' - x'}{\delta t}\,. \tag{5}$$

To prove this, one completes the square. Consider first a free particle ($V \equiv 0$). Without loss of generality set $m = 1$. The free propagator G_0 is given by 12.5 (1) with $H = K$. We express its matrix element as a Fourier integral by inserting the spectral projection $[p]$ for momentum, using the transformation function $\langle p|x\rangle$ from position eigenvectors $|x\rangle$ to momentum ones $|p\rangle$,

$$\langle p|x\rangle = \frac{1}{\sqrt{2\pi}}e^{ipx} \tag{6}$$

and completing the square:

$$\begin{aligned}\langle x''|G_0|x'\rangle &= \langle x''|e^{-iK\delta t}|x'\rangle \\ &= \langle x''|e^{-ip^2\delta t/2}|x'\rangle \\ &= \int dp[x''|e^{-ip^2\delta t/2}|p|p|x'] \\ &= \frac{1}{2}\int dp \exp\Big[-\frac{i}{2}p^2\delta t - ip\Delta x\,\delta t\Big]\end{aligned} \tag{7}$$

where $\Delta x := x'' - x'$. To complete the square we introduce a translated momentum variable $P = p + a$ and determine a so that

$$p^2 + 2p\Delta x + a^2 = P^2\,. \tag{8}$$

It follows that

$$a = \Delta x\,, \tag{9}$$

$$\langle x''|G_0|x'\rangle = \frac{1}{2\pi}\Big[\int dP \exp\Big[-\frac{i}{2}P^2\delta t\Big]\Big] \exp\Big[\frac{i}{2}\Delta x^2\delta t\Big]\,.$$

This integral is the standard Gaussian, integrated along a line in the complex plane rotated from the real axis by $\pi/4$:

$$\int dP\, e^{-iP^2\delta t/2} = \sqrt{\frac{2p}{i\delta t}}\,. \tag{10}$$

Therefore

$$\langle x''|G_0|x'\rangle = \frac{1}{\sqrt{2\pi i\delta t}} \exp\Big[\frac{i}{2}\Delta x^2\delta t\Big] = \frac{1}{\sqrt{2\pi i\delta t}}e^{iL_0\delta t}\,. \tag{11}$$

where $L_0 = K$ is the free Lagrangian. This establishes the desired result for the free particle and gives the complex normalization constant const $= (2\pi i\delta t)^{-1/2}$.

Next we turn on the potential. The infinitesimal propagator from t' to $t'' = t'+\delta t$ may be approximately factored as

$$G = e^{-iH\delta t} = e^{-i(K+V)\delta t} = e^{-iK\delta t}e^{-iV\delta t} + \mathrm{O}(\delta t^2) = G_0 e^{-iV\delta t} + \mathrm{O}(\delta t^2)\,. \tag{12}$$

The kinetic and potential energy now act alternately in succession instead of simultaneously. The error arises from neglecting the commutator $[K\delta t, V\delta t] = \mathrm{O}(\delta t^2)$. Let t be the interpolated time dividing the interval from t' to t'' into two equal halves, and let x be the variable position at time t. We propagate with potential energy for the first half of the time interval and with kinetic for the second. The matrix element of the potential propagator is

$$\langle x|e^{-iV\delta t}|x'\rangle = \delta(x - x')e^{-iV(x)\delta t}\,. \tag{13}$$

The matrix element of G is therefore

$$\begin{aligned} &\langle x''|G|x'\rangle \\ &= \frac{1}{\sqrt{2\pi i\delta t}}\int dx \exp\left[\frac{i}{2}\Delta x^2\delta t\right]\delta(x - x')\exp[-iV(x')\delta t] + \mathrm{O}(\delta t^{3/2}) \\ &= \frac{1}{\sqrt{2\pi i dt}}e^{iL\delta t} + \mathrm{O}(\delta t^{3/2})\,, \\ &L := \langle x''|L|x'\rangle = L(x, \dot{x})\,. \end{aligned} \tag{14}$$

This proves the infinitesimal result. It then follows for finite intervals by subdivision and composition. The number of intervals is $\mathrm{O}(\delta t^{-1})$, and so the accumulated error is $\mathrm{O}(\delta t^{1/2})$ and vanishes in the limit $\delta t \to 0$. Evidently the normalization constant const diverges as $\delta t \to 0$.

Note the sign difference between (1) and (2).

The propagator for finite intervals x'', x' is found by decomposing the interval into N subinterval with $N + 1$ points $x' = x_0, x_1, x_2, \cdots, x_N = x''$, using (2) for each, multiplying in chronological order, integrating over the intermediate variables $x_1, \cdots, x_{N-1}$, and taking the limit $N \to \infty$.

This shows the equivalence of the two forms of theory.

12.5.4 Schwinger Variational Principle

Neither of these equivalent forms of 12.5.3 (3) is quite satisfactory for a quantum dynamical principle. The Hamiltonian form 12.5.3 (1) is a quantum tensor but not a spacetime one. Since the exponential of the tensor $iL\,dt$ in 12.5.3 (3) is not a tensor, the Lagrangian form is a spacetime tensor (namely a scalar) but not a quantum one. This problem was resolved by Richard P. Feynman and Julian Schwinger by integral and differential methods respectively. We have already seen an example of Feynman's path integral theory of quantum dynamics. Now we illustrate the Schwinger variational theory.

All three of these modifications require us to give new meaning to the path integral that appears in our action principle. If there are basic odd quanta we must learn to integrate over first-grade Grassmann variables. If there are gauge potentials we must do integrals over non-dynamical degrees of freedom as well as dynamical. Since there are interactions we must integrate functions other than Gaussian exponentials, leading to divergences.

13.2 Gauge Physics

An adequate treatment of gauge physics takes a sizable volume. Here we merely summarize some of the features of gauge physics to which we will refer in later chapters.

13.2.1 Gauge History

The word "gauge" comes from the machinist's precision standard of length, the gauge or gauge block. After Einstein showed that gravity could be understood as a disturbance in the remote comparison of direction, Hermann Weyl (1922) proposed that electromagnetism was a disturbance in the remote comparison of length. He suggested a spacetime physics in which each experimenter not only provided a spacetime chart x^μ but also a field of "gauges" $g(x)$, one gauge (block) at each spacetime point, with which to measure local lengths. He postulated that physical laws and concepts must not only be invariant under chart transformations, as Einstein assumed, but also under arbitrary gauge transformations, $\Lambda(x) : g(x) \to g'(x) = \Lambda(x)g(x)$, by any non-zero real function Λ: $M^4 \to \Gamma$. Here Γ is the original gauge group, the multiplicative group $\mathbb{R}^+$ of positive real numbers. In gauge geometry a local physical quantity $\phi = \phi(x)$ not only defines a representation of the local group GL_4 by its tensor index structure but also defines a representation of the local gauge group Γ by its gauge weight n, the power of Λ in its gauge transformation law $\phi \to \Lambda^n\phi$ when $g \to \Lambda g$.

Under such a gauge transformation, the Lie derivative $\partial_\mu\phi$ and Einstein's covariant derivative $D_\mu\phi$ of any physical quantity ϕ both change by an additive term $\sim \partial_\mu\Lambda(x) \cdot \phi(x)$, which brings in the independent object ϕ. Therefore they do not have a gauge transformation by themselves, and are not gauge geometrical objects. Following the analogy of the covariant derivative of general relativity, Weyl postulated a new gauge-covariant derivative, necessarily of the form

$$D_\mu := \partial_\mu + \Gamma_\mu + A_\mu \tag{1}$$

where Γ_μ is the usual gravitational connection and A_μ is a new field, the gauge connection, with a change that compensates that of ∂_μ. The gauge field is the commutator $F_{\mu\nu} := [D_\mu, D_\nu]$. The action of the theory is the sum of the usual action for the sources, with the substitution $\partial \to D$, and the gauge field action $\alpha F_{\mu\nu}F^{\mu\nu}/4$. The analogue of the Bianchi identity for A_μ is one of Maxwell's equations, and the other Maxwell equation looks like a mere definition of the current. Therefore Weyl proposed to identify A_μ with the electromagnetic vector potential up to a factor.

To accord with the usual electromagnetic theory, Weyl identified α with the fine structure constant $\sim 1/137.04$. The quantum of electrical charge e now appears only in front of the electromagnetic action, as a kind of stiffness of the electromagnetic field, and nowhere else in physics, because Weyl absorbed it into the connection.

Perhaps we should do this today with $e/3$; the corresponding fine structure constant is then $\alpha = 9/137.04 = 1/15.23$.

Instead of accounting for the coupling constant, which is now formally 1, we must understand the stiffness α of the field. The electromagnetic coupling between unit charges is relatively weak because the field is stiff, as with masses supported against gravity on a taut elastic sheet. The fundamental variable of gauge physics is the connection A_μ, or better the gauge (covariant) derivation $D_\mu(x) = \partial_\mu + A_\mu$, a dual vector.

Weyl's theory was unviable because it implied that an atom of the solar atmosphere convecting around the sun (say) should grow in size by a fixed factor on each revolution, due to the sun's magnetic field, and therefore that we should see a mix of many atomic sizes and spectral wavelengths. We do not.

Dirac salvaged Weyl's theory by redefining its gauge group. Instead of stretching literal gauges, Dirac's gauge transformation shifts the phase of the wavefunction of all charged particles by $\epsilon^{i\theta}$. Dirac's gauge group is U_1, not $\mathbb{R}_+$, and acts on different variables. Nevertheless Dirac's gauge (Lie) algebra is the same as Weyl's: the trivial algebra on the vector space $\mathbb{R}$, with $[\alpha, \beta] \equiv 0$. Dirac's theory inherited the main formal properties of Weyl and agreed with Maxwell's theory and experiment, but no longer explained what electrical charge was or how charged particles differ from neutral ones in spacetime terms.

As a result of this success Weyl's theory was generalized still further. A gauge theory today has a local gauge variable γ in the episystem, generalizing Weyl's gauge block g, subject to a local gauge group Γ, not necessarily abelian, generalizing the gauge group $\mathbb{R}_+$. For convenience we coordinate the variable γ with a variable group element $\gamma \in \Gamma$. The theory has global gauge transformations, each described locally by a field $\gamma(x)$: $M^4 \to \Gamma$ of local gauge transformations, multiplied point by point. It has a gauge derivative $D(x)$, which changes locally under an infinitesimal gauge transformation $\Lambda = (\Lambda(x)) = (1+\lambda(x))$, where $\lambda \to 0$, according to

$$\Lambda : D_\mu \to D^\Lambda_\mu(x) = \Lambda(x)D(x)\Lambda(x)^{-1} = \partial_\mu + A^\Lambda_\mu\,. \tag{2}$$

Its gauge connection A_μ represents the infinitesimal change that the gauge variable γ undergoes during a congruent transport along the segment dx^μ and so takes on values in the Lie algebra of Γ:

$$d\gamma = A_\mu dx^\mu \tag{3}$$

A_μ transforms under (2) according to

$$A_\mu \to A_\mu^\Lambda = A_\mu + [\lambda, A_\mu] - \partial_\mu \lambda \,. \tag{4}$$

The gauge flux through a loop $x^\mu(\tau)$ is the gauge group element $\delta\gamma$ that acts on a gauge when it is carried congruently around the loop. In Weyl's theory, this is a magnetic flux for an infinitesimal loop $\delta_1 x \vee \delta_2 x$ if both δx_1 and δx_2 are along space axes, and an electric flux if one δx is along the time axis. In general, the transport around a loop $\delta_1 x \vee \delta_2 x$ results in a net second-order gauge transformation

$$\begin{aligned} \delta^{(2)}\gamma &= F_{\mu\nu}\delta_1 x^\mu \delta_2 x^\nu \,, \\ F_{\mu\nu} &:= [D_\mu, D_\nu] \end{aligned} \tag{5}$$

and the commutator F defining the loop transport is called the gauge field.

Gravity may be regarded as an exceptional kind of gauge theory where the gauge group acts on spacetime vectors dx^μ themselves. In all other gauge theories today, spacetime vectors are assumed to be invariant under the gauge group. For gravity, the gauge conection is the Christoffel connection $\Gamma_\kappa = (\Gamma^\mu_{\lambda\kappa})$ and the gauge field is the curvature tensor $F_{\lambda\kappa} = (R^\nu_{\mu\lambda\kappa})$. In this theory we may use the metric tensor $g_{\mu\nu}(x)$ to form the Hilbert action

$$L = \kappa R + \lambda \,, \tag{6}$$

with only two terms; L also has a common factor of the relative scalar $\sqrt{\det(-g_{\mu\nu})}$, which for simplicity we have absorbed into the volume element d^4x. The first term κR in this Lagrangian is linear in the gauge field and its coefficient κ is equivalent to Newton's gravitational constant G; the second term λ is the cosmological constant.

Gauge theory inherits one great virtue from Einstein's theory of gravity: Its action principle $L(x)$ is narrowly constrained by two natural postulates, gauge invariance and maximal locality. The gauge invariance postulate is inherent in the gauge theory itself. By maximal locality we mean that the action $L(x)$ formed from $A_\mu(x)$ has the lowest possible differential order. Since higher order terms vary as higher powers of energy-momentum, this postulate may be justified physically as a low-energy approximation to a more general action. For gravity it gives us the Hilbert action, and for electromagnetism the Maxwell action. Roughly speaking, one need merely specify a gauge group and a full-fledged dynamical theory follows.

Now to see the effect of the sun's magnetic field on an electron (say) we would have to do an interference experiment, splitting and recombining an electron beam and noticing the shift in the interference fringes as we slowly move the sun in and out of the beam loop. As Aharanov and Bohm emphasized, one should see a phase shift even if there is no magnetic field at the electron beam, provided only that the beam loop encloses flux. The Aharanov-Bohm experiment has been done (with magnetized iron whiskers instead of the sun) and is consistent with gauge theory.

The moral is that to describe locally the effect of electromagnetism (or other gauge field) on a quantum we must know the potential A_μ, not just the field $F_{\mu\nu}$.

Nevertheless all we can measure locally is a flux or a field $F_{\mu\nu}$, never a potential A_μ.

For ordinary gauge groups, which leave spacetime vectors fixed, the maximally local action $S = \int L\, dx$ that resembles the Maxwell action in being quadratic in the gauge field has the density

$$L = -\tfrac{1}{4}\alpha F^{\mu\nu} F_{\mu\nu}\,. \tag{7}$$

The quanta of the gauge connection are called gauge vector bosons. According to the Lagrangian (7) the physical quanta have spin 1 and (rest) mass 0. They are accompanied by unphysical longitudinal and timelike fields of spin 0, transmitting static forces that fall off as the inverse square of distance, with no length parameter to set their scale, and are therefore said to have infinite range.

In the early decades of gauge theory it was accepted that gauge forces inevitably have infinite range and massless quanta, like the prototype gauge fields, gravity and electromagnetism. Certainly a mass term like $\mu^2 A^2$ spoiled gauge invariance at the same time that it gave the force a range μ^{-1}. This made it hard to understand the short-range weak and strong forces as gauge forces.

E.C.G. Stückelberg then showed that a gauge vector boson could acquire mass and short range by interacting with a scalar field $f = f(x)$ that transformed additively under gauge transformations, according to

$$\Lambda : f \mapsto f + \ln \Lambda\,. \tag{8}$$

The standard gauge covariant Lagrangian for the field f,

$$\begin{aligned} L_f &= -\tfrac{1}{2} D_\mu f D^\mu f\,, \\ D_\mu f &:= \partial_\mu f + \partial_\mu \ln \Lambda \cdot f\,, \end{aligned} \tag{9}$$

then provides a mass for the gauge field.

Instead of the Stückelberg field f one could equivalently introduce its exponential, the field $\eta = e^f = \eta(x)$, which transforms multiplicatively with gauge weight 1, but then η must have a non-zero vacuum value $\eta = e^f = e^0 = 1$, corresponding to $f = 0$.

Quaternion quantum mechanics required just such a field, also called η, on fundamental grounds [Finkelstein, Jauch, Schiminovich and Speiser (1961a, b)]. The quaternionic field η replaces the constant complex factor $i\hbar$ that is used in complex quantization, just as Einstein's variable spacetime metric $g_{\mu\nu}$ replaces the constant Minkowski metric of special relativity. The η field is a pure imaginary quaternion with vacuum value subject to the constraint $|\eta| = \hbar = 1$ and defines the electromagnetic axis in the three-dimensional space of imaginary quaternions. It gives mass to a charged vector gauge boson, forming an SU_2 triplet with a massless photon-like boson . This seems to be the only field theory that provides charged gauge bosons with mass and is not ad hoc, though it leaves other problems of electroweak physics unresolved.

Higgs (1964) and others proposed to account for massive gauge vector bosons by couplings to such fields, called Higgs fields, which are essentially exponentials of Stückelberg fields. Instead of the nonlinear constraint $|\eta| = 1$, which is computationally intractable, Higgs fields have non-zero vaccuum expectation values because their non-quadratic action has a minimum at $\eta \neq 0$. Then t'Hooft (1971) showed that gauge theories of that kind retained the renormalizability of the massless gauge theories. This opened a new era of gauge theory.

13.2.2 Standard Model

We now sketch the standard model for the non-gravitational part of physics today, which has strong experimental support for energies up to 100 GeV and cries out for explanation. It sums up work of Sheldon Glashow, Abdul Salam, Steven Weinberg and others.

The standard model rests on the standard gauge group

$$G_{\text{standard}} = U_1 \otimes SU_2 \otimes SU_3 = \text{hypercharge}\otimes\text{isospin}\otimes\text{color}\,. \tag{1}$$

The U_1, SU_2 and SU_3 groups have dimensions 1, 3 and 8 and rank (maximal number of commuting generators) 1, 1 and 2. When used to represent particle symmetries, their respective charges or infinitesimal generators are called hypercharge Y, (weak) isospin T^i $(i = 1, 2, 3)$ and color C^c $(\gamma = 1, 2, \cdots, 8)$.

These are the matrix generators of the identity representations of these unitary groups. These are therefore one 1×1 fixed complex hypercharge matrix Y; three 2×2 isospin charges T^i; and eight 3×3 color charges C^c, respectively.

There is a gauge vector field for each of these $1+3+8$ generators. A 2-vector $|\tau\rangle$ supporting isospin is called an isospinor or SU_2 spinor and its two components are labeled *up* and *down*. A 3-vector $|\gamma\rangle$ supporting color SU_3 is called a color or SU_3 spinor and the three components are labeled *blue*, *green*, and *red*.

For orientation we mention that electric charge is $Q = Y + T_3$, where 3 labels a special direction in the three-dimensional isospin space called the electromagnetic axis. This direction is singled out by the Higgs field.

The fundamental fields of the standard model fall into two broad species by statistics, odd and even.

The odd fields are all left-handed spin 1/2 fields and their right-handed antiparticles. These divide again, but now in two independent ways:

- by symmetries into leptons, which are colorless and so have color operator

  $$C^{\gamma}_{\text{lepton}} = 0$$

  and quarks, which have the 3×3 color operators of the identity representation

  $$C^{\gamma}_{\text{quark}} = C^c\,;$$

- and by masses into three families also called flavors, labelled with a flavor index $F = 1, 2, 3$.

4.3 Differential Geometry in the Hodge Bundle

4.3.1 Riemannian and Lorentzian Structures on M

Next we introduce on M a smooth metric field $\mathbf{g} \in \sec T_2^0 M$ and gives the

Definition 229 *A pair* $(M, \mathbf{g})$*,* $\dim M = n$ *is a* n*-dimensional Riemann structure (or Riemann manifold) if* $\mathbf{g} \in \sec T_2^0 M$ *is a smooth* metric *of signature* $(n, 0)$*. If* $\mathbf{g}$ *has signature* (p, q) *with* $p + q = n$*,* $p \neq n$ *or* $q \neq n$ *then the pair* $(M, \mathbf{g})$ *is called a pseudo Riemannian manifold. When* $\mathbf{g}$ *has signature* $(1, n-1)$ *the pair* $(M, \mathbf{g})$ *is called an hyperbolic manifold. When* $\dim M = 4$ *and* $\mathbf{g}$ *has signature* $(1, 3)$ *the pair* $(M, \mathbf{g})$ *is called a Lorentzian manifold.*[8]

We already defined the concept of oriented manifold. Thus, we say that a Riemannian (or pseudo Riemannian or Lorentzian) manifold is orientable if and only if it admits a continuous metrical volume element field $\tau_{\mathbf{g}} \in \sec \bigwedge^n T^*M$ given in local coordinate functions $\{\mathbf{x}^i\}$ covering $U \subset M$ by

$$\tau_{\mathbf{g}} = \sqrt{|\det \mathbf{g}|} dx^1 \wedge ... \wedge dx^n \ , \tag{4.91}$$

where

$$\det \mathbf{g} = \det \left[\mathbf{g}\left(\frac{\partial}{\partial x^i}, \frac{\partial}{\partial x^j}\right) \right] \ . \tag{4.92}$$

Proposition 230 *Any* C^r *manifold* M*,* $\dim M = n$ *admits a* C^{r-1} *Riemannian metric* $\mathbf{g}$ *(signature* $(n, 0)$*) if, and only if, it is paracompact.*

Proof. For a proof see, e.g. [3]. ☐

Let us consider now a smooth oriented metric manifold $\mathsf{M} = (M, \mathbf{g}, \tau_{\mathbf{g}})$, $\dim M = n$, where $\mathbf{g}$ is a smooth metric field of signature (p, q) and $\tau_{\mathbf{g}} \in \sec \bigwedge^n T^*M$. We denote by $g \in \sec T_0^2 M$ the *metric* tensor of the cotangent bundle. Also we denote the scalar product induced on $\bigwedge T^*M$ by the metric tensor $g \in \sec T_0^2 M$ by[9] $\underset{\mathbf{g}}{\cdot} : \sec \bigwedge T^*M \times \sec \bigwedge T^*M \to \sec \bigwedge^0 T^*M$. If $A, B \in \sec \bigwedge^p T^*M$ we have (recall (2.121))

$$(A \underset{\mathbf{g}}{\cdot} B)\tau_{\mathbf{g}} = A \wedge \underset{\mathbf{g}}{\star} B. \tag{4.93}$$

---

[8] When Lorentzian manifolds serve as models of spacetimes it is also imposed that M is noncompact. See Sect. 4.4.1.

[9] When there is no chance of confusion we eventually used the symbol $\cdot$ instead of the symbol $\underset{\mathbf{g}}{\cdot}$ in order to simplify the notation.

4.3.2 Hodge Bundle

Definition 231 *The* Hodge bundle *of the structure* M*, is the triple*

$$\bigwedge(\mathsf{M}) = (\bigwedge T^*M, \underset{\mathbf{g}}{\cdot}, \tau_{\mathbf{g}}) \,. \tag{4.94}$$

The importance of the Hodge bundle is that besides the exterior derivative operator, we can now introduce a new differential operator called the Hodge codifferential. Equipped with these two operators we can write, e.g. Maxwell equations (with currents) in a *diffeomorphism* invariant way[10] (see Sect. 4.7.1). This is a very important fact, which is often not well known as it should be.

Definition 232 *The* Hodge codifferential *operator in the Hodge bundle of* $\bigwedge(\mathsf{M})$ *is the mapping* $\underset{\mathbf{g}}{\delta} : \sec \bigwedge T^*M \to \sec \bigwedge T^*M$*, given, for homogeneous multiforms, by:*

$$\underset{\mathbf{g}}{\delta} = (-1)^r \underset{\mathbf{g}}{\star}^{-1} d \underset{\mathbf{g}}{\star} \,, \tag{4.95}$$

where $\underset{\mathbf{g}}{\star}$ *is the Hodge star operator associated with the scalar product* $\underset{\mathbf{g}}{\cdot}$ *.*

Definition 233 *The* Hodge Laplacian *operator is the mapping*

$$\underset{\mathbf{g}}{\lozenge} : \sec \bigwedge T^*M \to \sec \bigwedge T^*M,$$

given by:

$$\underset{\mathbf{g}}{\lozenge} = -(d\underset{\mathbf{g}}{\delta} + \underset{\mathbf{g}}{\delta} d) \,. \tag{4.96}$$

The exterior derivative, the Hodge codifferential and the Hodge Laplacian satisfy the relations:

$$\begin{aligned}
& dd = \underset{\mathbf{g}}{\delta}\underset{\mathbf{g}}{\delta} = 0; \quad \underset{\mathbf{g}}{\lozenge} = (d - \underset{\mathbf{g}}{\delta})^2 \\
& d\underset{\mathbf{g}}{\lozenge} = \underset{\mathbf{g}}{\lozenge} d; \quad \underset{\mathbf{g}}{\delta}\underset{\mathbf{g}}{\lozenge} = \underset{\mathbf{g}}{\lozenge}\underset{\mathbf{g}}{\delta} \\
& \underset{\mathbf{g}}{\delta}\underset{\mathbf{g}}{\star} = (-1)^{r+1}\underset{\mathbf{g}}{\star} d; \quad \underset{\mathbf{g}}{\star}\underset{\mathbf{g}}{\delta} = (-1)^r d\underset{\mathbf{g}}{\star} \\
& d\underset{\mathbf{g}}{\delta}\underset{\mathbf{g}}{\star} = \underset{\mathbf{g}}{\star}\underset{\mathbf{g}}{\delta} d; \quad \underset{\mathbf{g}}{\star} d \underset{\mathbf{g}}{\delta} = \underset{\mathbf{g}}{\delta} d \underset{\mathbf{g}}{\star}; \quad \underset{\mathbf{g}}{\star}\underset{\mathbf{g}}{\lozenge} = \underset{\mathbf{g}}{\lozenge}\underset{\mathbf{g}}{\star} \,.
\end{aligned} \tag{4.97}$$

Remark 234 *When it is clear from the context which metric field is involved we use the symbols* $\star$*,* δ *and* $\lozenge$ *in place of the symbols* $\underset{\mathbf{g}}{\star}$*,* $\underset{\mathbf{g}}{\delta}$ *and* $\underset{\mathbf{g}}{\lozenge}$ *in order to simplify the writing of equations.*

---

[10] For the exact meaning of the concept of diffeomorphism invariance of a spacetime physical theory (as used in this text) see Sect. 5.5.3.

4.4 Classification of Geometries on M and Spacetimes

Definition 251 *Given a triple* $(M, \mathbf{g}, \nabla)$:

(a) *it is called a Riemann*-Cartan space if and only if

$$\nabla \mathbf{g} = 0 \qquad \text{and} \qquad \Theta[\nabla] \neq 0 \,. \tag{4.131}$$

(b) *it is called* Weyl space if and only if

$$\nabla \mathbf{g} \neq 0 \qquad \text{and} \qquad \Theta[\nabla] = 0 \,. \tag{4.132}$$

(c) *it is called a* Riemann space *if and only if*

$$\nabla \mathbf{g} = 0 \qquad \text{and} \qquad \Theta[\nabla] = 0 \,, \tag{4.133}$$

and in that case the pair $(\nabla, \mathbf{g})$ *is called* Riemannian structure *for* M*.*

(d) *it is called* Riemann-Cartan-Weyl space *if and only if*

$$\nabla \mathbf{g} \neq 0 \qquad \text{and} \qquad \Theta[\nabla] \neq 0 \,. \tag{4.134}$$

(e) *it is called (Riemann) flat if and only if*

$$\nabla \mathbf{g} = 0 \qquad \text{and} \qquad \mathbf{R}[\nabla] = 0 \,,$$

(f) *it is called teleparallel if and only if*

$$\nabla \mathbf{g} = 0, \;\; \Theta[\nabla] \neq 0 \text{ and } \mathbf{R}[\nabla] = 0. \tag{4.135}$$

For each metric tensor defined on the manifold M there exists one and only one connection in the conditions of (4.133). It is called *Levi-Civita connection* of the metric considered, and is denoted by D. If in a given context it is necessary to distinguish between the Levi-Civita connections of two different metric tensors $\mathring{\mathbf{g}}$ and $\mathbf{g}$ on the same manifold, we write $\mathring{D}$, D.

Remark 252 *When* $\dim M = 4$ *and the metric* $\mathbf{g}$ *has signature* $(1,3)$ *we sometimes substitute Riemann by Lorentz in the previous definitions* (c),(e) *and* (f)*.*

4.4.1 Spacetimes

From nowhere besides the constraints already imposed (Hausdorff and paracompact) on M, we suppose also that it is connected and noncompact [10, 29]. We now introduce the concept of *time orientability* on an oriented Lorentzian manifold structures $(M, \mathbf{g}, \tau_{\mathbf{g}})$, which plays a key role in physical theories.

Definition 253 *Let* $(M, \mathbf{g})$ *be a Lorentzian manifold,* $TM = \bigcup_{\mathfrak{e} \in M} T_{\mathfrak{e}} M$ *its tangent bundle and* $\pi : TM \to M$ *the canonical projection (see* Appendix*). The causal character of* $(\mathfrak{e}, \mathbf{v}) \in TM$ *is the causal character of* $\mathbf{v}$ (Definition 59)*.*

Definition 254 *A line element at* $x \in M$ *is a one-dimensional subspace of* $T_x M$.

Proposition 255 *Let* M *be a* C^1 *paracompact and Hausdorff manifold, with* $\dim M = 4$. *Then the existence of a continuous line element field on* M *is equivalent to the existence of a Lorentzian structure on* M.

Proof. For a proof see [3]. $\square$

Proposition 256 *The set* $\mathfrak{T} \subset TM$ *of timelike points is an open manifold and it has either one (connected) component or two.*

Proof. A proof of this important result can be found in [29]. $\square$

Definition 257 *A connected Lorentzian manifold* $(M, \mathbf{g})$ *is said to be time orientable if and only if* $\mathfrak{T}$ *has two components and one of the components is labeled the future* $\mathfrak{T}^+$ *and the other component* $\mathfrak{T}^-$ *is labeled the past. We denote by* ↑ *the time orientability of a Lorentzian manifold.*

Definition 258 *A spacetime is a pentuple* $\mathfrak{M} = (M, \mathbf{g}, \nabla, \tau_{\mathbf{g}}, \uparrow)$ *where* $(M, \mathbf{g})$ *is a Lorentzian oriented and time oriented manifold and* ∇ *is an arbitrary covariant derivative operator on* M.

Definition 259 *When* $(M, \mathbf{g}, \nabla, \tau_{\mathbf{g}}, \uparrow)$ *is a spacetime and* $\nabla = D$ *is the Levi-Civita connection of* $\mathbf{g}$ *the spacetime is said to be Lorentzian. When* $\nabla \mathbf{g} = 0$ *and* $\Theta[\nabla] \neq 0$ *we call the structure* $(M, \mathbf{g}, \nabla, \tau_{\mathbf{g}}, \uparrow)$ *a Riemann-Cartan spacetime. The particular Riemann-Cartan spacetime for which* $\mathbf{R}(D) = 0$ *is called teleparallel (or Weitzenböck) spacetime.*

Definition 260 *A Lorentzian spacetime structure* $\mathcal{M} = (M, \boldsymbol{\eta}, D, \tau_{\boldsymbol{\eta}}, \uparrow)$ *is said to be Minkowski spacetime if and only if* $M \simeq \mathbb{R}^4$ *and* $\mathbf{R}(D) = 0$.

Exercise 261 *Show that we can give to* $\mathcal{M}$ *the structure of a metric* affine space, i.e. a structure $(M, \mathbf{V}, -, \eta)$ *where* $\eta : \mathbf{V} \times \mathbf{V} \to \mathbb{R}$ *is a Minkowski metric and such that there exists a mapping* $- : M \times M \to \mathbf{V}, (x - y) \in V$ *satisfying the triangle equality* $(x - y) + (y - z) = (x - z)$. *Also, if* $\boldsymbol{\eta} \in \sec T_2^0 M$ *is the metric of* $\mathcal{M}$ *and if* $\{e_\mu\}$ *is an orthonormal basis of* TM *then there is an orthonormal basis* $\{\mathbf{e}_\mu\}$ *of* $\mathbf{V}$ *such that* $\boldsymbol{\eta}_x(e_\mu, e_\nu) = \eta(\mathbf{e}_\mu, \mathbf{e}_\nu) = \eta_{\mu\nu}$, $\forall x \in M$.

Remark 262 *We just establish that any Lorentzian manifold admits a continuous element field. If it is also time orientable, we can choose a direction for the continuous element field, and say that it is a* timelike *vector field pointing to the future. This is a nontrivial result and very important for our discussion of the Principle of Relativity* (Chap. 5).

4.5 Differential Geometry in the Clifford Bundle

It is well known [19] that the natural operations on metric vector spaces, such as, e.g. direct sum, tensor product, exterior power, etc. carry over canonically to vector bundles with metric tensors. Then we give the following definition:

Definition 263 *The* Clifford bundle *of differential forms of the pair* $(M, \mathbf{g})$ *is:*

$$\mathcal{C}\ell(M,\mathbf{g}) = \frac{\mathcal{T}M}{J_{\mathbf{g}}} = \bigcup_{x \in M} \mathcal{C}\ell(T_x^*M, \mathbf{g}_x) \ , \tag{4.136}$$

where $\mathcal{T}M$ *denotes the (covariant) tensor bundle of* M, $J_{\mathbf{g}} \subset \mathcal{T}M$ *is the bilateral ideal of* $\mathcal{T}M$ *generated by the elements of the form* $\alpha \otimes \beta + \beta \otimes \alpha - 2\mathbf{g}(\alpha, \beta)$, *with* $\alpha, \beta \in \sec T^*M \subset \mathcal{T}M$ *and* $\mathcal{C}\ell(T_x^*M, \mathbf{g}_x)$ *is the Clifford algebra of the metric vector space structure* $(T_x^*M, \mathbf{g}_x)$.

The even subbundle of $\mathcal{C}\ell(M,\mathbf{g})$ is denoted by $\mathcal{C}\ell^{(0)}(M,\mathbf{g})$.

It can be shown that the Clifford bundle $\mathcal{C}\ell(M,\mathbf{g})$ (as defined by (4.136)) is a vector bundle associated with the principal bundle of orthonormal frames $\mathbf{P}_{\mathrm{SO}^e(p,q)}$, i.e.

$$\mathcal{C}\ell(M,\mathbf{g}) = \mathbf{P}_{\mathrm{SO}^e_{p,q}} \times_{Ad} \mathbb{R}_{p,q} \ . \tag{4.137}$$

In (4.137) Ad is the *adjoint representation* of $\mathrm{Spin}^e(p,q)$, i.e. $Ad : \mathrm{SO}^e_{p,q} \to \mathrm{Aut}(\mathbb{R}_{p,q})$, $u \mapsto Ad_u$, with $Ad_u A = u^{-1}$, $\forall u \in \mathrm{SO}^e_{p,q}$, $\forall A \in \mathbb{R}_{p,q} \simeq \mathcal{C}\ell(T_x^*M, \mathbf{g}_x)$. Details on these groups have been given in Chap. 3. In Chap. 6 we scrutinize the vector bundle structure of the Clifford bundle of differential forms over a general Riemann-Cartan manifold modeling spacetime, showing in particular (4.137).

4.5.1 Representation of Clifford Fields as Sums of Non-homogeneous Differential Forms

Definition 264 *Sections of* $\mathcal{C}\ell(M,\mathbf{g})$ *are called Clifford fields.*

We recall some notations and conventions. By $F(U)$ we denote the frame bundle (see Appendix A.3) of $U \subset M$. A section of $F(U)$ will be denoted by $\{\mathbf{e}_\alpha\} \in \sec F(U)$. The dual frame of a frame $\{\mathbf{e}_\alpha\}$ will be denoted by $\{\theta^\alpha\}$, where $\theta^\alpha \in \sec T^*U \subset T^*M$. When $\{\mathbf{e}_\alpha\}$ is a coordinate frame associated with the coordinate functions $\{\mathbf{x}^\mu\}$ of a local chart covering U we use instead of $\mathbf{e}_\alpha$ the notation $e_\alpha = \partial_\alpha$ and in this case $\theta^\alpha = dx^\alpha$. When $\{\mathbf{e}_\alpha\}$ refers to an orthonormal frame we use instead of $\mathbf{e}_\alpha$ the notation $\mathbf{e}_{\mathbf{a}}$ and instead of θ^α the notation $\theta^{\mathbf{a}}$.

Recall that as a vector space over $\mathbb{R}$, $\mathcal{C}\ell(T_x^*M, \mathtt{g}_x)$ is isomorphic to the exterior algebra $\bigwedge T_x^*M$ of the cotangent space and

$$\bigwedge T_x^*M = \bigoplus\nolimits_{k=0}^{n} \bigwedge{}^k T_x^*M \ , \tag{4.138}$$

where $\bigwedge^k T_x^*M$ is the $\binom{n}{k}$-dimensional space of k-forms. Then, there is a natural embedding $\bigwedge T^*M \hookrightarrow \mathcal{C}\ell(M, \mathtt{g})$ [16] and sections of $\mathcal{C}\ell(M, \mathtt{g})$ –Clifford fields (Definition 264)– can be represented as a sum of non homogeneous differential forms.[17] Let $\{\mathbf{e_a}\}$ be an orthonormal basis for $TU \subset TM$, i.e. $\mathbf{g}(\mathbf{e_a}, \mathbf{e_b}) = \eta_{\mathbf{ab}} = \mathrm{diag}(1, 1, ..., -1, ..., -1)$ and $(\mathbf{a}, \mathbf{b}, \mathbf{i}, \mathbf{j}, ... = 1, 2, ..., n)$. Moreover, let $\{\theta^{\mathbf{a}}\} \in \sec \bigwedge^1 T^*M \hookrightarrow \sec \mathcal{C}\ell(M, \mathtt{g})$ such that the set $\{\theta^{\mathbf{a}}\}$ is the dual basis of $\{\mathbf{e_i}\}$. We denote by $\{\theta_{\mathbf{i}}\}$ the *reciprocal basis* of $\{\theta^{\mathbf{i}}\}$, i.e. $\theta_{\mathbf{i}} \underset{\mathtt{g}}{\cdot} \theta^{\mathbf{j}} = \delta_{\mathbf{i}}^{\mathbf{j}}$.

For the particular case of a 4−dimensional spacetime, of course, the range of the bold labels are $\mathbf{a}, \mathbf{b}, \mathbf{i}, ... = 0, 1, 2, 3$. Recall that the fundamental *Clifford product* is generated by

$$\theta^{\mathbf{i}}\theta^{\mathbf{j}} + \theta^{\mathbf{j}}\theta^{\mathbf{i}} = 2\eta^{\mathbf{ij}}. \tag{4.139}$$

If $\mathcal{C} \in \sec \mathcal{C}\ell(M, \mathtt{g})$ is a Clifford field, we have:

$$\mathcal{C} = s + v_{\mathbf{i}}\theta^{\mathbf{i}} + \frac{1}{2!}b_{\mathbf{ij}}\theta^{\mathbf{i}}\theta^{\mathbf{j}} + \frac{1}{3!}t_{\mathbf{ijk}}\theta^{\mathbf{i}}\theta^{\mathbf{j}}\theta^{\mathbf{k}} + p\theta^{\mathbf{5}} \ , \tag{4.140}$$

where $\theta^{\mathbf{5}} = \theta^{\mathbf{0}}\theta^{\mathbf{1}}\theta^{\mathbf{2}}\theta^{3}$ is the volume element and

$$s, v_{\mathbf{i}}, b_{\mathbf{ij}}, t_{\mathbf{ijk}}, p \in \sec \bigwedge{}^0 T^*M \hookrightarrow \sec \mathcal{C}\ell(M, \mathtt{g}) \ . \tag{4.141}$$

4.5.2 Pullbacks and Relation Between Hodge Star Operators

Let M be a n-dimensional manifold and $\mathbf{g}$,$\mathring{\mathbf{g}} \in \sec T_2^0M$ two metrics of the same signature with corresponding metrics $\mathtt{g}$,$\mathring{\mathtt{g}} \in \sec T_0^2M$. Let g and $\mathring{g}$ be the extensor fields associated with $\mathtt{g}$ and $\mathring{\mathtt{g}}$. Let $\mathtt{h}$: $M \to M$ be a diffeomorphism and suppose that

$$\mathbf{g} \ = \mathtt{h}^*\mathring{\mathbf{g}} \ . \tag{4.142}$$

From the algebraic results of Sect. 2.7 we easily infer that there exists a metric gauge extensor field $h = h^\dagger$ such that

$$g(a) \underset{\mathring{\mathtt{g}}}{\cdot} b = h(a) \underset{\mathring{\mathtt{g}}}{\cdot} h(b) \ , \tag{4.143}$$

for any $a, b \in \sec \bigwedge^1 T^*M$ and we write $g = h^2$. Then, as in the purely algebraic case discussed in Sect. 2.7 we can also show that we have the following relation between the Hodge star operators associated with $\mathbf{g}$ and $\mathring{\mathbf{g}}$,

$$\underset{\mathbf{g}}{\star} = \underline{h}^{-1} \underset{\mathring{\mathbf{g}}}{\star} \underline{h} \ . \tag{4.144}$$

---

[17] For this reason Clifford fields are also called (non homogeneous) multiform fields.

In this case we say that the metric gauge extensor h is related to the pullback mapping $\mathtt{h}^*$.

We now show the

Proposition 265 *Let* $\mathtt{h} : M \longrightarrow M$ *a diffeomorphism. Let* $\mathbf{g}$,$\mathring{\mathbf{g}} \in \sec T_2^0 M$ *two metrics of the same signature. Then for any* $\omega \in \sec \bigwedge^p T^*M$ *we have*

$$\underset{\mathbf{g}}{\star}\,\mathtt{h}^*\omega = \mathtt{h}^*\underset{\mathring{\mathbf{g}}}{\star}\,\omega\ . \tag{4.145}$$

Proof. As in Remark 180 take two charts (U,φ) and (V,χ), U, $\mathtt{h}(U), \subset V$ with coordinate functions $\boldsymbol{x}^i$ and $\boldsymbol{y}^i$ such that and $\mathbf{x}^i(\mathfrak{e}) = \boldsymbol{y}^i(\mathtt{h}(\mathfrak{e}))$, i.e. calling $\mathbf{x}^i(\mathfrak{e}) = x^i$, $\boldsymbol{y}^i(\mathtt{h}(\mathfrak{e})) = y^i$ we have $\partial y^i/\partial x^j = \delta^i_j$, $dx^i = dy^i$. Let also $\mathring{\mathbf{g}}(\partial/\partial y^k, \partial/\partial y^l) = \mathring{\mathbf{g}}_{kl}(y^i)$. Then it follows that $\mathbf{g}_{kl}(x^i) = \mathring{\mathbf{g}}_{kl}(y^j(x^i)) = \mathring{\mathbf{g}}_{kl}(x^i)$ and $\det \mathbf{g} = \det \mathring{\mathbf{g}}$. Now, if $\omega = \frac{1}{p!}\omega_{i_1 \ldots i_p}\left(x^i\right) dx^{i_1} \wedge \ldots \wedge dx^{i_p}$, we can write (taking into account that $\bigwedge^p T^*M \hookrightarrow \mathcal{C}\ell(M,\mathbf{g})$ and also $\bigwedge^p T^*M \hookrightarrow \mathcal{C}\ell(M,\mathring{\mathbf{g}})$)

$$\begin{aligned}
\underset{\mathbf{g}}{\star}\mathtt{h}^*\omega &= \widetilde{\mathtt{h}^*\omega}\underset{\mathbf{g}}{\lrcorner}\tau_{\mathbf{g}} = \widetilde{\mathtt{h}^*\omega}\tau_{\mathbf{g}} \\
&= \frac{1}{p!}\omega_{i_1 \ldots i_p}\left(y^i(x^j)\right)dx^{i_1}\,\widetilde{\wedge \ldots \wedge}\,dx^{i_p}\sqrt{|\det \mathbf{g}|}dx^1 \wedge \ldots \wedge dx^n \\
&= \frac{1}{p!}\omega_{i_1 \ldots i_p}(y^i(x^j))dy^{i_1}\,\widetilde{\wedge \ldots \wedge}\,dy^{i_p}\sqrt{|\det \mathring{\mathbf{g}}|}dy^1 \wedge \ldots \wedge dy^n \\
&= \frac{1}{p!}\omega_{i_1 \ldots i_p}\left(y^i\right)dy^{i_1}\,\widetilde{\wedge \ldots \wedge}\,dy^{i_p}\underset{\mathring{\mathbf{g}}}{\lrcorner}\sqrt{|\det \mathring{\mathbf{g}}|}dy^1 \wedge \ldots \wedge dy^n \\
&= \mathtt{h}^*\underset{\mathring{\mathbf{g}}}{\star}\,\omega\ ,
\end{aligned}$$

and the proposition is proved. □

Remark 266 *When* $\mathbf{g} = \mathtt{h}^*\mathring{\mathbf{g}}$, *there exists an associated metric gauge extensor field* h *satisfying* (4.143), *i.e.* $g = h^2$. *The relation* $\underset{\mathbf{g}}{\star}\mathtt{h}^*\omega = \mathtt{h}^*\underset{\mathring{\mathbf{g}}}{\star}\,\omega$ *and* $\underset{\mathbf{g}}{\star} = \underline{h}^{-1}\underset{\mathring{\mathbf{g}}}{\star}\,\underline{h}$ *permit us to write the suggestive* operator *identity*

$$\underset{\mathring{\mathbf{g}}}{\star}\,\underline{h}\mathtt{h}^*\omega = \underline{h}\mathtt{h}^*\underset{\mathring{\mathbf{g}}}{\star}\,\omega\ . \tag{4.146}$$

Exercise 267 *Consider any diffeomorphism* $\mathtt{h} : M \to M$, *and two metrics* $\mathbf{g}$ *and* $\mathring{\mathbf{g}}$ *such that* $\mathbf{g} = \mathtt{h}^*\mathring{\mathbf{g}}$. *Show that*

$$\underset{\mathbf{g}}{\star}\,d\underset{\mathbf{g}}{\star}\,\mathtt{h}^*\omega = \mathtt{h}^*\underset{\mathring{\mathbf{g}}}{\star}\,d\underset{\mathring{\mathbf{g}}}{\star}\,\omega\ , \tag{4.147}$$

for any $\omega \in \bigwedge T^*M$.

Solution: The first member of (4.147) can be writing successively using (4.145) as

$$
\begin{aligned}
\underset{\mathbf{g}}{\star} d \underset{\mathbf{g}}{\star} \mathtt{h}^{*} \omega &= \underset{\mathbf{g}}{\star} d \mathtt{h}^{*} \underset{\mathring{\mathbf{g}}}{\star} \omega \\
&= \underset{\mathbf{g}}{\star} \mathtt{h}^{*} d \underset{\mathring{\mathbf{g}}}{\star} \omega \\
&= \mathtt{h}^{*} \underset{\mathring{\mathbf{g}}}{\star} d \underset{\mathring{\mathbf{g}}}{\star} \omega \,.
\end{aligned}
$$

4.5.3 Dirac Operators

We now equip the Riemannian (pseudo-Riemannian, or Lorentzian) manifold $(M, \mathring{\mathbf{g}})$ with a *standard* (or fiducial) structure $(M, \mathring{\mathbf{g}}, \mathring{D})$, where $\mathring{D}$ is the Levi-Civita connection of $\mathring{\mathbf{g}}$.

We are going to introduce in the Clifford bundle of differential forms $\mathcal{C}\ell(M, \mathring{\mathtt{g}})$ a differential operator $\mathring{\boldsymbol{\partial}}$, called the standard Dirac operator[18], which is associated with the Levi-Civita connection of the structure $(M, \mathring{\mathbf{g}}, \mathring{D})$ and we study the properties of that operator. Next we define new Dirac-like operators associated with a connection different from the Levi-Civita one, i.e. to connections ∇ defining a general Riemann-Cartan-Weyl geometry $(M, \mathring{\mathbf{g}}, \nabla)$. Moreover, making use of the results developed in Sect. 2.7, we show that it is possible to introduce infinitely many others Dirac-like operators, one for each bilinear form field defined on the manifold M of the structure $(M, \mathring{\mathbf{g}}, \mathring{D})$. These constructions enable us to formulate the geometry of a Riemann-Cartan-Weyl space in the Clifford bundle $\mathcal{C}\ell(M, \mathring{\mathtt{g}})$. Some interesting geometrical concepts, like the Dirac *commutator* and *anticommutator*, are introduced. Moreover, we show a new decomposition of a general linear connection, identifying some relevant tensors which are important for a clear understanding of any formulation of the gravitational theory in flat Minkowski spacetime (Chap. 9) and other related subjects appearing in the literature.

The Standard Dirac Operator

Given $\mathbf{u} \in \sec TM$ and $A \in \sec \bigwedge^{r} T^{*}M \hookrightarrow \sec \mathcal{C}\ell(M, \mathring{\mathtt{g}})$ consider the tensorial mapping $A \mapsto \mathring{D}_{\mathbf{u}} A \in \sec \bigwedge^{r} T^{*}M \hookrightarrow \sec \mathcal{C}\ell(M, \mathring{\mathtt{g}})$. Since $\mathring{D}_{\mathbf{u}} J_{\mathring{\mathtt{g}}} \subseteq J_{\mathring{\mathtt{g}}}$, where $J_{\mathring{\mathtt{g}}}$ is the ideal used in the definition of $\mathcal{C}\ell(M, \mathring{\mathtt{g}})$, we see immediately that the notion of covariant derivative (related to the Levi-Civita connection[19]) pass to the quotient bundle $\mathcal{C}\ell(M, \mathring{\mathtt{g}})$, i.e. given $A, B \in \sec \bigwedge^{r} T^{*}M \hookrightarrow \sec \mathcal{C}\ell(M, \mathring{\mathtt{g}})$

---

[18] It is crucial to distinguish the Dirac operators introduced in this chapter and which act on sections of Clifford bundles with the spin Dirac operator introduced in Chap. 6 and which act on sections of spin-Clifford bundles.

[19] And more generally, to any metric compatible connection.

(%

Pág. 392 (403) -

→ transformation function $\langle p|x\rangle$

We express its matrix element as a Fourier integral by inserting the spectral projection $[p]$ for momentum, keying the transformation function $\langle p|x\rangle$ from position eigenvectors $|x\rangle$ to momentum ones $|p\rangle$.

$$\langle p|x\rangle = \frac{1}{\sqrt{2\pi}} e^{ipx} \qquad (6).$$

∴ this integral is the standard Gaussian, integrated along a line in the complex plane from the real axis by $\pi/4$:

$$\int dp\, e^{-ip^2 \delta t/2} = \sqrt{\frac{2p}{i\delta t}}. \qquad (10)$$

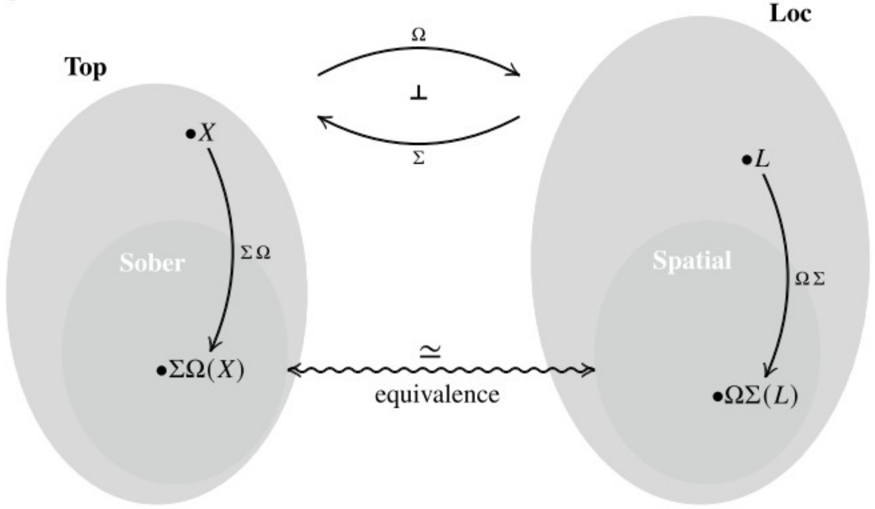
3.9 Classical and Generalized (Point-Free) Spaces

Now we are ready for a rough outline of the relation of the point-free and classical spaces.



"sobrification" of a space *"spatialization" of a locale*

On the one hand the point-free theory extends the classical one (or, at least a substantial part of it; precisely, the subcategory of sober spaces). On the other hand, the scope of the generalized is much larger; we will present two simple examples shortly. The reader may of course ask whether such an extension is useful. It turns out that it is, as will be hopefully apparent from the following sections.

3.9.1 Two Easy Examples First, consider a complete Boolean algebra B without atoms (e.g., the lattice of all *regular open sets*[2] of any Euclidean space). There are no primes at all: indeed, let p be one. Since it is not an atom, there is an x with $p < x < 1$. We have $x^* \wedge x = 0 \leq p$, hence $x^* = 0$ and $x = 1$, a contradiction.

Next, take such a B again and consider $L = \{(x, y) \in B \times B \mid x \leq y\}$. Since all the $(0, x)$ are in L we obtain by the same reasoning as above that a prime in L has to be of the form $(q, 1)$ and hence there are no primes to separate distinct $(0, a)$ and $(0, b)$.

The latter example seems to be very similar to the former, but it is in fact much more interesting. While Boolean frames are something like a generalization of discrete spaces (albeit constituting a much more colorful class), the frames L of this example are geometrically rather peculiar (do not forget that a subframe is, due to the contravariance, geometrically more like a quotient space, not like a subspace):

---

[2] That is, the opens $U = \operatorname{int}\overline{U}$, "open sets without lesions", the open sets one thinks about first.

interpreted as spaces they are behaving like Hausdorff ones, while on the other hand they are not even subfit (see 7.6.2 below) which is a property weaker than T_1!

4 Categorical Remarks

4.1 *Semilattices and a Free Functor*

Under a *semilattice* we here understand a *meet semilattice with 0 and 1*, and *semilattice homomorphisms* preserve $\wedge$, 0 and 1.

4.1.1 Biproduct Note that in the category of semilattices (similarly like in abelian groups), the cartesian product with the injections and projections as in the following diagram

$$\begin{tikzcd}
L_1 \arrow[dr, bend right=10, "\iota_1=(a\mapsto(a,1))"] & & L_1 \\
& L_1\times L_2 \arrow[ur, two heads, bend left=10, "p_1=((a_1,a_2)\mapsto a_1)"] \arrow[dr, two heads, bend right=10, "p_2=((a_1,a_2)\mapsto a_2)"'] & \\
L_2 \arrow[ur, bend left=10, "\iota_2=(a\mapsto(1,a))"'] & & L_2
\end{tikzcd}$$

constitutes a biproduct (note that $p_1\iota_1 \wedge p_2\iota_2 = \mathrm{id}$ and check the coproduct and product properties).

4.1.2 A Free Construction For a semilattice L consider the down-set lattice

$$\mathfrak{D}(L) = \{U \subseteq L \mid \emptyset \neq U = {\downarrow}U\}$$

ordered by inclusion. Further, define $\lambda = \lambda_L : L \to \mathfrak{D}(L)$ by setting $\lambda(a) = {\downarrow}a$. Obviously,

$\mathfrak{D}(L)$ is a frame and λ is a semilattice homomorphism

(since we take only the non-empty down-sets, the zero of $\mathfrak{D}(L)$ is $\{0\}$; all the other joins are the unions).

Proposition *Let M be a frame and let $h: L \to M$ be a semilattice homomorphism. Then there is precisely one frame homomorphism $\widetilde{h}: \mathfrak{D}(L) \to M$ such that the diagram*

2.6.4 Observation *Let* b *have a complement* b^{c} *in a distributive lattice* L. *Then*

$$a \wedge b \leq c \text{ iff } a \leq b^{\mathsf{c}} \vee c, \quad \text{and} \quad a \vee b \geq c \text{ iff } a \geq c \wedge b^{\mathsf{c}}.$$

Thus, in a Heyting algebra we have for any complemented element $b, b \to c = b^* \vee c$ *and in a coHeyting algebra we have for any complemented element* $b, c \smallsetminus b = c \wedge b^{\#}$.

Note All the assumptions are essential, though. In particular the formulas $b \to c = b^* \vee c$ resp. $c \smallsetminus b = c \wedge b^{\#}$ hold for complemented elements only; the Heyting resp. coHeyting operation cannot be thus reduced to pseudocomplementing resp. supplementing in no other case.

2.7 *Boolean Algebras*

A *Boolean algebra* is a distributive lattice in which every element is complemented. From 2.6.4 we immediately obtain

Corollary *A Boolean algebra is both a Heyting and a coHeyting algebra.*

3 Frames and Spaces

3.1 *The Category of Frames*

A *frame* (resp. *coframe*) is a complete lattice L satisfying the distributivity law

$$(\bigvee A) \wedge b = \bigvee \{a \wedge b \mid a \in A\} \tag{frm}$$

$$\text{(resp. } (\bigwedge A) \vee b = \bigwedge \{a \vee b \mid a \in A\}\text{)} \tag{cofrm}$$

for all $A \subseteq L$ and $b \in L$. A *frame homomorphism* $h\colon L \to M$ between two frames is a mapping preserving all joins and all finite meets. The resulting category will be denoted by

$$\mathsf{Frm}.$$

Similarly we have *coframe homomorphisms* between coframes preserving all meets and finite joins.

3.2 Spaces and Frames. The Functor Ω

A typical frame is the lattice $\Omega(X)$ of all open subsets of a topological space. Furthermore, if $f\colon X \to Y$ is a continuous mapping we have a frame homomorphism $\Omega(f)\colon \Omega(Y) \to \Omega(X)$ defined by $\Omega(f)(U) = f^{-1}[U]$. Thus we obtain a *contravariant* functor

$$\Omega\colon \mathsf{Top} \to \mathsf{Frm},$$

a basic link between classical spaces and what will turn out to be the generalized ones (see already in 3.5.2 below, then in 3.9, and again and again).

3.2.1 A Warning Let us agree that our spaces will be, from now on, always T_0: the frames $\Omega(X)$ will be central in our approach to spaces and it will make no sense to discuss classical points that cannot be distinguished by open sets. In particular we will, without further particular mentioning, use the following

Observation *Let $f, g\colon X \to Y$ be distinct continuous maps, and let Y be T_0. Then $\Omega(f) \neq \Omega(g)$.*

(Indeed, if $f(x) \neq g(x)$ consider a U such that, say, $g(x) \notin U \ni f(x)$. Then $x \in \Omega(f)(U) \smallsetminus \Omega(g)(U)$.)

3.2.2 Notes (a) Unlike plain (finite) distributivity, the frame distributivity typically does not carry over to the dual, that is, a frame is seldom simultaneously a coframe. Take e.g. any T_1-space X with a non-isolated point x and an open set $W \ni x$. Set $V = W \smallsetminus \{x\}$ and $\mathcal{U} = \{U \in \Omega(X) \mid x \in U\}$. Then $\bigwedge \mathcal{U} = \operatorname{int} \bigcap \mathcal{U} = \emptyset$ and hence $(\bigwedge \mathcal{U}) \cup V = V$ while $\bigwedge\{U \cup V \mid U \in \mathcal{U}\} = W \neq V$.
(b) As the example shows, coframes will seldom come as models of (generalized) spaces. They will play, however, a fundamental role in the study of the structure of generalized subspaces.

3.3 The Heyting Structure

Recall 2.6 (and 2.2). The distributivity rule (frm) makes a frame a Heyting algebra and computing with the Heyting operation will be extensively used; similarly we will use computing with the difference in coframes. But we have to keep in mind that the category Frm is not that of (complete) Heyting algebras: frame homomorphisms generally do not respect the Heyting operation.

6.4. NON-EUCLIDEAN GEOMETRY

The term **non-Euclidean Geometry** describes both *Hyperbolic Geometry* (or *Lobachevsky Geometry*, *Lobachevsky–Bolyai–Gauss Geometry*) and *Elliptic Geometry* (sometimes called also *Riemannian Geometry*) which are contrasted with *Euclidean Geometry* (or *Parabolic Geometry*). The essential difference between Euclidean and non-Euclidean Geometry is the nature of parallel lines. In Euclidean Geometry, if we start with a line l and a point a, which is not on l, then we can only draw one line through a that is parallel to l. In Hyperbolic Geometry there are infinitely many lines through a parallel to l. In Elliptic Geometry, parallel lines do not exist.

The *Spherical Geometry* is also “non-Euclidean”, but it fails the axiom that any two points determine exactly one line.

- **Spherical metric**

  Let $S^n(0,r) = \{x \in \mathbb{R}^{n+1} : \sum_{i=1}^{n+1} x_i^2 = r^2\}$ be a sphere in $\mathbb{R}^{n+1}$ with the center 0 and the radius $r > 0$.

  The **spherical metric** (or **great circle metric**) d_{sph} is a metric on $S^n(0,r)$, defined by

$$r \arccos\left(\frac{|\sum_{i=1}^{n+1} x_i y_i|}{r^2}\right),$$

  where arccos is the inverse cosine in $[0, \pi]$. It is the length of the *great circle* arc, passing through x and y. In terms of the standard *inner product* $\langle x, y\rangle = \sum_{i=1}^{n+1} x_i y_i$ on $\mathbb{R}^{n+1}$, the spherical metric can be written as $r \arccos \frac{|\langle x,y\rangle|}{\sqrt{\langle x,x\rangle\langle y,y\rangle}}$.

  The metric space $(S^n(0,r), d_{sph})$ is called *n-dimensional spherical space*. It is a space of curvature $1/r^2$, and r is the radius of curvature. It is a model of n-dimensional *Spherical Geometry*. The great circles of the sphere are its geodesics, all geodesics are closed and of the same length. (See, for example, [Blum70].)

- **Elliptic metric**

  Let $\mathbb{R}P^n$ be the real n-dimensional projective space. The **elliptic metric** d_{ell} is a metric on $\mathbb{R}P^n$, defined by

$$r \arccos \frac{|\langle x, y\rangle|}{\sqrt{\langle x, x\rangle\langle y, y\rangle}},$$

  where, for any $x = (x_1 : \ldots : x_{n+1})$, $y = (y_1 : \ldots : y_{n+1}) \in \mathbb{R}P^n$, one has $\langle x, y\rangle = \sum_{i=1}^{n+1} x_i y_i$, r is a fixed positive constant, and arccos is the inverse cosine in $[0, \pi]$.

  The metric space $(\mathbb{R}P^n, d_{ell})$ is called *n-dimensional elliptic space*. It is a model of n-dimensional *Elliptic Geometry*. It is the space of curvature $1/r^2$, and r is the radius of curvature. As $r \to \infty$, the metric formulas of Elliptic Geometry yield formulas of Euclidean Geometry (or become meaningless).

  If $\mathbb{R}P^n$ is viewed as the set $E^n(0,r)$, obtained from the sphere $S^n(0,r) = \{x \in \mathbb{R}^{n+1} : \sum_{i=1}^{n+1} x_i^2 = r^2\}$ in $\mathbb{R}^{n+1}$ with the center 0 and the radius r by identifying diametrically-opposite points, then the elliptic metric on $E^n(0,r)$ can be written as $d_{sph}(x, y)$ if

$d_{sph}(x, y) \leqslant \frac{\pi}{2}r$, and as $\pi r - d_{sph}(x, y)$ if $d_{sph}(x, y) > \frac{\pi}{2}r$, where d_{sph} is the **spherical metric** on $S^n(0, r)$. Thus, no two points of $E^n(0, r)$ have distance exceeding $\frac{\pi}{2}r$. The elliptic space $(E^2(0, r), d_{ell})$ is called *Poincaré sphere*.

If $\mathbb{R}P^n$ is viewed as the set E^n of lines through the zero element 0 in $\mathbb{R}^{n+1}$, then the elliptic metric on E^n is defined as the angle between the corresponding subspaces.

An n-dimensional elliptic space is a *Riemannian space* of constant positive curvature. It is the only such space which is topologically equivalent to a projective space. (See, for example, [Blum70], [Buse55].)

- **Hermitian elliptic metric**

Let $\mathbb{C}P^n$ be the n-dimensional complex projective space. The **Hermitian elliptic metric** d^H_{ell} (see, for example, [Buse55]) is a metric on $\mathbb{C}P^n$, defined by

$$r \arccos \frac{|\langle x, y\rangle|}{\sqrt{\langle x, x\rangle\langle y, y\rangle}},$$

where, for any $x = (x_1 : \dots : x_{n+1})$, $y = (y_1 : \dots : y_{n+1}) \in \mathbb{C}P^n$, one has $\langle x, y\rangle = \sum_{i=1}^{n+1} \overline{x}_i y_i$, r is a fixed positive constant, and arccos is the inverse cosine in $[0, \pi]$.

The metric space $(\mathbb{C}P^n, d^H_{ell})$ is called n-dimensional *Hermitian elliptic space* (cf. **Fubini–Study metric**).

- **Elliptic plane metric**

The **elliptic plane metric** is the **elliptic metric** on the *elliptic plane* $\mathbb{R}P^2$. If $\mathbb{R}P^2$ is viewed as the *Poincaré sphere* (i.e., a sphere in $\mathbb{R}^3$ with identified diametrically-opposite points) of diameter 1 tangent to the extended complex plane $\overline{\mathbb{C}} = \mathbb{C} \cup \{\infty\}$ at the point $z = 0$, then, under the stereographic projection from the "north pole" $(0, 0, 1)$, $\overline{\mathbb{C}}$ with identified points z and $-\frac{1}{\overline{z}}$ is a model of the elliptic plane, and the elliptic plane metric d_{ell} on it is defined by its *line element* $ds^2 = \frac{|dz|^2}{(1+|z|^2)^2}$.

- **Pseudo-elliptic distance**

The **pseudo-elliptic distance** (or *elliptic pseudo-distance*) dp_{ell} is a distance on the extended complex plane $\overline{\mathbb{C}} = \mathbb{C} \cup \{\infty\}$ with identified points z and $-\frac{1}{\overline{z}}$, defined by

$$\left|\frac{z - u}{1 + \overline{z}u}\right|.$$

In fact, $dp_{ell}(z, u) = \tan d_{ell}(z, u)$, where d_{ell} is the **elliptic plane metric**.

- **Hyperbolic metric**

Let $\mathbb{R}P^n$ be the n-dimensional real projective space. Let, for any $x = (x_1 : \dots : x_{n+1})$, $y = (y_1 : \dots : y_{n+1}) \in \mathbb{R}P^n$, the *scalar product* $\langle x, y\rangle = -x_1 y_1 + \sum_{i=2}^{n+1} x_i y_i$ be considered.

Chapter 8

Distances on Surfaces and Knots

8.1. GENERAL SURFACE METRICS

A *surface* is a real two-dimensional *manifold* M^2, i.e., a **Hausdorff space**, each point of which has a neighborhood which is homeomorphic to a plane $\mathbb{E}^2$, or a closed half-plane (cf. Chapter 7).

A compact orientable surface is called *closed* if it has no boundary, and it is called *surface with boundary*, otherwise. There are compact non-orientable surfaces (closed or with boundary); the simplest such surface is the *Möbius strip*. Non-compact surfaces without boundary are called *open*.

Any closed connected surface is homeomorphic to either a sphere with, say, g (cylindric) handles, or a sphere with, say, g *cross-caps* (i.e., caps with a twist like Möbius strip in them). In both cases the number g is called *genus* of the surface. In the case of handles, the surface is orientable; it is called *torus* (doughnut), *double torus*, and *triple torus* for $g = 1, 2$ and 3, respectively. In the case of cross-caps, the surface is non-orientable; it is called *real projective plane*, *Klein bottle*, and *Dyck's surface* for $g = 1, 2$ and 3, respectively. The genus is the maximal number of disjoint simple closed curves which can be cut from a surface without disconnecting it (the *Jordan curve theorem* for surfaces).

The *Euler–Poincaré characteristic* of a surface is (the same for all polyhedral decompositions of a given surface) the number $\chi = v - e + f$, where v, e and f are, respectively, the number of vertices, edges and faces of the decomposition. It holds $\chi = 2 - 2g$ if the surface is orientable, and $\chi = 2 - g$ if not. Every surface with boundary is homeomorphic to a sphere with appropriated number of (disjoint) *holes* (i.e., what remains if an open disk is removed) and handles or cross-caps. If h is the number of holes, then $\chi = 2 - 2g - h$ holds if the surface is orientable, and $\chi = 2 - g - h$ if not.

The *connectivity number* of a surface is the largest number of closed cuts that can be made on the surface without separating it into two or more parts. This number is equal to $3 - \chi$ for closed surfaces, and $2 - \chi$ for surfaces with boundaries. A surface with connectivity number 1, 2 and 3 is called, respectively, *simply, doubly* and *triply connected*. A sphere is simply connected, while a torus is triply connected.

A surface can be considered as a metric space with its own **intrinsic metric**, or as a figure in space. A surface in $\mathbb{E}^3$ is called *complete* if it is a **complete** metric space with respect to its intrinsic metric.

A surface is called *differentiable*, *regular*, or *analytic*, respectively, if in a neighborhood of each of its points it can be given by an expression

$$r = r(u, v) = r(x_1(u, v), x_2(u, v), x_3(u, v)),$$

where the *position vector* $r = r(u, v)$ is a differentiable, *regular* (i.e., a sufficient number of times differentiable), or *real analytic*, respectively, vector function satisfying the condition $r_u \times r_v \neq 0$.

Any regular surface has the intrinsic metric with the *line element* (or *first fundamental form*)

$$ds^2 = dr^2 = E(u, v)\,du^2 + 2F(u, v)\,du\,dv + G(u, v)\,dv^2,$$

where $E(u, v) = \langle r_u, r_u \rangle$, $F(u, v) = \langle r_u, r_v \rangle$, $G(u, v) = \langle r_v, r_v \rangle$. The length of a curve, defined on the surface by the equations $u = u(t)$, $v = v(t)$, $t \in [0, 1]$, is computed by

$$\int_0^1 \sqrt{Eu'^2 + 2Fu'v' + Gv'^2}\,dt,$$

and the distance between any points $p, q \in M^2$ is defined as the infimum of the lengths of all curves on M^2, connecting p and q. A **Riemannian metric** is a generalization of the first fundamental form of a surface.

For surfaces, two kinds of *curvature* are considered: *Gaussian curvature*, and *mean curvature*. To compute those curvatures at a given point of the surface, consider the intersection of the surface with a plane, containing a fixed *normal vector*, i.e., a vector which is perpendicular to the surface at this point. This intersection is a plane curve. The *curvature* k of this plane curve is called *normal curvature* of the surface at the given point. If we vary the plane, the normal curvature k will change, and there are two extremal values – the *maximal curvature* k_1, and the *minimal curvature* k_2, called *principal curvatures* of the surface. A curvature is taken to be *positive* if the curve turns in the same direction as the surface's chosen normal, otherwise it is taken to be *negative*. The *Gaussian curvature* is $K = k_1 k_2$ (it can be given entirely in terms of the first fundamental form). The *mean curvature* is $H = \frac{1}{2}(k_1 + k_2)$.

A *minimal surface* is a surface with mean curvature zero, or, equivalently, a surface of minimum area subject to constraints on the location of its boundary.

A *Riemann surface* is an one-dimensional *complex manifold*, or a two-dimensional real manifold with a complex structure, i.e., in which the local coordinates in neighborhoods of points are related by complex analytic functions. It can be thought as a deformed version of the complex plane. All Riemann surfaces are orientable. Closed Riemann surfaces are geometrical models of *complex algebraic curves*. Every connected Riemann surface can be turned into a *complete* two-dimensional *Riemannian manifold* with constant curvature -1, 0, or 1. The Riemann surfaces with the curvature -1 are called *hyperbolic*, the *unit disk* $\Delta = \{z \in \mathbb{C}: \ |z| < 1\}$ is the canonical example. The Riemann surfaces with the curvature 0 are called *parabolic*, $\mathbb{C}$ is a typical example. The Riemann surfaces with the curvature 1 are called *elliptic*, the *Riemann sphere* $\mathbb{C} \cup \{\infty\}$ is a typical example.

- **Regular metric**

The intrinsic metric of a surface is called **regular** if it can be specified using the *line element*

$$ds^2 = E\,du^2 + 2F\,du\,dv + G\,dv^2,$$

where the coefficients of the form ds^2 are regular functions.

Any regular surface, given by an expression $r = r(u, v)$, has a regular metric with the *line element* ds^2, where $E(u, v) = \langle r_u, r_u \rangle$, $F(u, v) = \langle r_u, r_v \rangle$, $G(u, v) = \langle r_v, r_v \rangle$.

- **Analytic metric**

  The intrinsic metric on a surface is called **analytic** if it can be specified using the *line element*

  $$ds^2 = E\,du^2 + 2F\,du\,dv + G\,dv^2,$$

  where the coefficients of the form ds^2 are real analytic functions.

  Any analytic surface, given by an expression $r = r(u, v)$, has an analytic metric with the *line element* ds^2, where $E(u, v) = \langle r_u, r_u \rangle$, $F(u, v) = \langle r_u, r_v \rangle$, $G(u, v) = \langle r_v, r_v \rangle$.

- **Metric of positive curvature**

  A **metric of positive curvature** is the intrinsic metric on a *surface of positive curvature*.

  A *surface of positive curvature* is a surface in $\mathbb{E}^3$ that has positive Gaussian curvature at every point.

- **Metric of negative curvature**

  A **metric of negative curvature** is the intrinsic metric on a *surface of negative curvature*.

  A *surface of negative curvature* is a surface in $\mathbb{E}^3$ that has negative Gaussian curvature at every point. A surface of negative curvature locally have a saddle-like structure. The intrinsic geometry of a surface of constant negative curvature (in particular, of a *pseudo-sphere*) locally coincides with the geometry of *Lobachevsky plane*. There exists no surface in $\mathbb{E}^3$, whose intrinsic geometry coincides completely with the geometry of Lobachevsky plane (i.e., a complete regular surface of constant negative curvature).

- **Metric of non-positive curvature**

  A **metric of non-positive curvature** is the intrinsic metric on a *saddle-like surface*.

  A *saddle-like surface* is a generalization of a surface of negative curvature: a twice continuously-differentiable surface is a saddle-like surface if and only if at each point of the surface its Gaussian curvature is non-positive. These surfaces can be seen as antipodes of *convex surfaces*, but they do not form such a natural class of surfaces as do convex surfaces.

- **Metric of non-negative curvature**

  A **metric of non-negative curvature** is the intrinsic metric on a *convex surface*.

  A *convex surface* is a *domain* (i.e., a connected open set) on the boundary of a *convex body* in $\mathbb{E}^3$ (in some sense, it is an antipode of saddle-like surface). The entire boundary of a convex body is called *complete convex surface*. If the body is finite (bounded), the complete convex surface is called *closed*. Otherwise, it is called *infinite* (an infinite convex surface is homeomorphic to a plane or to a circular cylinder).

Any convex surface M^2 in $\mathbb{E}^3$ is a *surface of bounded curvature*. The *total Gaussian curvature* $w(A) = \iint_A K(x)\,d\sigma(x)$ of a set $A \subset M^2$ is always non-negative (here $\sigma(.)$ is the *area*, and $K(x)$ is the *Gaussian curvature* of M^2 at a point x), i.e., a convex surface can be seen as a *surface of non-negative curvature*.

The intrinsic metric of a convex surface is a **convex metric** in the sense of surface theory, i.e., it displays the *convexity condition*: the sum of the angles of any triangle whose sides are shortest curves is not less that π.

- **Metric with alternating curvature**

A **metric with alternating curvature** is the intrinsic metric on a surface with alternating (positive or negative) Gaussian curvature.

- **Flat metric**

A **flat metric** is the intrinsic metric on a *developable surface*, i.e., a surface, on which the Gaussian curvature is everywhere zero.

- **Metric of bounded curvature**

A **metric of bounded curvature** is the intrinsic metric ρ on a *surface of bounded curvature*.

A surface M^2 with an intrinsic metric ρ is called *surface of bounded curvature* if there exists a sequence of **Riemannian metrics** ρ_n, defined on M^2, such that for any compact set $A \subset M^2$ one has $\rho_n \to \rho$ uniformly, and the sequence $|w_n|(A)$ is bounded, where $|w|_n(A) = \iint_A |K(x)|\,d\sigma(x)$ is *total absolute curvature* of the metric ρ_n (here $K(x)$ is the Gaussian curvature of M^2 at a point x, and $\sigma(.)$ is the *area*).

- ***Λ*-metric**

A ***Λ*-metric** (or *metric of type Λ*) is a **complete** metric on a surface with curvature bounded from above by a negative constant.

An Λ-metric does not have embeddings into $\mathbb{E}^3$. It is a generalization of the classical result of Hilbert (1901): no complete regular surface of constant negative curvature (i.e., a surface whose intrinsic geometry coincides completely with the geometry of Lobachevsky plane) exists in $\mathbb{E}^3$.

- **(*h*, *Δ*)-metric**

An (h, Δ)**-metric** is a metric on a surface with a slowly-changing negative curvature.

A **complete** (h, Δ)-metric does not permit a regular *isometric embedding* in three-dimensional Euclidean space (cf. ***Λ*-metric**).

- ***G*-distance**

A connected set G of points on a surface M^2 is called *geodesic region* if, for each point $x \in G$, there exists a *disk* $B(x, r)$ with center at x, such that $B_G = G \cap B(x, r)$ has one of the following forms: $B_G = B(x, r)$ (x is a *regular interior point* of G); B_G is a semi-disk of $B(x, r)$ (x is a *regular boundary point* of G); B_G is a sector of $B(x, r)$

other than a semi-disk (x is an *angular point* of G); B_G consists of a finite number of sectors of $B(x, r)$ with no common points except x (x is a *nodal point* of G).

The **G-distance** between any x and $y \in G$ is defined as the greatest lower bound of the lengths of all rectifiable curves connecting x and $y \in G$, and completely contained in G.

- **Conformally invariant metric**

Let R be a Riemann surface. A *local parameter* (or *local uniformizing parameter*, *local uniformizer*) is a complex variable z considered as a continuous function $z_{p_0} = \phi_{p_0}(p)$ of a point $p \in R$ which is defined everywhere in some neighborhood (*parametric neighborhood*) $V(p_0)$ of a point $p_0 \in R$ and which realizes a homeomorphic mapping (*parametric mapping*) of $V(p_0)$ onto the disk (*parametric disk*) $\Delta(p_0) = \{z \in \mathbb{C}\colon\ |z| < r(p_0)\}$, where $\phi_{p_0}(p_0) = 0$. Under a parametric mapping, any point function $g(p)$, defined in the parametric neighborhood $V(p_0)$, goes into a function of the local parameter z: $g(p) = g(\phi_{p_0}^{-1}(z)) = G(z)$.

A **conformally invariant metric** is a differential $\rho(z)|dz|$ on the Riemann surface R which is invariant with respect to the choice of the local parameter z. Thus, to each local parameter z ($z : U \to \overline{\mathbb{C}}$) a function $\rho_z : z(U) \to [0, \infty]$ is associated such that, for any local parameters z_1 and z_2, we have:

$$\frac{\rho_{z_2}(z_2(p))}{\rho_{z_1}(z_1(p))} = \left|\frac{dz_1(p)}{dz_2(p)}\right| \quad \text{for any } p \in U_1 \cap U_2.$$

Every linear differential $\lambda(z)dz$ and every *quadratic differential* $Q(z)dz^2$ induce conformally invariant metrics $|\lambda(z)\|dz|$ and $|Q(z)|^{1/2}\|dz|$, respectively (cf. **Q-metric**).

- **Q-metric**

An **Q-metric** is a **conformally invariant metric** $\rho(z)|dz| = |Q(z)|^{1/2}|dz|$ on a Riemann surface R, defined by a *quadratic differential* $Q(z)dz^2$.

A *quadratic differential* $Q(z)dz^2$ is a non-linear differential on a Riemann surface R which is invariant with respect to the choice of the local parameter z. Thus, to each local parameter z ($z : U \to \overline{\mathbb{C}}$) a function $Q_z : z(U) \to \overline{\mathbb{C}}$ is associated such that, for any local parameters z_1 and z_2, we have:

$$\frac{Q_{z_2}(z_2(p))}{Q_{z_1}(z_1(p))} = \left(\frac{dz_1(p)}{dz_2(p)}\right)^2 \quad \text{for any } p \in U_1 \cap U_2.$$

- **Extremal metric**

An **extremal metric** is a **conformally invariant metric** in the *modulus problem* for a family Γ of locally rectifiable curves on a Riemann surface R which realizes the infimum in the definition of the *modulus* $M(\Gamma)$.

Formally, let Γ be a family of locally rectifiable curves on a Riemann surface R, let P be a non-empty class of conformally invariant metrics $\rho(z)|dz|$ on R such that $\rho(z)$ is square-integrable in the z-plane for every local parameter z, and the integrals

$$A_\rho(R) = \iint_R \rho^2(z)\,dx\,dy \quad \text{and} \quad L_\rho(\Gamma) = \inf_{\gamma\in\Gamma}\int_y \rho(z)|dz|$$

are not simultaneously equal to 0 or ∞ (each of the above integrals is understood as a Lebesgue integral). The *modulus of the family of curves* Γ is defined by

$$M(\Gamma) = \inf_{\rho\in P}\frac{A_\rho(R)}{(L_\rho(\Gamma))^2}.$$

The *extremal length of the family of curves* Γ is equal to $\sup_{\rho\in P}\frac{(L_\rho(\Gamma))^2}{A_\rho(R)}$, i.e., is the reciprocal of $M(\Gamma)$.

The modulus problem for Γ is defined as follows: let P_L be the subclass of P such that, for any $\rho(z)|dz| \in P_L$ and any $\gamma \in \Gamma$, one has $\int_\gamma \rho(z)|dz| \geqslant 1$. If $P_L \neq \emptyset$, then the modulus $M(\Gamma)$ of the family Γ can be written as $M(\Gamma) = \inf_{\rho\in P_L} A_\rho(R)$. Every metric from P_L is called **admissible metric** for the modulus problem on Γ. If there exists ρ^* for which

$$M(\Gamma) = \inf_{\rho\in P_L} A_\rho(R) = A_{\rho^*}(R),$$

the metric $\rho^*|dz|$ is called **extremal metric** for the modulus problem on Γ.

- **Fréchet surface metric**

Let (X, d) be a metric space, M^2 be a compact two-dimensional manifold, f be a continuous mapping $f : M^2 \to X$, called *parameterized surface*, and $\sigma : M^2 \to M^2$ be a homeomorphism of M^2 onto itself. Two parameterized surfaces f_1 and f_2 are called *equivalent* if $\inf_\sigma \max_{p\in M^2} d(f_1(p), f_2(\sigma(p))) = 0$, where the infimum is taken over all possible homeomorphisms σ. A class f^* of parameterized surfaces, equivalent to f, is called *Fréchet surface*. It is a generalization of the notion of a surface in an Euclidean space to the case of an arbitrary metric space (X, d).

The **Fréchet surface metric** is a metric on the set of all Fréchet surfaces, defined by

$$\inf_\sigma \max_{p\in M^2} d\big(f_1(p), f_2\big(\sigma(p)\big)\big)$$

for any Fréchet surfaces f_1^* and f_2^*, where the infimum is taken over all possible homeomorphisms σ (cf. **Fréchet metric**).

8.2. INTRINSIC METRICS ON SURFACES

In this section we list intrinsic metrics, given by their *line elements* (which, in fact, are two-dimensional **Riemannian metrics**), for some selected surfaces.

- **Quadric metric**

A *quadric* (or *quadratic surface*, *surface of second order*) is a set of points in $\mathbb{E}^3$, whose coordinates in a Cartesian coordinate system satisfy an algebraic equation of degree two. There are 17 classes of such surfaces, among them are: *ellipsoids*, *one-sheet* and *two-sheet hyperboloids*, *elliptic paraboloids*, *hyperbolic paraboloids*, *elliptic*, *hyperbolic* and *parabolic cylinders*, and *conical surfaces*.

For example, a *cylinder* can be given by the following parametric equations:

$$x_1(u,v)=a\cos v,\quad x_2(u,v)=a\sin v,\quad x_3(u,v)=u.$$

The intrinsic metric on it is given by the *line element*

$$ds^2=du^2+a^2\,dv^2.$$

An *elliptic cone* (i.e., a cone with elliptical cross-section) has the following parametric equations:

$$x_1(u,v)=a\frac{h-u}{h}\cos v,\quad x_2(u,v)=b\frac{h-u}{h}\sin v,\quad x_3(u,v)=u,$$

where h is the *height*, a is the *semi-major axis*, and b is the *semi-minor axis* of the cone. The intrinsic metric on it is given by the *line element*

$$ds^2=\frac{h^2+a^2\cos^2 v+b^2\sin^2 v}{h^2}\,du^2+2\frac{(a^2-b^2)(h-u)\cos v\sin v}{h^2}\,du\,dv + \frac{(h-u)^2(a^2\sin^2 v+b^2\cos^2 v)}{h^2}\,dv^2.$$

- **Sphere metric**

A *sphere* is a *quadric*, given by the Cartesian equation $(x_1-a)^2+(x_2-b)^2+(x_3-c)^2=r^2$, where the point (a,b,c) is the *center* of the sphere, and $r>0$ is the *radius* of the sphere. The sphere of radius r, centered at the origin, can be given by the following parametric equations:

$$x_1(\theta,\phi)=r\sin\theta\cos\phi,\quad x_2(\theta,\phi)=r\sin\theta\sin\phi,\quad x_3(\theta,\phi)=r\cos\theta,$$

where the *azimuthal angle* $\phi\in[0,2\pi)$, and the *polar angle* $\theta\in[0,\pi]$. The intrinsic metric on it (in fact, the two-dimensional **spherical metric**) is given by the *line element*

$$ds^2=r^2\,d\theta^2+r^2\sin^2\theta\,d\phi^2.$$

A sphere of radius r has constant positive Gaussian curvature equal to r.

- **Ellipsoid metric**

  An *ellipsoid* is a *quadric* given by the Cartesian equation $\frac{x_1^2}{a^2} + \frac{x_2^2}{b^2} + \frac{x_3^2}{c^2} = 1$, or by the following parametric equations:

  $$x_1(\theta, \phi) = a\cos\phi\sin\theta, \quad x_2(\theta, \phi) = b\sin\phi\sin\theta, \quad x_3(\theta, \phi) = c\cos\theta,$$

  where the *azimuthal angle* $\phi \in [0, 2\pi)$, and the *polar angle* $\theta \in [0, \pi]$. The intrinsic metric on it is given by the *line element*

  $$\begin{aligned} ds^2 = {} & \big(b^2\cos^2\phi + a^2\sin^2\phi\big)\sin^2\theta\, d\phi^2 + \big(b^2 - a^2\big)\cos\phi\sin\phi\cos\theta\sin\theta\, d\theta\, d\phi \\ & + \big(\big(a^2\cos^2\phi + b^2\sin^2\phi\big)\cos^2\theta + c^2\sin^2\theta\big)\, d\theta^2. \end{aligned}$$

- **Spheroid metric**

  A *spheroid* is an *ellipsoid* having two axes of equal length. It is also a *rotation surface*, given by the following parametric equations:

  $$x_1(u, v) = a\sin v\cos u, \quad x_2(u, v) = a\sin v\sin u, \quad x_3(u, v) = c\cos v,$$

  where $0 \leqslant u < 2\pi$, and $0 \leqslant v \leqslant \pi$. The intrinsic metric on it is given by the *line element*

  $$ds^2 = a^2\sin^2 v\, du^2 + \frac{1}{2}\big(a^2 + c^2 + \big(a^2 - c^2\big)\cos(2v)\big)\, dv^2.$$

- **Hyperboloid metric**

  A *hyperboloid* is a *quadric* which may be one- or two-sheeted. The one-sheeted hyperboloid is a *surface of revolution* obtained by rotating a hyperbola about the perpendicular bisector to the line between the foci, while the two-sheeted hyperboloid is a surface of revolution obtained by rotating a hyperbola about the line joining the foci. The one-sheeted circular hyperboloid, oriented along the x_3-axis, is given by the Cartesian equation $\frac{x_1^2}{a^2} + \frac{x_2^2}{a^2} - \frac{x_3^2}{c^2} = 1$, or by the following parametric equations:

  $$x_1(u, v) = a\sqrt{1 + u^2}\cos v, \quad x_2(u, v) = a\sqrt{1 + u^2}\sin v, \quad x_3(u, v) = cu,$$

  where $v \in [0, 2\pi)$. The intrinsic metric on it is given by the *line element*

  $$ds^2 = \left(c^2 + \frac{a^2u^2}{u^2 + 1}\right) du^2 + a^2\big(u^2 + 1\big)\, dv^2.$$

- **Rotation surface metric**

  A *rotation surface* (or *surface of revolution*) is a surface generated by rotating a two-dimensional curve about an axis. It is given by the following parametric equations:

  $$x_1(u, v) = \phi(v)\cos u, \quad x_2(u, v) = \phi(v)\sin u, \quad x_3(u, v) = \psi(v).$$

The intrinsic metric on it is given by the *line element*

$$ds^2 = \phi^2\, du^2 + \left(\phi'^2 + \psi'^2\right) dv^2.$$

- **Pseudo-sphere metric**

  A *pseudo-sphere* is a half of the *rotation surface*, generated by rotating a *tractrix* about its asymptote. It is given by the following parametric equations:

  $$x_1(u, v) = \operatorname{sech} u \cos v, \quad x_2(u, v) = \operatorname{sech} u \sin v, \quad x_3(u, v) = u - \tanh u,$$

  where $u \geqslant 0$, and $0 \leqslant v < 2\pi$. The intrinsic metric on it is given by the *line element*

  $$ds^2 = \tanh^2 u\, du^2 + \operatorname{sech}^2 u\, dv^2.$$

  The pseudo-sphere has constant negative Gaussian curvature equal to -1, and in this sense is an analog of the sphere which has constant positive Gaussian curvature.

- **Torus metric**

  A *torus* is a surface having genus one. A torus azimuthally symmetric about the x_3-axis is given by the Cartesian equation $(c - \sqrt{x_1^2 + x_2^2})^2 + x_3^2 = a^2$, or by the following parametric equations:

  $$x_1(u, v) = (c + a\cos v)\cos u, \quad x_2(u, v) = (c + a\cos v)\sin u, \quad x_3(u, v) = a\sin v,$$

  where $c > a$, and $u, v \in [0, 2\pi)$. The intrinsic metric on it is given by the *line element*

  $$ds^2 = (c + a\cos v)^2\, du^2 + a^2\, dv^2.$$

- **Helical surface metric**

  A *helical surface* (or *surface of screw motion*) is a surface described by a plane curve γ which, while rotating around an axis at a uniform rate, also advances along that axis at a uniform rate. If γ is located in the plane of the axis of rotation x_3 and is defined by the equation $x_3 = f(u)$, the position vector of the helical surface is

  $$r = (u\cos v,\ u\sin v,\ f(u) = hv), \quad h = \text{const},$$

  and the intrinsic metric on it is given by the *line element*

  $$ds^2 = \left(1 + f'^2\right) du^2 + 2hf'\, du\, dv + \left(u^2 + h^2\right) dv^2.$$

  If $f = \text{const}$, one has a *helicoid*; if $h = 0$, one has a *rotation surface*.

- **Catalan surface metric**

  The *Catalan surface* is a *minimal surface*, given by the following parametric equations:

$$x_1(u,v) = u - \sin u \cosh v, \quad x_2(u,v) = 1 - \cos u \cosh v,$$
$$x_3(u,v) = 4\sin\left(\frac{u}{2}\right)\sinh\left(\frac{v}{2}\right).$$

  The intrinsic metric on it is given by the *line element*

$$ds^2 = 2\cosh^2\left(\frac{v}{2}\right)(\cosh v - \cos u)\,du^2 + 2\cosh^2\left(\frac{v}{2}\right)\left(\cosh v - \cos u\right)dv^2.$$

- **Monkey saddle metric**

  The *monkey saddle* is a surface, given by the Cartesian equation $x_3 = x_1(x_1^2 - 3x_2^2)$, or by the following parametric equations:

$$x_1(u,v) = u, \quad x_2(u,v) = v, \quad x_3(u,v) = u^3 - 3uv^2.$$

  This is a surface which a monkey can straddle with both legs and his tail. The intrinsic metric on it is given by the *line element*

$$ds^2 = \left(1 + \left(su^2 - 3v^2\right)^2\right)du^2 - 2\left(18uv\left(u^2 - v^2\right)\right)du\,dv + \left(1 + 36u^2v^2\right)dv^2.$$

8.3. DISTANCES ON KNOTS

A *knot* is a closed, non-self-intersecting curve that is embedded in S^3. The *trivial knot* (or *unknot*) O is a closed loop that is not knotted. A knot can be generalized to a link which is a set of disjoint knots. Every link has its *Seifert surface*, i.e., a compact oriented surface with given link as boundary. Two knots (links) are called *equivalent* if one can be smoothly deformed into another. Formally, a link is defined as a smooth one-dimensional *submanifold* of the 3-sphere S^3; a knot is a link consisting of one component; links L_1 and L_2 are called *equivalent* if there exists an orientation-preserving homeomorphism $f : S^3 \to S^3$ such that $f(L_1) = L_2$.

All the information about a knot can be described using a *knot diagram*. It is a projection of a knot onto a plane such that no more than two points of the knot are projected to the same point on the plane, and at each such point it is indicated which strand is closest to the plane, usually by erasing part of the lower strand. Two different knot diagrams may both represent the same knot. Much of knot theory is devoted to telling when two knot diagrams represent the same knot.

An *unknotting operation* is an operation which changes the overcrossing and the undercrossing at a double point of a given knot diagram. The *unknotting number* of a knot K is the minimum number of unknotting operations needed to deform a diagram of K into

Chapter 15

Solution of System of Linear Equation

Introduction

There are many direct methods to solve simultaneous linear equations. In this chapter, we shall discuss Crout's method to solve a system of Linear Equations. Crout's method provides the solution after a computation that is known in advance. This chapter also describes an iterative or indirect method: Gauss-Seidel Method to solve a system of Linear Equations. In Gauss-Seidel Method, the solution starts from an approximation to the true solution and if convergent, we get a sequence of closer solution. The computations are repeated till the required accuracy is obtained. In direct method: Crout's method, amount of computation is fixed, while in iteration method: Gauss-Seidel Method, the amount of computation depends upon the required accuracy of the solution.

15.1 Crout's Method

This method is based upon the fact that every square matrix A can be expressed as the product of a lower triangular matrix (L), an upper triangular matrix (U). Let AX = B is a system of linear equation. So, if a matrix decomposition of a matrix A is such that A = LDU being L is a unit lower triangular matrix, D is a diagonal matrix and U is a unit upper triangular matrix, then Crout's method produces A = (LD)U. After the LU decomposition of A , the solution to the system of linear equations AX = L U X = B is solved by solving the system of linear equations LY = B by forward substitution for Y, and then solving the system of linear equations UX = Y by backward substitution for X. Now consider we want solve the system of linear equation $AX = B$, which can be written as,

$$\begin{bmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{bmatrix} \begin{bmatrix} x_1 \\ y_1 \\ z_1 \end{bmatrix} = \begin{bmatrix} b_1 \\ b_2 \\ b_2 \end{bmatrix} \qquad \text{...(15.1)}$$

Let the cofficient matrix can be written as

$$A = LU$$

where

$$L = \begin{bmatrix} l_{11} & 0 & 0 \\ l_{21} & l_{22} & 0 \\ l_{31} & l_{32} & l_{33} \end{bmatrix} \text{and} \, U = \begin{bmatrix} 1 & u_{12} & u_{13} \\ 0 & 1 & u_{23} \\ 0 & 1 & 1 \end{bmatrix}$$

Then Eqn (15.1) becomes

Let $LUX = B$ ...(15.2)

$$UX = Y \qquad \text{....(15.3)}$$

so that Eqn (15.2) becomes

$$LY = B \qquad \text{....(15.4)}$$

i.e. $$\begin{bmatrix} l_{11} & 0 & 0 \\ l_{21} & l_{22} & 0 \\ l_{31} & l_{32} & l_{33} \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \\ y_3 \end{bmatrix} = \begin{bmatrix} b_1 \\ b_2 \\ b_3 \end{bmatrix}$$

$$\therefore l_{11}y_1 = b_1;\ \ l_{21}y_1 + l_{22}y_2 = b_2;\ \ l_{31}y_1 + l_{32}y_2 + l_{33}y_3 = b_3 \qquad \text{...(15.5)}$$

By forward substitution, y_1, y_2 and y_3 can be found out if L is known. Now L and U can be found from $LU = A$.

$$\begin{bmatrix} l_{11} & 0 & 0 \\ l_{21} & l_{22} & 0 \\ l_{31} & l_{32} & l_{33} \end{bmatrix} \begin{bmatrix} 1 & u_{12} & u_{13} \\ 0 & 1 & u_{23} \\ 0 & 0 & 1 \end{bmatrix} = \begin{bmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{bmatrix}$$

or $$\begin{bmatrix} l_{11} & l_{11}u_{12} & l_{11}u_{13} \\ l_{21} & l_{21}u_{12} + l_{22} & l_{21}u_{13} + l_{22}u_{23} \\ l_{31} & l_{31}u_{12} + l_{32} & l_{31}u_{13} + l_{32}u_{23} + l_{33} \end{bmatrix} = \begin{bmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{bmatrix}$$

Equating the corresponding elements on both sides, we get

$$l_{11} = a_{11}, l_{21} = a_{21}, l_{31} = a_{31}$$
$$l_{11}u_{12} = a_{12} \ \therefore u_{12} = a_{12}/a_{11}$$
$$l_{11}u_{13} = a_{13} \ \therefore u_{13} = a_{13}/a_{11}$$
$$l_{21}u_{12} + l_{22} = a_{22} \ \therefore l_{22} = a_{22} - l_{21}u_{12}$$
$$l_{31}u_{12} + l_{32} = a_{32} \ \therefore u_{32} = \{a_{12} - l_{21}u_{13}\}/u_{23}$$
$$l_{31}u_{13} + l_{32}u_{23} + l_{33} = a_{33} \ \therefore l_{33} = a_{33} - l_{31}u_{13} - l_{31}u_{23}$$

Thus all the 12 unknowns are determined and the solution, as show already, is obtained from Eqn (15.5)The whole procedure is illustrated by some suitable examples which are given below.

Illustrative Examples

Ex.1: Solve the system

$$2x + y + 4z = 12, \quad 8x + 3y + 2z = 20, \quad 4x + 11y + z = 33$$

by Crout's method. (*M.U, B.E., 1991*)

Sol : Argumented matrix,

$$[A/B] = \left[\begin{array}{ccc|c} 2 & 1 & 4 & 12 \\ 8 & -3 & 2 & 20 \\ 4 & 11 & -1 & 23 \end{array}\right]$$

Let the derived matrix (DM)

$$= \begin{bmatrix} l_{11} & u_{12} & u_{13} & y_1 \\ l_{21} & l_{22} & u_{23} & y_2 \\ l_{31} & l_{32} & l_{33} & y_3 \end{bmatrix}$$

$$\begin{bmatrix} 1 & -1 & 2 \\ 0 & 1 & -\frac{2}{5} \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} 0 & y_{12} & y_{13} \\ 0 & 1 & y_{13} \\ 0 & 0 & 1 \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

We get $y_{12} = 1,\ y_{13} = -8/5;\ y_{23} = 2/5$

$$\therefore \quad L^{-1} = \begin{bmatrix} \frac{1}{2} & 0 & 2 \\ -\frac{1}{5} & \frac{1}{5} & 0 \\ 0 & 0 & 1 \end{bmatrix} \text{and}\, U^{-1} = \begin{bmatrix} 1 & 1 & -\frac{8}{5} \\ 0 & 1 & \frac{2}{5} \\ 0 & 0 & 1 \end{bmatrix}$$

$$A^{-1} = U^{-1}L^{-1} = \begin{bmatrix} -\frac{1}{2} & \frac{1}{5} & \frac{-8}{5} \\ 0 & \frac{1}{5} & \frac{2}{5} \\ \frac{1}{2} & 0 & 1 \end{bmatrix}$$

15.3 Gauss-Seidel Method

In certain cases, when a system of equations is large, iterative methods of solving equations are more advantageous. Elimination methods, such as Gaussian elimination, are prone to large round-off errors for a large set of equations. Iterative methods, such as the Gauss-Seidel method, give the user control of the round-off error. After reading Gauss-Seidel Method, you should be able to solve a set of equations using Gauss-Seidel method, recognize the advantages and pitfalls of Gauss-Seidel method, determine under what conditions Gauss Seidel method always converges. Given a general set of n equations and n unknowns, we have

$$\begin{aligned} a_{11}x_1 + a_{12}x_2 + a_{13}x_3 + \ldots\ldots + a_{1n}x_n &= c_1 \\ a_{21}x_1 + a_{22}x_2 + a_{23}x_3 + \ldots\ldots + a_{2n}x_n &= c_2 \\ \cdots \qquad \cdots \qquad &\cdots \\ \cdots \qquad \cdots \qquad &\cdots \\ a_{n1}x_1 + a_{n2}x_2 + a_{n3}x_3 + \ldots\ldots + a_{nn}x_n &= c_n \end{aligned}$$

If the diagonal elements are non-zero, each equation is rewritten for the corresponding unknown, that is, the first equation is rewritten with x_2 on the left hand side, second equation is rewritten with on the left hand side and so on as follows

$$x_2 = \frac{c_2 - a_{21}x_1 - a_{23}x_3 \ldots\ldots\ldots\ldots - a_{2n}x_n}{a_{22}}$$

$$\vdots$$

$$\vdots$$

$$x_{n-1} = \frac{c_{n-1} - a_{n-1,1}x_1 - a_{n-1,2}x_2 \ldots\ldots\ldots - a_{n-1,n-2}x_{n-2} - a_{n-1,n}x_n}{a_{n-1,n-1}}$$

$$x_n = \frac{c_n - a_{n1}x_1 - a_{n2}x_2 - \ldots\ldots - a_{n,n-1}x_{n-1}}{a_{nn}}$$

These equations can be rewritten in a summation form as

$$x_1 = \frac{c_1 - \sum_{\substack{j=1 \\ j \neq 1}}^{n} a_{1j}x_j}{a_{11}}, \; x_2 = \frac{c_2 - \sum_{\substack{j=1 \\ j \neq 2}}^{n} a_{2j}x_j}{a_{22}}$$

$$x_{n-1} = \frac{c_{n-1} - \sum_{\substack{j=1 \\ j \neq n-1}}^{n} a_{n-1,j}x_j}{a_{n-1,n-1}}, \; x_n = \frac{c_n - \sum_{\substack{j=1 \\ j \neq 2}}^{n} a_{nj}x_j}{a_{nn}}$$

Hence for any row i,

$$x_i = \frac{c_i - \sum_{\substack{j=1 \\ j \neq 1}}^{n} a_{ij}x_j}{a_{ii}}, i = 1, 2, \ldots, n.$$

Now to find x_i's, one assumes an initial guess for the x_i 's and then uses the rewritten equations to calculate the new estimates. Remember, one always uses the most recent estimates to calculate the next estimates x_i. At the end of each iteration, one calculates the absolute relative approximate error for each x_i as

$$|\varepsilon_a|_i = \left| \frac{x_i^{new} - x_i^{old}}{x_i^{new}} \right| \times 100$$

where x_i^{new} is the recently obtained value of x_i, and x_i^{old}s the previous value of x_i. When the absolute relative approximate error for each x_i is less than the pre-specified tolerance, the iterations are stopped.

for the better understanding of Gauss-Seidel's method some examples are given below.

Ex.5: The upward velocity of a rocket is given at three different times in the following table

Time, t is second	Velocity, v m/s
5	106.8
8	177.2
12	279.2

The velocity data is approximated by a polynomial as $v(t) = a_1 t^2 + a_2 t + a_3$, $5 \le t \le 12$.

Find the values of a_1, a_2 and a_3 using Gauss-Seidel Method. Assume an initial guess of the solution as $a_1 = 1, a_2 = 2, a_3 = 5$.

Sol: The polynomial is going through three data points $(t_1, v_1), (t_2, v_2)$, and (t_3, v_3) where from the above table

$$t_1 = 5, v_1 = 106.8$$
$$t_2 = 8, v_2 = 177.2$$
$$t_3 = 12, v_3 = 279.2$$

Requiring that $v(t) = a_1 t^2 + a_2 t + a_3$,passes through the three data points gives

$$v(t_1) = v_1 = a_1 t_1^2 + a_2 t_1 + a_3$$
$$v(t_2) = v_2 = a_1 t_2^2 + a_2 t_2 + a_3$$
$$v(t_3) = v_3 = a_1 t_3^2 + a_2 t_3 + a_3$$

Substituting the data $(t_1, v_1), (t_2, v_2), (t_3, v_3)$ gives

$$a_1(5^2) + a_2(5) + a_3 = 106.8$$
$$a_1(8^2) + a_2(8) + a_3 = 177.2$$
$$a_1(12^2) + a_2(12) + a_3 = 279.2$$

or

$$25a_1 + 5a_2 + a_3 = 106.8$$
$$64a_1 + 8a_2 + a_3 = 177.2$$
$$144a_1 + 12a_2 + a_3 = 279.2$$

The coefficients for the above expression are given by

$$\begin{bmatrix} 25 & 5 & 1 \\ 64 & 8 & 1 \\ 144 & 12 & 1 \end{bmatrix} \begin{bmatrix} a_1 \\ a_2 \\ a_3 \end{bmatrix} = \begin{bmatrix} 106.8 \\ 177.2 \\ 279.2 \end{bmatrix}$$

Rewriting the equations gives

$$a_1 = \frac{106.8 - 5a_2 - a_3}{25}$$
$$a_2 = \frac{177.2 - 64a_1 - a_3}{8}$$
$$a_3 = \frac{279.2 - 144a_1 - 12a_2}{1}$$

Iteration #1

Given the initial guess of the solution vector as $a_1 = 1, a_2 = 2, a_3 = 5$

we get

$$a_1 = \frac{106.8 - 5(2) - (5)}{25} = 3.6720$$
$$a_2 = \frac{177.2 - 64(3.6720) - (5)}{8} = -7.8150,$$
$$a_3 = \frac{279.2 - 144(3.6720) - 12(-7.8510)}{1} = -155.36$$

The absolute relative approximate error for each x_i then is

$$|\varepsilon_a|_3 = \left|\frac{3.6720 - 1}{3.6720}\right| \times 100 = 72.76\%$$

$$|\varepsilon_a|_2 = \left|\frac{-7.8510 - 2}{-7.8510}\right| \times 100 = 125.47\%$$

$$|\varepsilon_a|_3 = \left|\frac{155.36 - 5}{-155.36}\right| \times 100 = 103.22\%$$

At the end of the first iteration, the estimate of the solution vector is

$$\begin{bmatrix} a_1 \\ a_2 \\ a_3 \end{bmatrix} = \begin{bmatrix} 3.6720 \\ -7.8510 \\ -155.36 \end{bmatrix}$$

and the maximum absolute relative approximate error is 125.47%.

Iteration #2

The estimate of the solution vector at the end of Iteration #1 is

$$\begin{bmatrix} a_1 \\ a_2 \\ a_3 \end{bmatrix} = \begin{bmatrix} 3.6720 \\ -7.8510 \\ -155.36 \end{bmatrix}$$

Now we get

$$a_1 = \frac{106.8 - 5(-7.8510) - (-155.36)}{25} = 12.056$$

$$a_2 = \frac{177.2 - 64(12.056) - (-155.36)}{8} = -54.882$$

$$a_3 = \frac{279.2 - 144(12.056) - 12(-54.882)}{1} = -798.34$$

The absolute relative approximate error for each then is

$$|\in_a|_1 = \left|\frac{12.056 - 3.6720}{12.056}\right| \times 100 = 69.543\%$$

$$|\in_a|_2 = \left|\frac{-54.882 - (-7.8510)}{-54.882}\right| \times 100 = 85.695\%$$

$$|\in_a|_3 = \left|\frac{-798.34 - (-155.36)}{-798.34}\right| \times 100 = 80.540\%$$

At the end of the second iteration the estimate of the solution vector is

$$\begin{bmatrix} a_1 \\ a_2 \\ a_3 \end{bmatrix} = \begin{bmatrix} 12.056 \\ -54.882 \\ -798.54 \end{bmatrix}$$

and the maximum absolute relative approximate error is 85.695%.

Conducting more iteration gives the following values for the solution vector and the corresponding absolute relative approximate errors.

Iteration	a_1	$\lvert\in_a\rvert_1\%$	a_2	$\lvert\in_a\rvert_2\%$	a_3	$\lvert\in_a\rvert_3\%$
1	3.6720	72.767	-7.8510	125.47	-155.36	103.22
2	12.056	69.543	-54.882	85.695	-798.34	80.540
3	47.182	74.447	-255.51	78.521	-3448.9	76.852
4	193.33	75.595	-1093.4	76.632	-14440	76.116
5	800.53	75.850	-4577.2	76.112	-60072	75.963
6	3322.6	75.906	-19049	75.972	-249580	75.931

As seen in the above table, the solution estimates are not converging to the true solution of $a_1 = 0.29048$, $a_2 = 19.690$, $a_3 = 1.0857$

The above system of equations does not seem to converge? Why?

Well, a pitfall of most iterative methods is that they may or may not converge. However, the solution to a certain classes of systems of simultaneous equations does always converge using the Gauss-Seidel method. This class of system of equations is where the coefficient matrix $[A]$ in $[A][X] = [C]$ is diagonally dominant, that is $|a_{ii}| \geq \sum_{\substack{j=1 \\ j\neq 1}}^{n} |a_{ij}|$ for all, and $|a_{ii}| \geq \sum_{\substack{j=1 \\ j\neq 1}}^{n} |a_{ij}|$ for at least one i. If a system of equations has a coefficient matrix that is not diagonally dominant, it may or may not converge. Fortunately, many physical systems that result in simultaneous linear equations have a diagonally dominant coefficient matrix, which then assures convergence for iterative methods such as the Gauss-Seidel method of solving simultaneous linear equations.

Ex. 6: Find the solution to the following system of equations using the Gauss-Seidel method

$$12x_1 + 3x_2 - 5x_3 = 1$$
$$x_1 + 5x_2 + 3x_3 = 28$$
$$3x_1 + 7x_2 + 13x_3 = 76$$

Use $x_1 = 1, x_2 = 0, x_3 = 1$, as the initial guess and conduct two iterations.

Sol: The coefficient matrix

$$[A] = \begin{bmatrix} 12 & 3 & -5 \\ 1 & 5 & 3 \\ 3 & 7 & 13 \end{bmatrix}$$

is diagonally dominant as

$$|a_{11}| = |12| = 12 \geq |a_{12}| + |a_{13}| = |3| + |-5| = 8$$
$$|a_{22}| = |5| = 5 \geq |a_{21}| + |a_{23}| = |1| + |3| = 4$$
$$|a_{33}| = |13| = 13 \geq |a_{31}| + |a_{32}| = |3| + |7| = 10$$

and the inequality is strictly greater than for at least one row. Hence, the solution should converge using the Gauss-Seidel method.

Rewriting the equations, we get

$$x_1 = \frac{1-3x_2+5x_3}{12},\ x_2 = \frac{28-x_1-3x_3}{5},\ x_3 = \frac{76-3x_1-7x_2}{13}$$

Assuming an initial guess of . $x_1 = 1, x_2 = 0, x_3 = 1.$

Iteration#1:

$$x_1 = \frac{1-3(0)+5(1)}{12} = 0.50000,$$

$$x_2 = \frac{28-(0.50000)-3(1)}{5} = 4.9000$$

$$x_3 = \frac{76-3(0.50000)-7(4.9000)}{13} = 3.0923$$

The absolute relative approximate error at the end of first iteration is

$$|\in_a|_1 = \left|\frac{0.50000-1}{0.50000}\right| \times 100 = 100.000\%$$

$$|\in_a|_2 = \left|\frac{4.9000-0}{4.9000}\right| \times 100 = 100.000\%$$

$$|\in_a|_3 = \left|\frac{3.0923-1}{3.0923}\right| \times 100 = 67.662\%$$

The maximum absolute relative approximate error is 100.000%

Iteration 2:

$$x_1 = \frac{1-3(4.9000)+5(3.0923)}{12} = 0.14679$$

$$x_2 = \frac{28-(0.14679)-3(3.0923)}{12} = 3.7153$$

$$x_3 = \frac{76-3(0.14679)-7(3.7153)}{13} = 3.8118$$

At the end of second iteration, the absolute relative approximate error is

$$|\in_a|_1 = \left|\frac{0.14679-0.50000}{0.14679}\right| \times 100 = 240.61\%$$

$$|\in_a|_2 = \left|\frac{3.7153-4.9000}{3.7153}\right| \times 100 = 31.889\%$$

$$|\in_a|_3 = \left|\frac{3.8118-3.0923}{3.8118}\right| \times 100 = 18.874\%$$

The maximum absolute relative approximate error is 240.61%. This is greater than the value of 100.00% we obtained in the first iteration. Is the solution diverging? No, as you conduct more iteration, the solution converges as follows.

Iteration	a_1	$\|\in_a\|_1\%$	a_2	$\|\in_a\|_2\%$	a_3	$\|\in_a\|_3\%$
1	0.50000	100.00	4.9000	100.00	3.0923	67.662
2	0.14679	240.61	3.7153	31.889	3.8118	18.874
3	0.74275	80.236	3.1644	17.408	3.9708	4.0064
4	0.94675	21.546	3.0281	4.4996	3.9971	0.65772
5	0.99177	4.5391	3.0034	0.82499	4.0001	0.074383
6	0.99919	0.74307	3.0001	0.10856	4.0001	0.00101

This is close to the exact solution $x_1 = 1, x_2 = 3, x_3 = 4$

Ex.7: For a system of equations

$$\begin{aligned} 3x_1 + 7x_2 + 13x_3 &= 76 \\ x_1 + 5x_2 + 3x_3 &= 28 \\ 12x_1 + 3x_2 - 5x_3 &= 1 \end{aligned}$$

find the solution using Gauss-Seidel method. Use $[x_1, x_2, x_3] = [1 \ \ 0 \ 1]$ as the initial guess.

Sol: Rewriting the equations, we get

$$x_1 = \frac{76 - 7x_2 - 13x_3}{3}, x_2 = \frac{28 - x_1 - 3x_3}{5}, \ x_3 = \frac{1 - 12x_1 - 3x_2}{-5}$$

Assuming an initial guess of $x_1 = 1, x_2 = 0, x_3 = 1$,the next six iterative values are given in the table below

Iteration	a_1	$\|\in_a\|_1\%$	a_2	$\|\in_a\|_2\%$	a_3	$\|\in_a\|_3\%$
1	21.000	95.238	0.80000	100.00	50.680	98.027
2	-196.15	110.71	14.421	94.453	-462.30	110.96
3	1995.0	109.83	-116.02	112.43	4718.1	109.80
4	-20149	109.90	1204.6	109.63	-47636	109.90
5	2.0364×10^5	109.89	-12140	109.92	4.8144105	109.89
6	-2.0579×10^6	109.89	1.2272×10^5	109.89	-4.8653×10^6	109.89

You can see that this solution is not converging and the coefficient matrix is not diagonally dominant. The coefficient matrix

$$[A] = \begin{bmatrix} 3 & 7 & 13 \\ 1 & 5 & 3 \\ 12 & 3 & -5 \end{bmatrix}$$

is not diagonally dominant as $|a_{11}| = |3| = 3 \le |a_{12}| + |a_{13}| = |7| + |13| = 20$ Hence, the Gauss-Seidel method may or may not converge. However, it is the same set of equations as the previous example and that converged. The only difference is that we exchanged first and the third equation with each other and that made the coefficient matrix not diagonally dominant. Therefore, it is possible that a system of equations can be made diagonally dominant if one exchanges the equations with each other. However, it is not possible for all cases. For example, the following set of equations.

$$x_1 + x_2 + x_3 = 3$$
$$2x_1 + 3x_2 + 4x_3 = 9$$
$$x_1 + 7x_2 + x_3 = 9$$

cannot be rewritten to make the coefficient matrix diagonally dominant.

Ex. 8 : Solve the system of Equation by Gauss - Seidel's Method.

$$8x - 3y + 2z = 20$$
$$6x + 3y + 12z = 35$$
$$4x + 11y - z = 33$$

Sol. From the given equations, we have

$$x = \frac{1}{8}(20 + 3y - 2z) \qquad \text{....(i)}$$

$$y = \frac{1}{11}(33 - 4x + z) \qquad \text{....(ii)}$$

$$z = \frac{1}{12}(35 - 6x - 3y) \qquad \text{....(iii)}$$

Putting $y = 0,\ z = 0$ in RHS of (i), we get $x = \frac{20}{8} = 2.5$

Putting $x = 2.5$, $z = 0$ in RHS of (ii), we get

$$y = \frac{1}{11}[33 - 4(2.5)] = 2.0909091$$

Putting $x = 2.5$, $y = 2.0909091$in RHS of (iii), we get

$$z_1 = \frac{1}{12}[35 - 6(2.5) - 3(2.0909091)] = 1.1439394$$

For the *second approximation*,

$$x_2 = \frac{1}{8}[20 + 3y_1 - 2z_1]$$
$$= \frac{1}{8}[20 + 3(2.0909091) - 2(1.1439394)] = 2.9981061$$

$$y_2 = \frac{1}{11}[33 - 4x_2 + z_1]$$
$$= \frac{1}{11}[33 - 4(2.9981061) + 1.1439394] = 2.0137741$$

$$z_2 = \frac{1}{12}[35 - 6x_2 - 3y_2]$$
$$= \frac{1}{12}[35 - 6(2.9981061) - 3(2.0137741)] = 0.9141701$$

Third approximation :

$$x_3 = \frac{1}{8}[20 + 3(2.0137741) - 2(0.9141701)] = 3.0266228$$

$$y_3 = \frac{1}{11}[33-4(3.0266228+0.9141701)] = 1.9825163$$

$$z_3 = \frac{1}{12}[35-6(3.0266228)-3(1.9825163)] = 0.9077262$$

Fourth approximation :

$$x_4 = \frac{1}{8}[20-3(1.9825163)-2(0.9077262)] = 3.0165121$$

$$y_4 = \frac{1}{11}[33-4(3.0165121)+(0.9077262)] = 1.9856071$$

$$z_4 = \frac{1}{12}[35-6(3.0165121)-3(1.9856071)] = 0.9120088$$

Fifth approximation :

$$x_5 = \frac{1}{8}[20+3(1.9856071)-2(0.9120088)] = 3.0166005$$

$$y_5 = \frac{1}{11}[33-4(3.0166005)+0.9120088] = 1.9859643$$

$$z_5 = \frac{1}{12}[35-6(3.0166005)-3(1.9859643)] = 0.9118753$$

Sixth approximation :

$$x_6 = \frac{1}{8}[20+3(1.9859643)-2(0.9118753)] = 3.0167678$$

$$y_6 = \frac{1}{11}[33-4(3.0167678)+0.9118753] = 1.9858913$$

$$z_6 = \frac{1}{12}[35-6(3.0167678)-3(1.9858913)] = 0.9118099$$

Seventh approximation :

$$x_7 = \frac{1}{8}[20+3(1.9858913)-2(0.9118099)] = 3.0167568$$

$$y_7 = \frac{1}{11}[33-4(3.0167568)+0.9118099] = 1.9858894$$

$$z_7 = \frac{1}{12}[35-6(3.0167568)-3(1.9858894)] = 1.9118159$$

Since at the sixth and seventh approximations, the values of x,y,z are the same, correct four decimal places, we can stop the iteration process.

$\therefore\ x = 3.0167, \quad y = 1.9858, \ z = 0.9118$

We find that 12 iterations are needed in Gauss–Jacobi method to get the same accuracy as achieved by 7 iterations in Gauss–Seidel method.

Ex. 9: Solve by Gauss–Seidel method, the following system of equations

$$28x + 4y - z = 32, x + 3y + 10z = 24,$$

and $2x + 17y + 4z = 35$ (*B.U,1997, M.U, 1991*)

Sol : The coefficient matrix of the given system is not diagonally dominant. Hence, we rearrange the equations as follows, such that the elements in the coefficient matrix are diagonally dominant.

$$28x + 4y - z = 32$$

$$2x + 17y + 4z = 35$$

$$x + 3y + 10z = 24$$

Hence we can apply Gauss–Seidel iteration method.

From the above equations

$$x = \frac{1}{28}[32 - 4y + z] \qquad \text{....(i)}$$

$$y = \frac{1}{17}[35 - 2x - 4z] \qquad \text{....(ii)}$$

$$z = \frac{1}{10}[24 - x - 3y] \qquad \text{....(iii)}$$

First approximation

Putting $y = z = 0$ in (i), we get

$$x_1 = \frac{1}{28}(32) = 1.1428571$$

Putting $x = 1.1428571,\ z = 0$ in (ii), we get

$$y_1 = \frac{1}{17}[35 - 2(1.1428571)] = 1.9243697$$

Putting $x = 1.1428571,\ y = 1.9243697$ in (iii), we get

$$z_1 = \frac{1}{10}[24 - 1.1428571 - 3(1.9243697)] = 1.7084034$$

Second approximation

$$x_2 = \frac{1}{28}[32 - 4(1.9243697) + 1.7084034] = 0.9289615$$

$$y_2 = \frac{1}{17}[35 - 2(0.9289615) - 4(1.7084034)] = 1.5475567$$

$$z_2 = \frac{1}{10}[24 - 0.9289615 - 3(1.5475567)] = 1.8428368$$

Third approximation

$$x_3 = \frac{1}{28}[32 - 4(1.5475667) + 1.8428368] = 0.9875932$$

$$y_3 = \frac{1}{17}[35 - 2(0.9875932) - 4(1.8428368)] = 1.5090274$$

$$z_3 = \frac{1}{10}[24 - 0.9875932 - 3(1.5090274)] = 1.8485325$$

Fourth approximation

$$x_4 = \frac{1}{28}[32 - 4(1.5090274) + 1.8485325] = 0.9933008$$

$$y_4 = \frac{1}{17}[35 - 2(0.9933008)] = 4(1.8485325)] = 1.5070158$$

$$z_4 = \frac{1}{10}[24 - 0.9933008 - 3(1.5070158)] = 1.8485625$$

Fifth approximation

$$x_5 = \frac{1}{28}[32 - 4(1.5070158) + 1.8485625] = 0.9935893$$

$$y_5 = \frac{1}{17}[35 - 2(0.9935893) - 4(1.8485652)] = 1.5069741$$

$$z_5 = \frac{1}{10}[24 - 0.9935893 - 3(1.5069741)] = 1.8485488$$

Sixth approximation

$$x_6 = \frac{1}{28}[32 - 4(1.5069741) + 1.8485488] = 0.9935947$$

$$y_6 = \frac{1}{17}[35 - 2(0.9935947) - 4(1.8485488)] = 1.5069774$$

$$z_6 = \frac{1}{10}[24 - 0.9935947 - 3(1.5069774)] = 1.8485473$$

$\because$ The values of x, y, z in the fourth and fifth iteration are same upto four decimals, we stop the process here.

Hence $\quad x = 0.9936,\ y = 1.5069,\ z = 1.8485$

Ex.10: Using Gauss–Seidel iteration method, solve the system of equations.

$$10x - 2y - z - w = 3; -2x + 10y - z - w = 15;$$

$$-x - y + 10z - 2w = 27; -x - y - 2z + 10w = -9$$

(M.U, B.E., 1987)

Sol : The coefficient matrix of the given system is diagonally dominant. Hence we can apply Gauss–Seidel iteration method.

From the given equations, we can write

$$x = \frac{1}{10}[3 + 2y + z + w] \quad \text{....(i)}$$

$$y = \frac{1}{10}[15 + 2x + z + w] \quad \text{....(ii)}$$

$$z = \frac{1}{10}[27 + x + y + 2w] \quad \text{....(iii)}$$

$$w = \frac{1}{10}[-9 + x + y + 2z] \quad \text{....(iv)}$$

First approximation :

Putting $y = z = w = 0$ on RHS of (i), we get $x_1 = \frac{3}{10} = 0.3$

Putting $x = 0.3,\ z = w = 0$ on RHS of (ii),

we get $y_1 = \frac{1}{10}[15 + 2(0.3)] = 1.56$

Putting $x = 0.3, y = 1.56, w = 0$ on RHS of (iii),

we get $z_1 = \frac{1}{10}[27 + 0.3 + 1.56,] = 2.886$

Putting $x = 0.3,\ y = 1.56,\ z = 2.886$ on RHS of (iv),

we get $w_1 = \frac{1}{10}[-9 + 0.3 + 1.56 + 2(2.886)] = -0.1368$

Second approximation :

$$x_2 = \frac{1}{10}[3 + 2(1.56)] + 2.886 - 0.1368] = 0.88692$$

$$y_2 = \frac{1}{10}[15 + 2(0.88692) + 2.886 - 0.1368] = 1.952304$$

$$z_2 = \frac{1}{10}[27 + 0.88692 + 1.952304 + 2(-0.1368)] = 2.9565624$$

$$w_2 = \frac{1}{10}[-9 + 0.88692 + 1.952304 + 2(2.9565624)] = -0.0247651$$

Third approximation :

$$x_3 = \frac{1}{10}[3 + 2(1.952304) + 2.9565624 - 0.0247651] = 0.9836405$$

$$y_3 = \frac{1}{10}[15 + 2(0.9836405) + 2.9565624 - 0.0247651] = 1.9899087$$

$$z_3 = \frac{1}{10}[27 + 0.9836405 + 1.9899087 + 2(-0.0247651)] = 2.9924019$$

$$w_3 = \frac{1}{10}[-9 + 0.983405 + 1.9899087 + 2(2.9924019)] = -0.0041647$$

Fourth approximation :

$$x_4 = \frac{1}{10}[3 + 2(1.9899087) + 2.9924019 - 0.0041647] = 0.9968054$$

$$y_4 = \frac{1}{10}[15 + 2(0.9968054) + 2.9924019 - 0.0041647] = 1.9981848$$

$$z_4 = \frac{1}{10}[27 + 0.9968054 + 1.9981848 + 2(-0.0041647)] = 2.9986661$$

$$w_4 = \frac{1}{10}[-9 + 0.9968054 + 1.9981848 + 2(2.9986661)] = -0.0007677$$

Fifth approximation :

$$x_5 = \frac{1}{10}[3 + 2(1.9981848) + 2.9986661 - 0.0007677] = 0.9994268$$

$$y_5 = \frac{1}{10}[15 + 2(0.9994268) + 2.998666 - 0.0007677] = 1.9996752$$

$$z_5 = \frac{1}{10}[27 + 0.9994268 + 1.9996752 + 2(-0.0007677)] = 2.9997567$$

$$w_5 = \frac{1}{10}[-9 + 0.9994268 + 1.9996752 + 2(2.9997567)] = -0.0001384$$

Sixth approximation :

$$x_6 = \frac{1}{10}[3 + 2(1.9996752) + 2.9997567 - 0.0001384] = 0.9998968$$

$$y_6 = \frac{1}{10}[15 + 2(0.9998968) + 2.9997567 - 0.0001384] = 1.9999412$$

$$z_6 = \frac{1}{10}[27 + 0.9998968 + 1.9999412 + 2(-0.0001384)] = 2.9999561$$

$$w_6 = \frac{1}{10}[-9 + 0.9998968 + 1.9999412 + 2(2.9999561)] = -0.0002498$$

Seventh approximation :

$$x_7 = \frac{1}{10}[3 + 2(1.9999412) + 2.9999561 - 0.0002498] = 0.9999588$$

$$y_7 = \frac{1}{10}[15 + 2(0.9999588) + 2.9999561 - 0.0002498] = 1.9999624$$

$$z_7 = \frac{1}{10}[27 + 0.9999588 + 1.9999264 + 2(-0.0002498)] = 2.9999422$$

$$w_7 = \frac{1}{10}[-9 + 0.9999588 + 1.9999624 + 2(2.9999422)] = -0.0001945$$

Now, from sixth and seventh approximations the values of x, y, z and w correct to four decimal places are

$$x = 0.9999 \quad y = 1.9999 \quad z = 2.9999 \quad w = 0.0002$$

Exercises

Objective Type Questions

Multiple Choice Questions

Tick the correct answer :

1. Crout's method is also known as :

(a) direct method (b) iterative method

(c) Indirect method (d) rotational method.

2. Crout's method is suited for :

(a) computer operation (b) manipulating the data

(c) everywhere (d) none of these.

3. Crout's method can be applied to get :

(a) inverse of a Matrix (b) transpose of a Matrix

(c) the value of a determinant (d) no where in numerical problems.

4. Gauss-Seidel's method is an :

(a) direct method (b) iterative method

(c) indirect method (d) none of these.

5. Gauss-Seidel's method is used to solve :

(a) a system of linear equation (b) a system of non linear equation

(c) a system of algebsic equation (d) none of these.

Fill in the Blanks

1. In Gauss-Seidel method the $(K+1)^{th}$ iterations are given as below,

$x_{k+1} = \dots\dots\dots$

$y_{k+1} = \dots\dots\dots$

and $z_{k+1} = \dots\dots\dots$

where $a_1, b_1, c_1, a_2, b_2, c_2, a_3, b_3, c_3, d_1, b_2$ and d_3 are taken from

$$\begin{bmatrix} a_1 & b_1 & c_1 \\ a_2 & b_2 & c_2 \\ a_3 & b_3 & c_3 \end{bmatrix}\begin{bmatrix} x \\ y \\ z \end{bmatrix}\begin{bmatrix} d_1 \\ d_2 \\ d_3 \end{bmatrix}$$

2. If x_0, y_0, z_0 are approximation, then the next approximations x_1, y_1, z_1 are given as below,

"   -256-   -   -*   ! - /
!   !   ! I "   I   I   A!K .3 1"
(%' $/   ' !L   > !   7!   ?!

4 Maxwell equations

Previously, electrical vibrations in a wire were considered. In a general case, ***electromagnetic waves*** are considered[25]. The electromagnetic field is characterized by four vector functions that are ***electric field strength*** **E**, ***magnetic field strength*** **H**, ***electric induction*** **D** and ***magnetic induction*** **B**. Each of these values has three components.

The mathematical models of electrodynamics are based on ***Maxwell equations*** connecting the above values. These include the ***Gauss law***

$$\mathrm{div}\mathbf{D} = 4\pi\rho,$$

according to which an electric charge is a source of electric induction. Here ρ is the charge density, and the divergence div of the vector $\mathbf{D}= \ (D_1, D_2, D_3)$ is characterized by the equality[26]

$$\mathrm{div}\mathbf{D} = \frac{\partial D_1}{\partial x} + \frac{\partial D_2}{\partial y} + \frac{\partial D_3}{\partial z}.$$

Then we have the ***Gauss law of magnetic field***

$$\mathrm{div}\mathbf{B} = 0,$$

postulating the absence of magnetic charges. By the ***Faraday law of induction***

$$\mathrm{rot}\mathbf{E} = -\frac{1}{c}\frac{\partial \mathbf{B}}{\partial t}.$$

the change in magnetic induction generates a vortex electric field, where c is the ***velocity of light*** in vacuum, and the ***rotor*** rot of the vector $\mathbf{E} = (E_1, E_2, E_3)$ is characterized by the equality

$$\mathrm{rot}\mathbf{E} = \Big(\frac{\partial E_3}{\partial y} - \frac{\partial E_2}{\partial z}, \frac{\partial E_1}{\partial z} - \frac{\partial E_3}{\partial x}, \frac{\partial E_2}{\partial x} - \frac{\partial E_1}{\partial y}\Big).$$

Finally, the equality

$$\mathrm{rot}\mathbf{H} = \frac{1}{c}\frac{\partial \mathbf{D}}{\partial t} + \frac{4\pi}{c}\mathbf{j},$$

means that electric current and a change in electric induction generate a vortex magnetic field, where **j** is the ***density of the electric current***. The above relations are supplemented by ***material field equations***

$$\mathbf{D} = \varepsilon\mathbf{E}, \ \ \mathbf{B} = \mu\mathbf{H}, \ \ \mathbf{j} = \sigma\mathbf{E}, \tag{12.32}$$

where ε is the ***dielectric constant***, μ is the ***magnetic permeability***, and σ is the ***conductivity of the medium***.

Under certain conditions, the Maxwell equations can be simplified[27]. In particular, in a vacuum in the absence of charges and currents for $\varepsilon = 1$, $\mu = 1$, after excluding the induction of electric and magnetic fields using equalities (12.32), we obtain the following relations

$$\mathrm{div}\mathbf{E} = 0, \ \ \mathrm{div}\mathbf{H} = 0, \ \ \mathrm{rot}\mathbf{E} = -\frac{1}{c}\frac{\partial \mathbf{H}}{\partial t}, \ \ \mathrm{rot}\mathbf{H} = \frac{1}{c}\frac{\partial \mathbf{E}}{\partial t}. \tag{12.33}$$

Acting on the third equality (12.33) by the operator rot and taking into account the possibility of its permutation with the time derivative, we have

$$\mathrm{rot}\,\mathrm{rot}\mathbf{E} = -\frac{1}{c}\frac{\partial}{\partial t}\mathrm{rot}\mathbf{H} = -\frac{1}{c^2}\frac{\partial^2 \mathbf{E}}{\partial t^2} \tag{12.34}$$

by fourth equality (12.33).

It can be shown that for any vector function **E**, the following equality holds

$$\operatorname{rot}\operatorname{rot}\mathbf{E} = \nabla \operatorname{div}\mathbf{E} - \Delta\mathbf{E},$$

where ∇ is the ***gradient***, i.e., the vector whose components are partial derivatives with respect to spatial variables, and Δ is the Laplace operator, i.e., sum of second order derivatives with respect to spatial variables. Then, taking into account the first equality (12.33), we transform the relation (12.34) to the following form

$$\mathbf{E}_{tt} = c^2\Delta\mathbf{E}. \tag{12.35}$$

Analogically, from the equalities (12.33) it follows

$$\mathbf{H}_{tt} = c^2\Delta\mathbf{H}. \tag{12.36}$$

Note that the strength of electric and magnetic fields are vector quantities. Thus, under the assumptions made, it turns out that all its components satisfy the wave equation (12.31), and the velocity of light acts as the parameter a here. In Section 3, it was noted that this coefficient is associated with the wave velocity. Thus, electromagnetic waves propagate at the light velocity.

5 Finite difference method for the vibrating string equation

As already noted, an analytical solution of differential equations can be found only in exceptional cases. In the previous chapter, the finite difference method for the approximate solving of the heat equation was described. It can also be used to solve boundary value problems for the vibrating string equation[28].

Considered the non-homogeneous vibrating string equation

$$u_{tt}(x,t) = a^2u_{xx}(x,t) + f(x,t),\ \ 0 < x < L,\ 0 < t < T \tag{12.37}$$

with initial conditions

$$u(x,0) = \varphi(x),\ u_t(x,0) = \psi(x),\ 0 < x < L \tag{12.38}$$

and boundary conditions

$$u(0,t) = \alpha(t),\ u(L,t) = \beta(t),\ t > 0, \tag{12.39}$$

where the numbers a and L and the functions f, φ, ψ, α, and β are known.

The interval $[0,T]$ is divided into parts with a step $\tau = T/N$ by the points $t_j = \tau j$, $j = 0,...,N$, and the interval $[0,L]$ is divided with a step $h = L/M$ by the points $x_i = hi$, $i = 0,...,M$. A solution to the problem is sought at the grid nodes (x_i,t_j). The second derivatives in equation (12.37) are approximated as follows

$$\frac{\partial^2u(x_i,t_j)}{\partial t^2} \approx \frac{u(x_i,t_{j-1}) - 2u(x_i,t_j) + u(x_i,t_{j+1})}{\tau^2},$$

$$\frac{\partial^2u(x_i,t_j)}{\partial x^2} \approx \frac{u(x_{i-1},t_j) - 2u(x_i,t_j) + u(x_{i+1},t_j)}{h^2}.$$

Then we obtain the equality

$$\frac{u_i^{j-1} - 2u_i^j + u_i^{j+1}}{\tau^2} = a^2\frac{u_{i-1}^j - 2u_i^j + u_{i+1}^j}{h^2} + f_i^j,$$

CHAPTER 3

Areas by Slicing and Scaling

The most fruitful and powerful ideas in the study of areas and volumes are *slicing* and *scaling*. The Greeks used these ideas in finding the fundamental shape that must be taken by formulas for lengths, areas and volumes.

Archimedes showed that the formulas for the circumference and area of a circle and the surface area and volume of a sphere are related by constants involving π. His ideas eventually led to the notion of integration in calculus.

It is easy to see that the results Archimedes obtained are, in many cases, easy consequences of the first results on integration learned in first-semester calculus. The point is, however, that calculus as a body of knowledge did not exist at the time of Archimedes and that the extremely clever arguments used by Archimedes were the arguments that eventually led to calculus.

Wallis used basic calculations of calculus to discover a beautiful product formula for π. Fourier used Wallis's formula for π in solving a special case of the heat equation which he had developed. And this solution led Fourier to what are now called Fourier series. This chapter will relate those discoveries.

3.1. Slicing and Scaling

The principles of slicing and scaling are most easily described in a coordinate plane or coordinate 3-space, though versions were developed before Euclidean coordinates became common and standard. We shall take the principles of slicing and scaling as given. Here is a description.

Slicing principle: Two (reasonably nice) objects A and B in the plane have the same area if each of the horizontal slices in A and B have the same length. See Figure 1. In 3-space, objects A and B have the same volume if each of the horizontal slices in A and B have the same area.

We saw in the chapter on the Pythagorean Theorem how the slicing principle was proved by Euclid in the case of two parallelograms. A fairly rigorous proof for planar sets can be adapted from this Euclidean theorem. This slicing principle is also at the basis of the area and volume formulas in first-year calculus. An advanced version for quite general sets requires Lebesgue measure and is called Fubini's Theorem.

Scaling principle: Let A be a reasonably nice object in 2- or 3-space and k a positive number. Then $k \cdot A$ is said to be a *scaled version* of A with *scale factor* k. If B is congruent to a scaled version kA of A, then A and B are said to be *similar*. The *scaling principle* says that lengths ℓ in A correspond to length $k\ell$ in B. Areas a in A correspond to areas k^2a in B. Volumes v in A correspond to volumes k^3v in B.

The scaling principle is obvious for the interval, the square, and the cube. See Figure 2. For a nice object A, lengths, areas, and volumes are nicely approximated

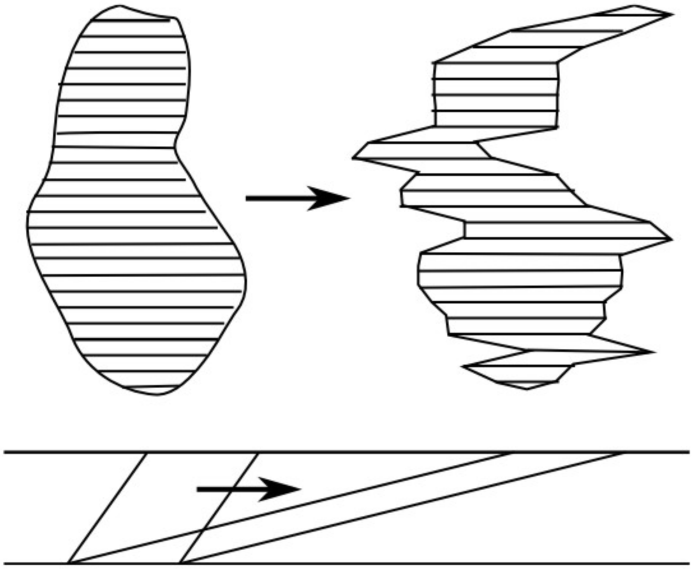

FIGURE 1. The slicing principle

by intervals, squares, and cubes, so that the truth of the scaling principle is apparent. Figure 2 illustrates the principle for the interval, square, and cube with scale factor $k = 2$.

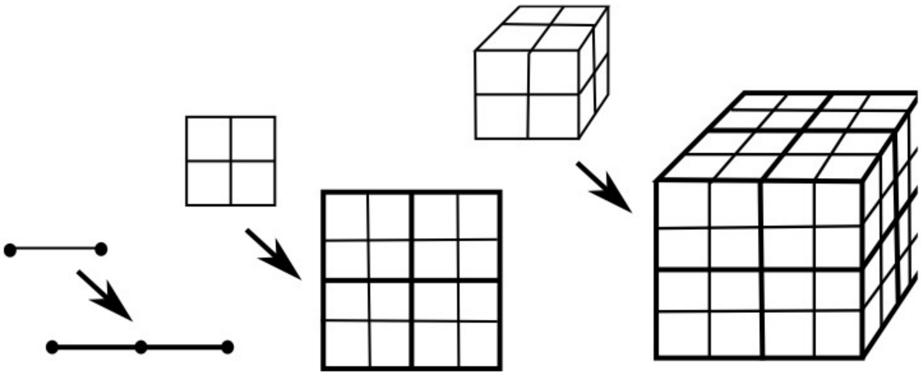

FIGURE 2. The scaling principle again

We need to make a careful distinction between the circle, which is 1-dimensional (a curve) and is called a simple closed curve, and the union of a planar circle with its interior, which is 2-dimensional and which we call a circular 2-dimensional disk or ball. Likewise, we distinguish between the 1-dimensional boundary of a triangle and the 2-dimensional set that is the union of that 1-dimensional set and its interior, which is called a disk or triangular disk. Likewise, we distinguish between the 2-dimensional sphere that is the boundary of a 3-dimensional (solid) ball. The former is called a 2-sphere, the latter a 3-ball or 3-disk.

For our purposes, we used the slicing principle in the Euclidean proof of the Pythagorean Theorem and the scaling principle in the Einstein proof. We now observe that the scaling principle yields the basic form of the standard classical formulas for the circumference of a circle and area of a circular disk, and for the surface area of a 2-sphere and volume of the 3-ball. (Compare Dunham's treatment of Archimedes in [23].)

Theorem 3.1. *Let $C(r)$ denote the circumference of a circle of radius r, and let $A(r)$ denote the area of the circular disk of radius r. Let $S(r)$ denote the surface area of the sphere of radius r, and let $V(r)$ denote the volume of the round 3-ball of radius r. Then*

$$C(r) = r \cdot C(1); \quad A(r) = r^2 \cdot A(1); \quad S(r) = r^2 \cdot S(1); \quad \textit{and } V(r) = r^3 \cdot V(1).$$

Proof. The circle of radius r is a scaled version of the unit circle with scale factor r. The 2-disk of radius r is a scaled version of the unit 2-disk with scale factor r. The 2-sphere is a scaled version of the unit sphere with scale factor r. The 3-ball of radius r is a scaled version of the unit ball with scale factor r. Hence the theorem follows directly from the scaling principle. ☐

3.2. What Is π?

Of course, we all know that $C(1)$, $A(1)$, $S(1)$, and $V(1)$ are closely related: $C(1) = 2\pi$, $A(1) = \pi$, $S(1) = 4\pi$, and $V(1) = (4/3)\pi$. But what is π? and how do we find these basic formulas?

The beginning is easy:

Definition 3.2. π is *by definition* the area $\pi = A(1)$ of the unit 2-disk.

We shall see next, from the slicing principle, that $C(1) = 2 \cdot A(1)$ and that $S(1) = 3 \cdot V(1)$. It remains then only to find the volume $V(1) = (4/3)\pi$ of the unit ball. Given first-year calculus, that is an easy calculation. But we need to remember that Archimedes, who discovered the formula, did not have calculus. His wonderful derivation—extremely clever—suggested ideas that eventually *led* to calculus. The story of his discovery, which I learned from Georg Pólya's *Mathematics and Plausible Reasoning*, is one of my favorite stories. Remember that integration had not as yet been invented.

But first we apply the slicing principle:

Theorem 3.3. *The area of a triangular disk is $(1/2)ab$, where a is the altitude and b is the base.*

Proof. This fact is essentially a consequence of the slicing principle for parallelograms. If the parallelogram is right angled, then the area of the parallelogram is obviously ab, where a is the altitude and b is the base. If the parallelogram is not right angled, then the same result is a consequence of the slicing principle. The triangle is half of the appropriate parallelogram. ☐

Theorem 3.4. *The volume of a 3-dimensional triangular cone is $(1/3)ab$, where a is the altitude and b is the area of the base.*

*D

Proof. This fact is essentially a consequence of the slicing principle for triangular pyramids:

If the pyramid is right angled, then the volume is obviously ab, where a is the altitude and b is the base. If the pyramid is not right angled, then the same result is a consequence of the slicing principle.

It therefore suffices to show that the triangular cone is $1/3$ the volume of the triangular pyramid. This fact requires two further applications of the slicing principle. See Figure 3.

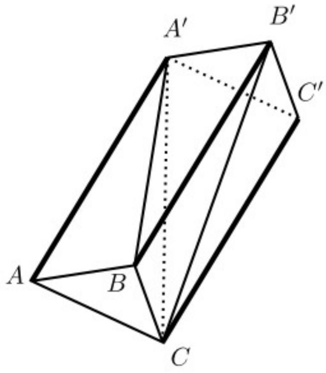

Figure 3. The Triangular Pyramid Cut in Thirds

We may assume that the triangular pyramid has parallel ends ABC and $A'B'C'$. Then the pyramid is the union of three triangular cones, namely $ABCA'$, $BCA'B'$, and $CA'B'C'$. The first two share a triangular base BCA' with altitudes determined by A and B', respectively, at the same distance from the common base. Hence their volumes are equal by the slicing principle. Likewise, $BCA'B'$ and $CA'B'C'$ have the same volume. This completes the proof that the triangular cone is $1/3$ the volume of the triangular pyramid. ☐

Theorem 3.5. *$C(1) = 2A(1) = 2\pi$, so that $C(r) = 2\pi r$ and $A(r) = \pi r^2$.*

Proof. See Figure 4. Approximate the circle of radius 1 closely by a polygonal path made up of segments $S_1, S_2, \ldots, S_n$ of lengths $\ell_1, \ell_2, \ldots, \ell_n$. Let x denote the center of the circle. Then the circular disk is closely approximated by the triangles $xS_1, xS_2, \ldots, xS_n$. The altitude of each triangle is approximately 1, so that the area of the triangle xS_i is approximately $(1/2) \cdot 1 \cdot \ell_i$. Then

$$A(1) \approx (1/2)(\ell_1 + \ell_2 + \cdots + \ell_n) \approx (1/2)C(1).$$

☐

Theorem 3.6. *$S(1) = 3V(1)$.*

Proof. See Figure 5. Approximate the surface of the ball of radius 1 closely by a polyhedral surface made up of triangles $T_1, T_2, \ldots, T_n$ of areas $a_1, a_2, \ldots, a_n$. Let x denote the center of the ball. Then the ball is closely approximated by the triangular cones $xT_1, xT_2, \ldots, xT_n$. The altitude of each cone is approximately 1, so that the volume of the triangular cone xT_i is approximately $(1/3) \cdot 1 \cdot a_i$. Then

$$V(1) \approx (1/3)(a_1 + a_2 + \cdots + a_n) \approx (1/3)S(1).$$

☐

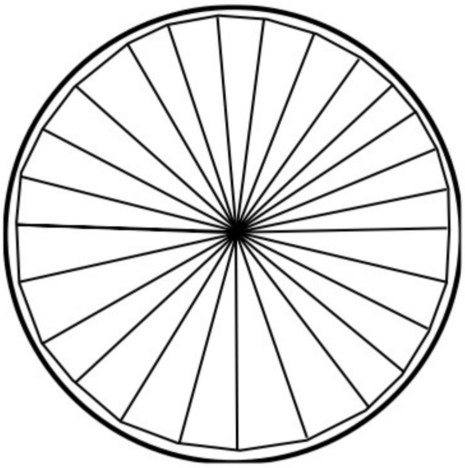

FIGURE 4. The disk as a cone over its center

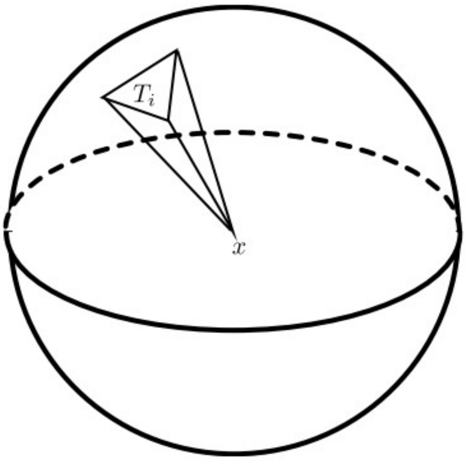

FIGURE 5. The ball as a cone over its center

3.3. Archimedes Discovers the Volume of a Sphere

See [10].

Archimedes knew:

(1) The Pythagorean Theorem, which gives the following equation for the circle in the plane centered at $(1, 0)$ of radius 1: $(x - 1)^2 + (y - 0)^2 = 1^2$, or

$$x^2 + y^2 = 2x.$$

(2) The area of a circle: $A(r) = \pi r^2$.

(2) The volume of a cylinder: $V_{cyl} = a \cdot b$, where a is the altitude and b is the area of the base.

(3) The volume of a cone: $V_{cone} = (1/3)a \cdot b$, where a is the altitude and b is the area of the base. Archimedes also realized that the formula was derived by

examining cross sections in the cone. (Was this fact originally discovered by a form of the slicing principle?).

(4) The principle of the balance: See Figure 6. Suppose weight w_1 is suspended at distance d_1 from the center of the balance and that weight w_2 is suspended at distance d_2 from the center on the opposite side of the balance. Then the condition for balance is that $d_1 \cdot w_1 = d_2 \cdot w_2$.

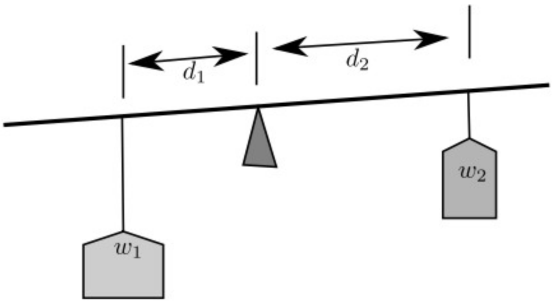

FIGURE 6. The principle of the balance

Archimedes derived the principle of the balance from the principle of the center of mass, which he had found experimentally:

(5) The principle of the center of mass: See Figure 7. Starting in a position of balance, any individual portion of the weights may be rearranged symmetrically about its own individual center of mass. [Thus, if we have dominos stacked on the balance arm in a position of balance, then we may move any domino to the left n units if we also move another domino to the right n units. For example, in the figure, we have 9 dominos stacked at the center, obviously balancing by symmetry. It is only the total number of units moved in each direction that matters. Thus 6 left, one unit each, balances 3 right, two units each. It is by such arguments that Archimedes developed the principle of the balance.]

It is great fun to make a simple balance at home and experiment with stacks of dominos on the balance. We don't need to make the balance perfectly symmetric. After all, even commercial balances recognize the necessity of adjustments. Just move the original stacks of dominos on our imperfect balance to a position of balance and then start moving dominos, a pair at a time, one left a unit, one right a unit. The resulting positions that balance often look totally unlikely.

Now what did Archimedes set out to do? He identifies volume with weight. He considers the solid ball B of radius 1, and the right circular cone C and cylinder D with base radius 2 and height (altitude) 2. By an unbelievably clever argument he shows that B and C suspended at distance 2 from the center of the balance on one arm of the balance should balance the cylinder D suspended at distance 1 from the center on the other arm of the balance. See Figure 8.

In other words, by the principle of the balance,

$$2 \cdot (\mathrm{Vol}_{sph} + \mathrm{Vol}_{cone}) = 1 \cdot \mathrm{Vol}_{cyl}\,.$$

Since he knows that $\mathrm{Vol}_{cone} = (1/3)\,\mathrm{Vol}_{cyl} = (1/3)(\pi \cdot 2^2 \cdot 2)$, he can solve for the one unknown Vol_{sph}:

$$V(1) = \mathrm{Vol}_{sph} = (1/2)\,\mathrm{Vol}_{cyl} - (1/3)\,\mathrm{Vol}_{cyl} = (1/6)\,\mathrm{Vol}_{cyl} = (8/6)\pi = (4/3)\pi.$$

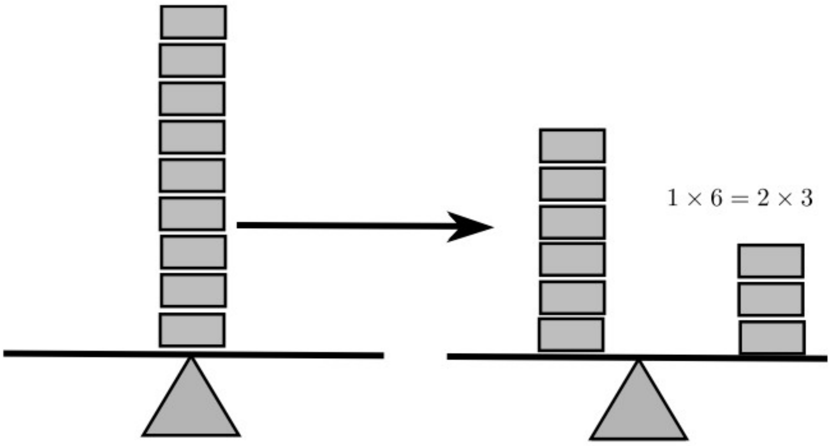

FIGURE 7. Balancing dominos — the center of mass

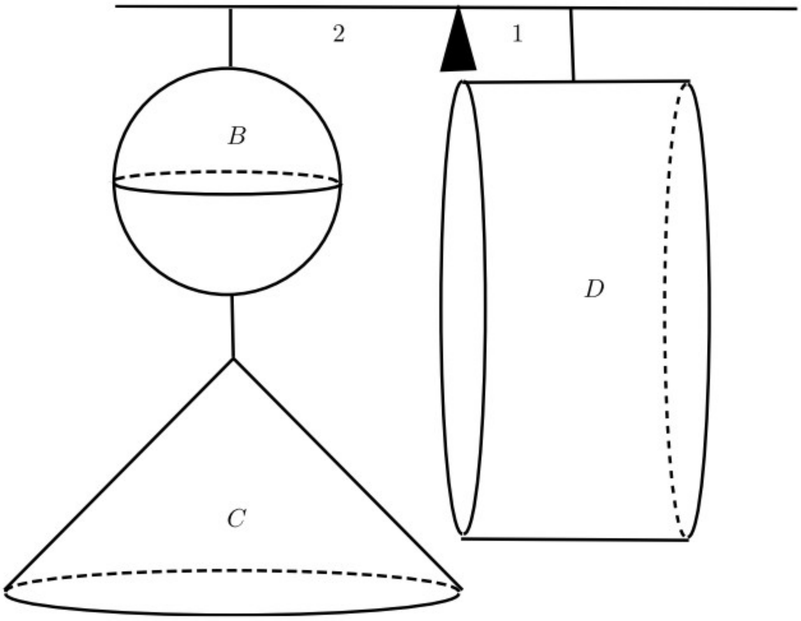

FIGURE 8. The final balance

What is Archimedes's argument?

Archimedes begins with the circle $x^2 + y^2 = 2x$ of radius 1 centered at $(1, 0)$ and given by the Pythagorean Theorem. He rotates this circle about the x-axis to obtain the desired boundary sphere of the ball being considered. Thinking of the fact that the volume of the cone was discovered by considering cross sections in the cone, he considers cross sections in the ball defined by setting x equal to a constant. The area of that cross section is πy^2. Since y^2 appears in the circle equation, Archimedes multiplies the equation by π and seeks to interpret the terms obtained:

$$\pi x^2 + \pi y^2 = \pi 2x.$$

His interpretation is obtained by rotating Figure 9 about the x-axis. The result is pictured in Figure 10.

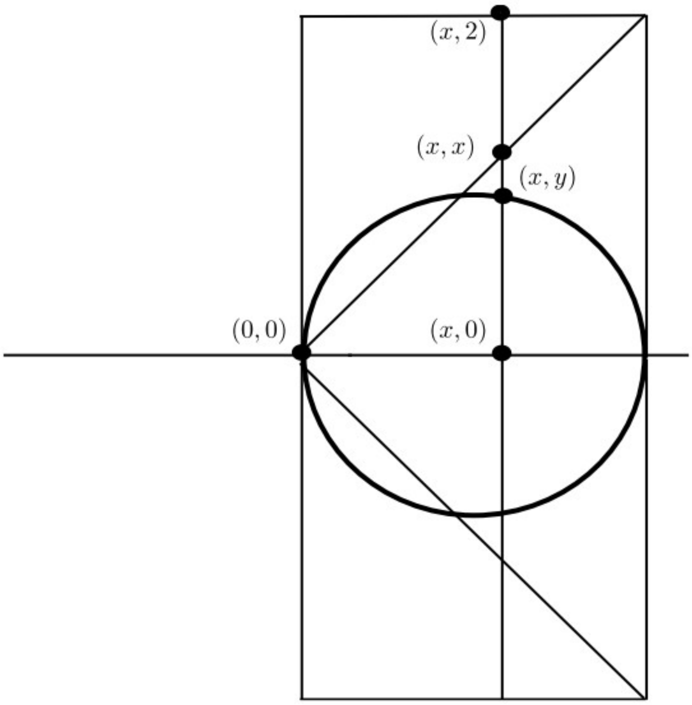

FIGURE 9. The sphere, cone, and cylinder of Archimedes

He observes that πx^2 is also the area of a circle. What circle? As x varies, the circles of radius x concentric with the spherical cross sections of radius y form a cone, namely a cone of base radius 2 and altitude 2. This cone is obtained by rotating the large triangle of the diagram about the x-axis.

Since Archimedes knows the volume of the cone, this seems like progress. Is it possible to interpret the final term $\pi 2x$ in terms of a circular cross-section? It is not at all obvious what to do. What does Archimedes do? He multiplies by 2. He obtains the equation

$$2 \cdot (\pi x^2 + \pi y^2) = x \cdot (\pi 2^2).$$

The factor $\pi 2^2$ is the area of a circle of radius 2. As x varies, the circles become cross sections of constant radius 2 that sweep out a circular cylinder of base radius 2 and altitude 2. This large cylinder is created by rotating the large rectangle of the diagram about the x-axis.

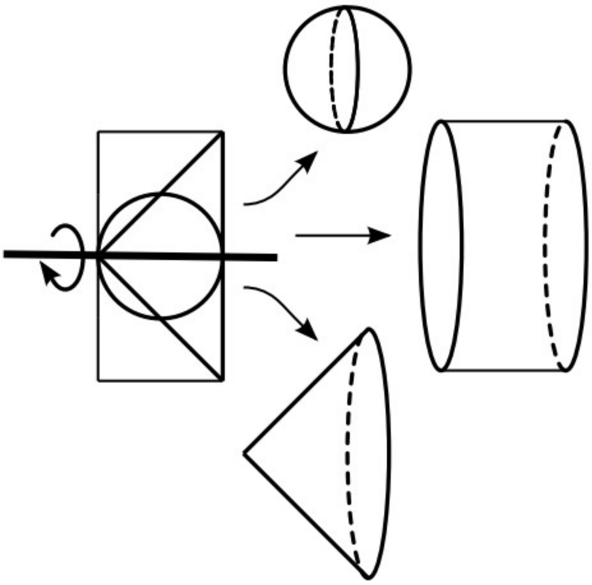

FIGURE 10. The rotation

Archimedes interprets each of the circular cross sections as a weight. He interprets the factor 2 on the left-hand side of the equation as the length of a lever arm and the factor x on the right-hand side of the equation as the length of another lever arm. Then the equation becomes the condition for a balance: Hang the sphere and cone cross sections at distance 2 from the balance center on the left; hang the cylinder cross-section at distance x from the balance center on the right. That configuration balances.

If this configuration balances for one set of cross-sections, why not for all cross sections taken together (addition of infinitely many infinitesimal weights!). That is, hang the entire ball and cone on the left-hand side at distance 2 from the center. Leave the cylinder sections where they are, so that the cylinder remains unmoved. But now apply the principle of center of mass: the cylinder has an obvious center of mass at $(1, 0)$. Hence we may hang the entire cylinder at distance 1 from the center. This completes Archimedes's construction.

The idea of adding infinitely many infinitesimal weights became one of the central ideas leading to calculus. For many years, integration was interpreted precisely as such an operation.

3.4. Wallis Discovers a Product Formula for π

See [11].

In the last section, we spent a good deal of time in finding how Archimedes originally discovered formulas for the area and circumference of a disk and the surface area and volume of a ball. We used slicing and scaling principles, as well as properties of balance and center of mass.

In this section we will admit that we know the basics of calculus and explain two nice results that are usually passed over in our undergraduate classes.

(1) Wallis's formula for π:

$$\frac{\pi}{4} = \frac{2}{3} \cdot \frac{4}{3} \cdot \frac{4}{5} \cdot \frac{6}{5} \cdot \frac{6}{7} \cdot \frac{8}{7} \cdot \frac{8}{9} \cdot \frac{10}{9} \cdots .$$

(2) The volume of the higher dimensional ball $\mathbb{B}^n$:

$$\mathrm{Vol}(\mathbb{B}^n) = \mathrm{Vol}\{(x_1, \cdots, x_n) \mid x_1^2 + \cdots + x_n^2 \leq 1\}.$$

The calculations used for (2) give precisely the results needed for (1). The calculation is by an induction on dimension which uses both the slicing principle and the scaling principle, but in all finite dimensions. A ball of dimension $n+1$ has sections or slices that are balls of dimension n. Assuming that the n-dimensional volume of an n-dimensional ball of radius 1 is known, the n-volume of each slice or section is given by the scaling principle. Thus we obtain a specifically known integral whose value will be the required $n+1$-dimensional volume. That integral can be simplified by one integration by parts (a process well-known from first-year calculus, but which we shall review).

The formula for volume that we obtain is slightly strange. Does the numerical value of the n-volume of the n-ball get larger or smaller as n increases? After all, the n-ball is contained in the $n+1$-ball. We shall see.

Wallis's formula is not particularly useful for approximating π because it converges to $\pi/4$ so slowly. Nevertheless, it is a beautiful formula, and it played a very interesting role in Fourier's development of the heat equation. We will spend a little time explaining Fourier's account without proofs.

3.4.1. Volume of the n-dimensional ball. Our goal is to calculate the volume $V^{(n)}(r)$ of the n-ball $\mathbb{B}^n = \{(x_1, \ldots, x_n) : x_1^2 + \cdots + x_n^2 \leq r^2\}$ of radius r. It suffices to calculate the volume $V^{(n)} = V^{(n)}(1)$, since, by the similarity principle, $V^{(n)}(r) = V^{(n)} \cdot r^n$.

It is obvious that $V^{(1)} = 2$ since $\mathbb{B}^1$ is an interval of length 2. By the very definition of π, $V^{(2)} = \pi$. We proceed by induction.

For $(n+1) \geq 2$, we slice $\mathbb{B}^{n+1}$ by the plane $x_{n+1} = t \in (-1, 1)$ and obtain as cross-section in $\mathbb{B}^{n+1}$ an n-ball of radius $r(t) = (1-t^2)^{\frac{1}{2}}$ and of volume $V^{(n)} \cdot r(t)^n$. Hence

$$V^{(n+1)} = \int_{-1}^{1} V^{(n)} \cdot r(t)^n \, dt = V^{(n)} \cdot \int_{-1}^{1} (1-t^2)^{\frac{n}{2}} \, dt.$$

Setting $\square[n] = \int_{-1}^{1} (1-t^2)^{\frac{n}{2}} \, dt$, we obtain the basic formula

$$V^{(n+1)} = V^{(n)} \cdot \square[n].$$

Since $V^{(1)} = \square[0] = 2$, it follows immediately from equation (1) that

$$V^{(n+1)} = \square[0] \cdot \square[1] \cdot \square[2] \cdots \square[n]. \tag{1}$$

Thus it suffices to calculate $\square[n]$. The integrals $\square[n]$ are precisely the integrals that John Wallis calculated in developing his infinite product representation of $\pi/4$.

We will need to integrate once by parts. The formula for integration by parts is simply the application of the product rule for derivatives to integration:

$$\frac{d}{dx}(u(x) \cdot v(x)) = u(x) \cdot v'(x) + u'(x) \cdot v(x).$$

Hence

$$\int_a^b u(x)dv(x) = u(x)v(x)\Big|_a^b - \int_a^b v(x)du(x),$$

where $dv(x) = v'(x)dx$ and $du(x) = u'(x)dx$. In shorthand,

$$\int udv = uv - \int vdu.$$

The easy cases are

$$\Box[0] = 2 = V^{(1)} \text{ and } \Box[1] = V^{(2)}/V^{(1)} = \pi/2. \tag{2}$$

For $n \geq 2$, we peel off one copy of $(1-t^2)$ in order to split the integral $\Box[n]$ in two:

$$\Box[n] = \int_{-1}^{1} (1-t^2)^{\frac{n-2}{2}}\, dt + \int_{-1}^{1} t \cdot [-t(1-t^2)^{\frac{n-2}{2}}]\, dt.$$

The first of the two resulting integrals is obviously $\Box[n-2]$. Since the derivative of $v(t) = (1/n)\cdot(1-t^2)^{\frac{n}{2}}$ is $[-t(1-t^2)^{\frac{n-2}{2}}]$, the second integral can be integrated by parts, with $u(t) = t$:

$$\int_{-1}^{1} u(t)dv(t) = \Big[u(t)\cdot v(t)\Big]_{-1}^{1} - (1/n)\int_{-1}^{1} (1-t^2)^{\frac{2}{2}}\, dt = 0 - \frac{1}{n}\Box[n].$$

Hence we obtain the reduction formula

$$\Box[n] = \frac{n}{n+1}\Box[n-2]. \tag{3}$$

Equations (1), (2), and (3) yield recursive definitions of all integrals $\Box[n]$ and all volumes $V^{(n)}$. We easily obtain the results

$$\Box[2n] = 2\cdot\frac{2}{3}\cdot\frac{4}{5}\cdots\frac{2n}{2n+1} = n!\cdot\frac{2}{1}\cdot\frac{2}{3}\cdot\frac{2}{5}\cdots\frac{2}{2n+1} \quad \text{and} \tag{4}$$

$$\Box[2n-1] = \frac{\pi}{2}\cdot\frac{3}{4}\cdot\frac{5}{6}\cdots\frac{2n-1}{2n} = \frac{\pi}{n!}\cdot\frac{1}{2}\cdot\frac{3}{2}\cdot\frac{5}{2}\cdots\frac{2n-1}{2}, \tag{5}$$

from which it is easy to deduce that

$$V^{(2n)} = \frac{\pi^n}{n!},$$

$$V^{(2n+1)} = \pi^n\cdot\frac{2}{1}\cdot\frac{2}{3}\cdot\frac{2}{5}\cdots\frac{2}{2n+1}.$$

EXERCISE 3.7. Calculate $\lim_{n\to\infty} V^{(n)}$.

Those familiar with the Γ function will recognize the latter two formulas as expressing

$$V^{(m)} = \frac{\pi^{\frac{m}{2}}}{\Gamma(\frac{m}{2}+1)}.$$

3.4.2. Volume of the n-dimensional ball. Since equations (4) and (5) so easily imply Wallis's product formula, we include the derivation here:

The integral $\square[n]$ is a decreasing function of n. Hence

$$\square[2n] < \square[2n-1] < \square[2n-2].$$

That is,

$$2 \cdot \frac{2}{3} \cdot \frac{4}{5} \cdots \frac{2n}{2n+1} < \frac{\pi}{2} \cdot \frac{3}{4} \cdot \frac{5}{6} \cdots \frac{2n-1}{2n} < 2 \cdot \frac{2}{3} \cdot \frac{4}{5} \cdots \frac{2n-2}{2n-1}.$$

Solving these inequalities for $\pi/4$, we find

$$\frac{2}{3} \cdot \frac{4}{3} \cdot \frac{4}{5} \cdot \frac{6}{5} \cdots \frac{2n-2}{2n-1} \cdot \frac{2n}{2n-1} \cdot \frac{2n}{2n+1} < \frac{\pi}{4} < \frac{2}{3} \cdot \frac{4}{3} \cdot \frac{4}{5} \cdot \frac{6}{5} \cdots \frac{2n-2}{2n-1} \cdot \frac{2n}{2n-1}.$$

The difference between the larger right-hand side and the smaller left-hand side is $1/(2n)$ times the left-hand side. Hence both the left-hand expression and the right-hand expression converge to $\pi/4$ as $n \to \infty$. Thus we obtain Wallis's expression:

$$\pi/4 = \frac{2}{3} \cdot \frac{4}{3} \cdot \frac{4}{5} \cdot \frac{6}{5} \cdot \frac{6}{7} \cdot \frac{8}{7} \cdot \frac{8}{9} \cdot \frac{10}{9} \cdots.$$

PROBLEM 3.8. Can you devise a way to use Wallis's formula so as to obtain more rapid approximations to π?

3.5. Fourier Discovers Fourier Series

See [13].

Contrary to almost everything else in this book, the following will be only an outline of some mathematics, rather than a complete proof.

Fourier saw, in the problem of heat, his chance to make an historic contribution to physics. He developed a differential equation called the heat equation, and sought to understand its behavior in basic situations. In particular, he considered an infinite, solid, homogeneous slab whose planar slice looked like Figure 11.

The vertical sides were to be cooled to freezing. Fourier chose units so that freezing was a temperature of 0. The bottom was to be heated to boiling. He chose units so that boiling was a temperature of 1. He wrote:

> The present question consists in determining the permanent temperature of a rectangular infinite solid, when the sides are maintained at freezing temperature and the bottom at boiling temperature.
>
> The consideration of such simple and basic questions is one of the most certain means of discovering the laws of natural phenomena, and we see by the history of science that all theories are formed following this method.

Fourier applies the general *heat equation*

$$\frac{d\nu}{dt} = \frac{K}{CD} \times \left(\frac{\partial^2 \nu}{\partial x^2} + \frac{\partial^2 \nu}{\partial y^2} + \frac{\partial^2 \nu}{\partial z^2} \right).$$

The variable ν represents temperature. The parameters K, C, and D are constants determined experimentally: K refers to how rapidly a quantity of heat can move through the solid, C to the capacity of the substance to store heat, D the density of the substance.

-256- - -* ! - / 1 1"
E 2 7 3
('% $ B

On the other hand, the formalism of modular symbols allows one to write for this number an expression having the same structure as (2.4):

$$1 - \lambda_p + p = \sum_{p=\Delta\Delta'+\delta\delta'} y_{11}(\Delta, \delta). \tag{2.6}$$

This time, however, $y_{11}(\Delta, \delta)$ is not a polynomial: it depends only on $(\Delta : \delta) \bmod 11$: for the values of the latter $0, \infty, \pm 1, \pm 2, \pm 3, \pm 4, \pm 5 \bmod 11$, the values of y_{11} are respectively $2, -2, 0, 10, 5, -5, -10$.

Thus, we have connected solutions modulo p of the equation (2.5) "depending on 11" as its conductor with solutions modulo 11 of the equation $p = \Delta\Delta' + \delta\delta'$ depending on p. This justifies the name "non–commutative reciprocity law" suggested for (2.6) and its generalizations in [**Man72**].

Such formulas can be used to make more explicit the exact arithmetic content of special cases of the very general and therefore somewhat abstruse Langlands formalism.

Proofs of formulas for coefficients such as (2.4), (2.6) consist of two steps. For simplicity, we will illustrate this for the case of weight two cusp form $f(z)$ which is an eigenform with respect to a Hecke operator T_n so that $T_n f = a_n f$. We integrate this identity, say, from 0 to $i\infty$ and get

$$\int_0^{\infty} T_n f dz = a_n \int_0^{i\infty} f dz.$$

Now, use the explicit definition of the Hecke operator T_n on the left hand side and make a change of variables. We will get a sum of modular symbols. Using a continued fraction trick and a lemma initially proved by Heilbronn, we finally reduce the left hand side to a sum over solutions of $n = \Delta\Delta' + \delta\delta'$.

2.6. Relations with noncommutative geometry and a real analog of p–adic integration. The role of the upper half-plane in our constructions is of course explained by the fact that it parametrizes elliptic curves: complex tori $\mathbf{C}/\langle 1, \tau \rangle$, $\tau \in H$. The action of the modular group extends to this family, and the respective quotient is a non–complete algebraic variety. The cusps $\tau \in \mathbf{P}^1(\mathbf{Q})$ can be added to compactify this quotient by degenerate elliptic curves. However, for irrational values $\theta \in \mathbf{R} \setminus \mathbf{Q}$, the quotient $\mathbf{C}/\langle 1, \theta \rangle = \mathbf{C}^*/(e^{2\pi i \theta})$ is a "bad" topological group, and the common wisdom is that it is best represented by a non–commutative space, (a version of) the quantum torus T_θ.

Tori T_θ are parametrized by $\theta \in \mathbf{R}$. However, if one considers only tori modulo Morita equivalence, then they are parametrized by $PGL\,(2, \mathbf{Z}) \setminus \mathbf{P}^1(\mathbf{R})$. Set–theoretically, $PGL\,(2, \mathbf{Z}) \setminus \mathbf{P}^1(\mathbf{R})$ = the set of equivalence classes of $\alpha \in [0, 1)$ modulo the relation

$$\alpha \equiv \beta \ \Leftrightarrow\ \exists\, n_0, n_1\ \forall n > 0, \quad k_{n+n_0}(\alpha) = k_{n+n_1}(\beta).$$

Here $k_n(\alpha)$ are successive components of the continued fraction of α.

Thus, we can imagine an "invisible boundary" of the modular tower supporting a family of non–commutative spaces, the phantom of the classical modular family.

This viewpoint was discussed in [**MM02**], see also [**Mar05**], and in particular the Gauss problem on the distribution of continued fractions and its generalizations were treated as a measure theory on the "non–commutative modular curves".

We will describe here one result of this study, which produces an "∞–adic analogue" of the theory of p–adic integration used to construct p–adic Mellin transforms of cusp forms in [**Man73**].

Fix a prime number $N > 0$ and put $G_0 = \Gamma_0(N)$. We will assume that the genus of $X_{G_0} = X_0(N)$ is ≥ 1. Consider a $\Gamma_0(N)$–invariant differential $\omega = f(z)dz$ on H such that $f(z)$ is a cusp eigenform of weight two for all Hecke operators and denote by $L_f^{(N)}(s)$ (resp. $\zeta^{(N)}(s)$) its Mellin transform (resp. Riemann's zeta) with omitted Euler N–factor. More precisely, the coefficients of $L_f^{(N)}(s)$ are Hecke eigenvalues of f.

For $\alpha \in (0,1)$, denote by $p_n(\alpha)/q_n(\alpha)$ the n–th convergent of α.

Theorem. *We have for* $\mathrm{Re}\, t > 0$*:*

$$\int_0^1 d\alpha \sum_{n=0}^{\infty} \frac{q_{n+1}(\alpha) + q_n(\alpha)}{q_{n+1}(\alpha)^{1+t}} \int_0^{q_n(\alpha)/q_{n+1}(\alpha)} f(z)\, dz =$$

$$\left[\frac{\zeta(1+t)}{\zeta(2+t)} - \frac{L_f^{(N)}(2+t)}{\zeta^{(N)}(2+t)^2}\right] \int_0^{i\infty} f(z)\, dz. \tag{2.7}$$

If $\int_0^{i\infty} f(z)\, dz \neq 0$, we can read (2.7) as an expression for $L_f^{(N)}(s)$ which has striking structural similarities to the p–adic Mellin integral. In particular, both formulas involve a construction of a measure out of modular symbols, on $(0,1)$ and on $\mathbf{Z}_p^*$ respectively.

The proof of (2.7) given in [**MM02**] combines an old lemma by P. Lévy with the continued fractions trick alluded to above.

The Theorem above does not involve directly the non–commutative geometry of the invisible boundary. However, it was shown in [**MM02**], Sec. 4, and [**Mar05**], Sec. 6 of Ch. 4, that modular symbols themselves can be identified with specific elements in the K–theory of this space, giving additional weight to the geometric intuition behind this picture.

3. Iterated modular symbols

3.1. Multiple zeta values and iterated integrals. The theory of iterated modular symbols (cf. [**Man06**], [**Man05**]) is a simultaneous generalization of two constructions–of classical modular symbols and of multiple zeta values–and is an elaboration of a special case of Chen's iterated integrals theory ([**Che77**]) in a holomorphic setting.

Multiple zeta values are the numbers given by the k–multiple Dirichlet series

$$\zeta(m_1, \ldots, m_k) = \sum_{0<n_1<\cdots<n_k} \frac{1}{n_1^{m_1} \cdots n_k^{m_k}} \tag{3.1}$$

which converge for all integer $m_i \geq 1$ and $m_k > 1$, or equivalently by the m–multiple iterated integrals, $m = m_1 + \cdots + m_k$,

$$\zeta(m_1, \dots, m_k) = \int_0^1 \frac{dz_1}{z_1} \int_0^{z_1} \frac{dz_2}{z_2} \int_0^{z_2} \cdots \int_0^{z_{m_{k-1}}} \frac{dz_{m_k}}{1 - z_{m_k}} \cdots \tag{3.2}$$

where the sequence of differential forms in the iterated integral consists of consecutive subsequences of the form $\dfrac{dz}{z}, \dots, \dfrac{dz}{z}, \dfrac{dz}{1-z}$ of lengths $m_k, m_{k-1}, \dots, m_1$.

Easy combinatorial considerations allow one to express in two different ways products $\zeta(l_1, \dots, l_j) \cdot \zeta(m_1, \dots, m_k)$ as linear combinations of multiple zeta values.

If one uses for this the integral representation (3.2), one gets a sum over shuffles which enumerate the simplices of highest dimension occurring in the natural simplicial decomposition of the product of two integration simplices.

If one uses instead (3.1), one gets sums over shuffles with repetitions which enumerate some simplices of lower dimension as well.

These relations and their consequences are called double shuffle relations. Both types of relations can be succinctly written down in terms of formal series on free noncommuting generators. One can include in these relations regularized multiple zeta values for arguments where the convergence of (3.1), (3.2) fails. A clear and systematic exposition of these results can be found in [**Del01**] and [**Rac00**], [**Rac02**].

In fact, the formal generating series for (regularized) iterated integrals (3.2) appeared in the famous Drinfeld paper [**Dri90**], essentially as *the Drinfeld associator*, and more relations for multiple zeta values were implicitly deduced there. The question about interdependence of (double) shuffle and associator relations does not seem to be settled at the moment of writing this: cf. [**Rac04**]. The problem of completeness of these systems of relations is equivalent to some difficult transcendence questions.

Multiple zeta values are interesting, because they and their generalizations appear in many different contexts involving mixed Tate motives ([**DG05**], [**Ter02**]), deformation quantization ([**Kon99**]), knot invariants, etc.

In order to make contact with modular symbols, notice first that the differentials $\dfrac{dz}{z}, \dfrac{dz}{1-z}$ span the space of meromorphic differential forms with no more than logarithmic singularities at points $\{0, 1, \infty\}$ of $\mathbf{P}^1(\mathbf{C})$. We can identify

$$(\mathbf{P}^1(\mathbf{C}), \{0, 1, \infty\}) \cong \Gamma_0(4) \setminus (\overline{H}, cusps).$$

Then $\dfrac{dz}{z}, \dfrac{dz}{1-z}$ lift to Eisenstein series of weight two for $\Gamma_0(4) \subset SL(2, \mathbf{Z})$.

In the general theory sketched below, $\Gamma_0(4)$ is replaced by an arbitrary (congruence) subgroup Γ of $SL(2, \mathbf{Z})$, Eisenstein series of weight two are replaced by (cusp form + Eisenstein series) with respect to Γ, multiplied by $z^{s-1}dz$ for appropriate s. (We mostly focus on cusp forms; in the presence of logarithmic singularities, the necessary regularization procedure is described for weight two in Sec. 3.6.)

Finally, ordinary integrals along geodesics connecting two cusps are replaced by iterated integrals.

characteristic 0 enjoys similar properties, through the Gauss-Manin connection and the Kodaira-Spencer map.

Theorem 2.4. $\boxed{\textbf{BB}}$ (Grothendieck-Messing) *Let* $X_0 \to \mathrm{Spec}(R_0)$ *be an* p*-divisible group over a commutative ring* R_0.

(i) *To every locally nilpotent* DP *extension* $(R, I, (\gamma_i)_{i\in\mathbb{N}})$ *of* R_0 *there is a functorially attached locally free* R*-module* $\mathbb{D}(X_0)_R = \mathbb{D}(X0)_{(R,I,(\gamma_i))}$ *of rank* $\mathrm{ht}(X_0)$. *The functor* $\mathbb{D}(X_0)$ *is called the covariant Dieudonné crystal attached to* X_0.

(ii) *Let* $(R, I, (\gamma_i)_{i\in\mathbb{N}})$ *be a locally nilpotent* DP *extension of* R_0. *Suppose that* $X \to \mathrm{Spec}(R)$ *is a* p*-divisible group extending* $X_0 \to \mathrm{Spec}(R_0)$. *Then there is a functorial short exact sequence*

$$0 \to \mathrm{Lie}(X^t/R)^\vee \to \mathbb{D}(X_0)_R \to \mathrm{Lie}(X/R) \to 0\,.$$

Here $\mathrm{Lie}(X/R)$ *is the tangent space of the* p*-divisible group* $X \to \mathrm{Spec}(R)$, *which is a projective* R*-module of rank* $\dim(X/R)$, *and* $\mathrm{Lie}(X^t/R)^\vee$ *is the* R*-dual of the tangent space of the Serre dual* $X^t \to \mathrm{Spec}(R)$ *of* $X \to \mathrm{Spec}(R)$.

(iii) *Let* $(R, I, (\gamma_i)_{i\in\mathbb{N}})$ *be a locally nilpotent* DP *extension of* R_0. *Suppose that* $A \to \mathrm{Spec}(R)$ *is an abelian scheme such that there exists an isomorphism*

$$\beta : A[p^\infty] \times_{\mathrm{Spec}(R)} \mathrm{Spec}(R_0) \xrightarrow{\sim} X_0$$

of p*-divisible groups over* R_0. *Then there exists a natural isomorphism*

$$\mathbb{D}(X_0)_R \to \mathrm{H}_1^{\mathrm{DR}}(A/R)\,,$$

where $\mathrm{H}_1^{\mathrm{DR}}(A/R)$ *is the first de Rham homology of* $A \to \mathrm{Spec}(R)$. *Moreover the above isomorphism identifies the short exact sequence*

$$0 \to \mathrm{Lie}(A[p^\infty]^t/R)^\vee \to \mathbb{D}(X_0)_R \to \mathrm{Lie}(A[p^\infty]/R) \to 0$$

described in (ii) *with the Hodge filtration*

$$0 \to \mathrm{Lie}(A^t/R)^\vee \to \mathrm{H}_1^{\mathrm{DR}}(A/R) \to \mathrm{Lie}(A/R) \to 0$$

on $\mathrm{H}_1^{\mathrm{DR}}(A/R)$.

(iv) *Let* $(R, I, (\gamma_i)_{i\in\mathbb{N}})$ *be a locally nilpotent* DP *extension of* R_0. *Denote by* $\mathfrak{C}$ *the category whose objects are short exact sequences*

$$0 \to F \to \mathbb{D}(X_0)_R \to Q \to 0$$

such that F *and* Q *are projective* R*-modules, plus an isomorphism from the short exact sequence*

$$(0 \to F \to \mathbb{D}(X_0)_R \to Q \to 0) \otimes_R R_0$$

of projective R_0*-modules to the short exact sequence*

$$0 \to \mathrm{Lie}(X_0^t)^\vee \to \mathbb{D}(X_0)_{R_0} \to \mathrm{Lie}(X) \to 0$$

attached to the p*-divisible group* $X_0 \to \mathrm{Spec}(R_0)$ *as a special case of* (ii) *above. The morphisms in* $\mathfrak{C}$ *are maps between diagrams. Then the functor from the category of* p*-divisible groups over* R *lifting* X_0 *to the category* $\mathfrak{C}$ *described in* (ii) *is an equivalence of categories.*

Theorem 2.4 is a summary of the main results in Chapter IV of [**49**].

Corollary 2.5. *Let* X_0 *be a* p*-divisible group over a perfect field* $K \supset \mathbb{F}_p$*. Let* $d = \dim(X_0)$*,* $c = \dim(X_0^t)$*. The deformation functor* $\mathrm{Def}(X_0/W(K))$ *of* X_0 *is representable by a smooth formal scheme over* $W(K)$ *of dimension* cd*. In other words,* $\mathrm{Def}(X_0/W(K))$ *is non-canonically isomorphic to the functor represented by the formal spectrum* $\mathrm{Spf}\,(W(K)[[x_1, \ldots, x_{cd}]])$*.*

Proof. Recall that formal smoothness of $\mathrm{Def}(X_0/W(K))$ means that the natural map

$$\mathrm{Def}(X_0/W(K))(R) \to \mathrm{Def}(X_0/W(K))(R')$$

attached to any surjective ring homomorphism $R \to R'$ is surjective, for any Artinian local rings $R, R' \in \mathrm{Art}_{W(K)}$. To prove this, we may and do assume that the kernel I of the surjective homomorphism $R \to R'$ satisfies $I^2 = (0)$. Apply Theorem 2.4 to the trivial DP structure on pairs (R, I) with $I^2 = (0)$, we see that $\mathrm{Def}(X_0/W(K))$ is formally smooth over $W(K)$. Applying Theorem 2.4 again to the pair $K[t]/(t^2), tK[t]/(t^2)$, we see that the dimension of the tangent space of $\mathrm{Def}(X_0/K)$ is equal to cd. □

2.6. We set up notation for the Serre-Tate Theorem 2.7, which says that deforming an abelian variety A_0 over a field of characteristic p is the same as deforming the p-divisible group $A_0[p^\infty]$ attached to A_0. Recall that $A_0[p^\infty]$ is the inductive system formed by the p^n-torsion subgroup schemes $A_0[p^n]$ of A_0, where n runs through positive integers. In view of Theorem 2.4 one can regard the p-divisible group $A_0[p^\infty]$ as a refinement of the first homology group of A_0.

Let p be a prime number. Let S be a scheme such that p is locally nilpotent in $\mathcal{O}_S$. Let $I \subset \mathcal{O}_S$ be a coherent sheaf of ideals such that I is locally nilpotent. Let $S_0 = \mathrm{Spec}(\mathcal{O}_S/I)$. Denote by AV_S the category of abelian schemes over S. Denote by $\mathrm{AVBT}_{S_0,S}$ the category whose objects are triples $(A_0 \to S_0, X \to S, \epsilon)$, where $A_0 \to S_0$ is an abelian scheme over S_0, $X \to S$ is a p-divisible group over S, and $\epsilon : X \times_S S_0 \to A_0[p^\infty]$ is an isomorphism of p-divisible groups. A morphism from $(A_0 \to S_0, X \to S, \epsilon)$ to $(A_0' \to S_0, X' \to S, \epsilon')$ is a pair (h, f), where $h_0 : A_0 \to A_0'$ is a homomorphism of abelian schemes over S_0, and $f : X \to X'$ is a homomorphism of p-divisible groups over S, such that $h[p^\infty] \circ \epsilon = \epsilon' \circ (f \times_S S_0)$. Let

$$\mathbb{G}_{S_0,S} : \mathrm{AV}_S \to \mathrm{AVBT}_{S_0,S}$$

be the functor which sends an abelian scheme $A \to S$ to the triple

$$((A \times_S S_0, A[p^\infty], \mathrm{can}),$$

where can is the canonical isomorphism $A[p^\infty] \times_S S_0 \xrightarrow{\sim} (A \times_S S_0)[p^\infty]$.

Theorem 2.7. $\boxed{\textbf{BB}}$ (Serre-Tate) *Notation and assumptions as in the above paragraph. The functor* $\mathbb{G}_{S_0,S}$ *is an equivalence of categories.*

Remark. See [**46**]. A proof of Theorem 2.7 first appeared in print in [**49**]. See also [**41**].

Corollary 2.8. *Let* A_0 *be an abelian variety over a perfect field* K*. Let*

$$\mathbb{G} : \mathrm{Def}(A_0/W(K)) \to \mathrm{Def}(A_0[p^\infty]/W(K))$$

be the functor which sends any object

$$\Big(A \to \mathrm{Spec}(R), \epsilon : A \times_{\mathrm{Spec}(R)} \mathrm{Spec}(R/\mathfrak{m}_R) \xrightarrow{\sim} A_0 \times_{\mathrm{Spec}(k)} \mathrm{Spec}(R/\mathfrak{m}_R)\Big)$$

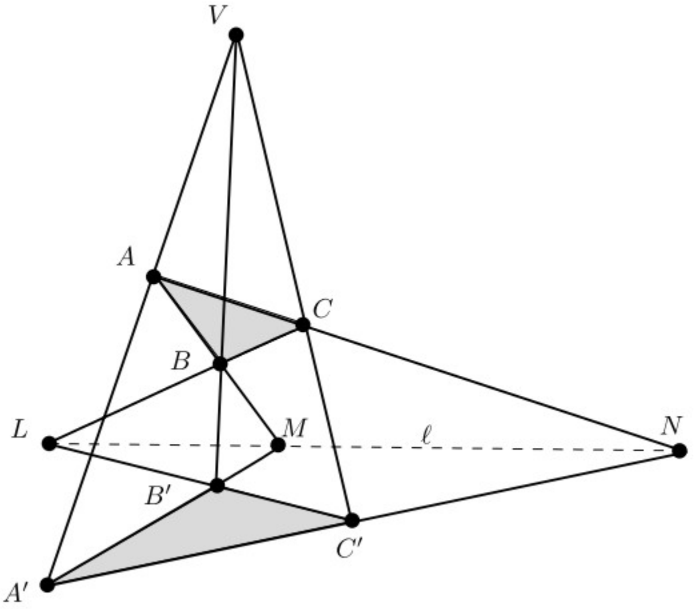
2 Introduction

The Desargues' and Pappus' configurations

Definition 2.1 *In the Euclidean plane,* $\mathbb{R}^2 = \{(x, y) \mid x, y \in \mathbb{R}\}$

1. *Points which lie on the same line are said to be* **collinear**.
2. *Lines which pass through the same point are said to be* **concurrent**.

Convince yourself (by drawing with the help of a straight edge and a pencil) that the following two theorems *may well in general be true* in the Euclidean plane $\mathbb{R}^2 = \{(x, y) : x, y \in \mathbb{R}\}$.



The Desargues' configuration

Theorem 2.2 *(***Desargues' Theorem***) Let* $ABC, A'B'C'$ *be two triangles, with distinct vertices, such that the lines* AA', BB', CC' *are concurrent in the point* V*. Then the points*

$$L = BC \cap B'C',$$
$$M = AB \cap A'B',$$
$$N = AC \cap A'C'$$

are collinear (on a line ℓ*).*

Definition 2.3 *With respect to the Desargues' configuration above,*

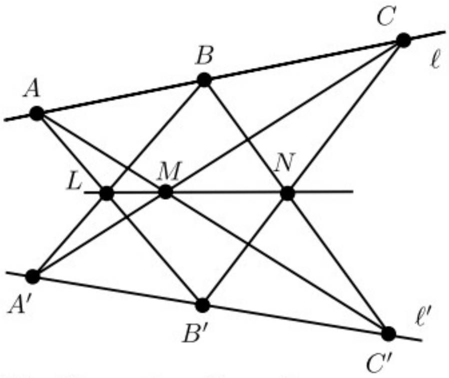
1. *The two triangles* $ABC, A'B'C'$ *are said to be* **in perspective from** *the point* V*, and from the line* ℓ.
2. *The point* V *is called the* **vertex**, *and the line* ℓ *is called the* **axis** *of the* **perspectivity**.

Theorem 2.4 *(***Pappus' Theorem***) Let* ℓ, ℓ' *be two lines of the plane.*

Let

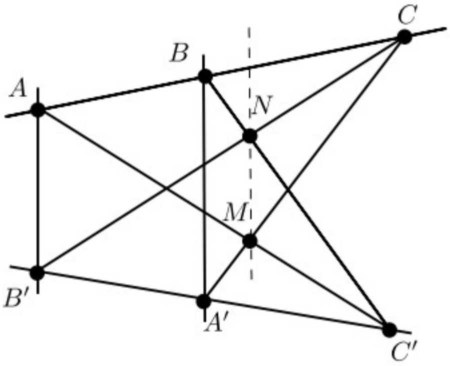
1. A, B, C *be points of* ℓ*;*
2. A', B', C' *be points of* ℓ'*;*
3. *all these points be distinct from* $\ell \cap \ell'$.

Then, $L = AB' \cap A'B$, $M = AC' \cap A'C$, $N = BC' \cap B'C$ *are collinear (i.e. L, M, and N lie on a line).*



The Pappus' configuration

The extended Euclidean plane



A few drawings do not constitute a proof. But your drawings may have convinced you that in the Euclidean plane, the theorems of Pappus and Desargues (Theorems 2.4 and 2.2) may well be true in general; these theorems are definitely not true in the cases where some of the relevant lines are parallel. For example, (see the adjoining diagram), if AB' and BA' are parallel, then $L = AB' \cap A'B$ does not exist, and therefore in this case Pappus' Theorem does not hold. It is to be noted that, in this case,

1. If M and N exist, then the line MN is parallel to AB' and BA'.
2. If M does not exist, which is the case when AC' is parallel to $A'C$, then N also does not exist.

Parallelism is a feature of the Euclidean plane. We need to consider whether there is anything to be gained if the Euclidean plane is *modified* to allow parallel lines to intersect.

In order to develop the theory, it is convenient to use the following terminology. We define a **triple $(\mathcal{P}, \mathcal{L}, \mathcal{I})$** to be

- A set $\mathcal{P}$ whose elements are called *points*, together with
- A set $\mathcal{L}$ of subsets of $\mathcal{P}$ whose elements are called *lines* (or *blocks*),
- An *incidence relation* $\mathcal{I}$ which describes precisely which points belong to which lines (blocks).

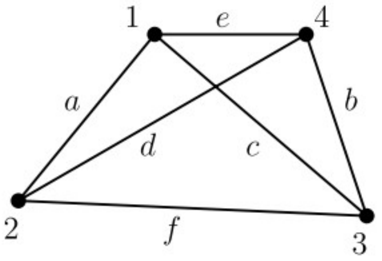
For example, the Euclidean plane is a triple $(\mathcal{P}, \mathcal{L}, \mathcal{I})$, where

$\mathcal{P} = \{(x, y) \mid x, y \in \mathbb{R}\}$,

$\mathcal{L} = \{[a, b, c] \mid a, b, c \in \mathbb{R}, a, b$ not both zero$\}$;

$\mathcal{I}$: point (x, y) lies on line $[a, b, c]$ if and only if $ax + by + c = 0$.

Note 3 *It is sometimes convenient, particularly when $\mathcal{P}$ and $\mathcal{L}$ are finite sets, to express $\mathcal{I}$ as a subset of $\mathcal{P} \times \mathcal{L}$. For example, consider the triple $(\mathcal{P}, \mathcal{L}, \mathcal{I})$ given by*



$\mathcal{P} = \{1, 2, 3, 4\}$,

$\mathcal{L} = \{a, b, c, d, e, f\}$,

$\mathcal{I} = \{(1, a), (2, a), (3, b), (4, b), (1, c), (3, c), (2, d), (4, d), (1, e), (4, e), (2, f), (3, f)\}$.

This means that points 1 and 2 lie on line a, points 3 and 4 lie on line b, and so on.

Definition 2.5 (The extended Euclidean plane)

1. *Consider the Euclidean plane $\mathbb{R}^2$.*
2. *Given a line ℓ of $\mathbb{R}^2$, the set consisting of ℓ, and all lines parallel to ℓ is called a* **pencil** *of parallel lines. To each pencil of parallel lines, add an abstract entity P_∞ called the* **point at infinity** *of the pencil. The lines of the pencil are said to intersect at P_∞. A line ℓ together with its point at infinity is called an* **extended line**, *and is denoted by ℓ^*.*
3. *Stipulate that distinct pencils of lines have distinct points at infinity.*
4. *The set of all points at infinity is called the* **line at infinity**, *and is denoted by ℓ_∞.*

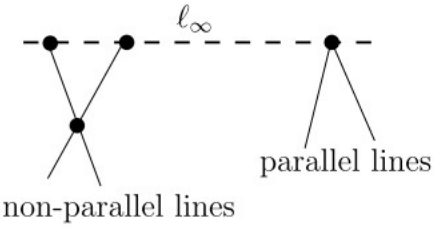
Then the **extended Euclidean Plane** *(EEP) is a triple* $(\mathcal{P}, \mathcal{L}, \mathcal{I})$ *with:*

- *Points* $\mathcal{P}$ *are the points of* $\mathbb{R}^2$ *and the points* P_∞ *at infinity,*
- *Lines* $\mathcal{L}$ *are the extended lines and the line* ℓ_∞.
- *Incidence relation* $\mathcal{I}$ *is the inherited one, namely*
  - (a) *the point* P *not at infinity lies on* ℓ^* *if and only if* P *lies on* ℓ.
  - (b) P_∞ *lies on* ℓ^* *if and only if* P_∞ *is the point at infinity of the pencil of parallel lines determined by* ℓ.
  - (c) *All the points at infinity lie on* ℓ_∞.

Note 4 *We will prove that the theorems of Pappus and Desargues, as stated in Theorems 2.4 and 2.2, are valid in the EEP.*

Theorem 2.6 *In the EEP, we have*

1. *Two distinct points* lie *on a* unique *line.*
2. *Two distinct lines* intersect *in a* unique *point.*

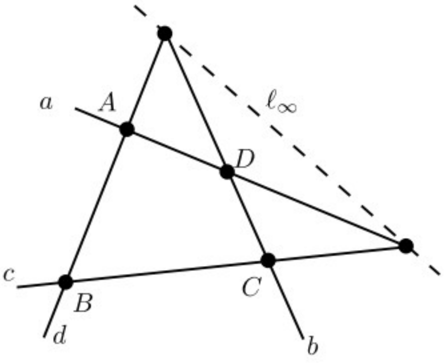


Proof. As in Definition 2.5, a line $\ell \in \mathbb{R}^2$ when extended is denoted by ℓ^*.

1. Let A and B be two distinct points of the EEP.
   - (a) If A and B are two distinct points of $\mathbb{R}^2$, then $(AB)^*$ is the unique line of the EEP which contains them.
   - (b) If A and B are two distinct points at ∞, then ℓ_∞ is the unique line of the EEP which contains them.
   - (c) Suppose $A \in \mathbb{R}^2$, and $B \in \ell_\infty$. Then B is the point at infinity of a unique pencil of parallel lines. There is a unique line ℓ of that pencil passing through A. Then ℓ^* is the unique line of the EEP which contains A and B.
2. Three cases to be considered.
   - (a) Let ℓ and m be two distinct non-parallel lines of $\mathbb{R}^2$. Therefore they intersect in a unique point P of $\mathbb{R}^2$. Then P is the unique point of intersection of ℓ^* and m^*.
   - (b) Let ℓ and m be two distinct parallel lines of $\mathbb{R}^2$. Then the pencil of parallel lines containing ℓ and m has a unique point P_∞ at infinity: P_∞ is the unique point of intersection of ℓ^* and m^*.
   - (c) The unique point at infinity of a line ℓ^* is the unique point of intersection of ℓ^* and ℓ_∞.

□

Definition 2.7 *In the EEP, a set of four points $A, B, C, D,$* no three collinear *is called a* **quadrangle**. *A set of four lines $a, b, c, d,$* no three concurrent *is called a* **quadrilateral**. *(The diagram here represents a parallelogram $ABCD$ in $\mathbb{R}^2$, that is a quadrilateral with opposite sides a, c parallel, since a and c intersect at a point at infinity, and opposite sides b, d parallel since b and d intersect at a point at infinity.)*



Definition 2.8 *If K is a configuration, then its* **dual configuration** *is the configuration obtained by making the following changes:*

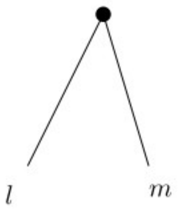
$$\begin{aligned} point &\longleftrightarrow line, \\ collinear &\longleftrightarrow concurrent, \\ join &\longleftrightarrow intersection. \end{aligned}$$

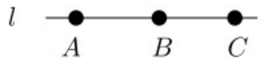
Example 2.9 A quadrangle and a quadrilateral are dual configurations, since
a quadrangle is a set of four *points*, no three *collinear*,
a quadrilateral is a set of four *lines*, no three *concurrent*.

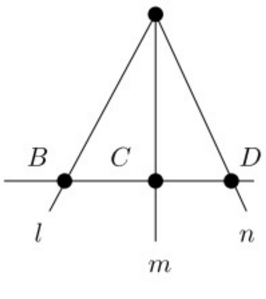
Similarly, a triangle and a **trilateral** are dual configurations, since
a triangle is a set of three *non-collinear points*,
a trilateral is a set of three *non-concurrent lines*.

Thus, a triangle (considered as a set of three points and three sides) is a self-dual configuration.

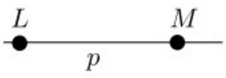
Example 2.10 Consider the following configurations: (1) two lines l, m intersecting in the point P, (2) three collinear points A, B, C, and (3) a line intersecting three concurrent lines l, m, n in the points B, C, D.

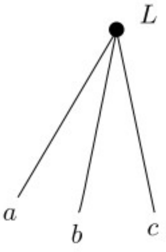


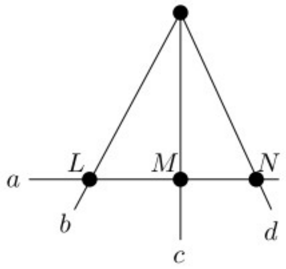




The dual configurations are respectively: (1) two points L, M on line p, (2) three concurrent lines a, b, c through the point L, and (3) three concurrent lines b, c, d intersected by line a in the points L, M, N.







Consider the two statements in Theorem 2.6, namely that in the EEP, two distinct points lie on a *unique* line and two distinct lines intersect in a *unique* point. Either statement can be obtained from the other by the simple interchange of the words 'point' and 'line' and of the words 'lie' and 'intersect'. It follows that any theorem deducible from these two statements remains valid when these words are interchanged. We formally present this important fact as a theorem.

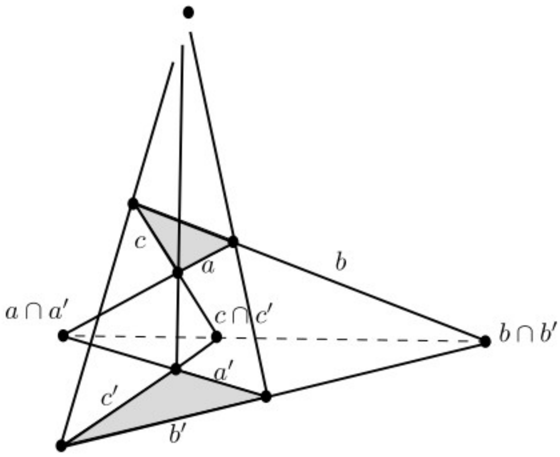
Theorem 2.11 *(***The Principle of Duality***) If $\mathcal{T}$ is a theorem valid in the EEP, and $\mathcal{T}'$ is the statement obtained from $\mathcal{T}$ by making the following changes:*

$$\begin{aligned} \textit{point} &\longleftrightarrow \textit{line}, \\ \textit{collinear} &\longleftrightarrow \textit{concurrent}, \\ \textit{join} &\longleftrightarrow \textit{intersection}, \end{aligned}$$

and whatever grammatical adjustments that are necessary, then $\mathcal{T}'$ (called the **Dual Theorem***) is a valid theorem in the EEP.*

Example 2.12 The following example shows how to dualise a theorem:

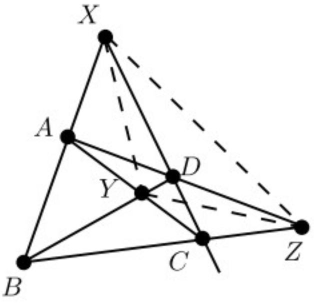
Desargues' Theorem	**Dual**
If two triangles $ABC, A'B'C'$	If two trilaterals $abc, a'b'c'$
with distinct vertices	with distinct sides
are such that the lines	are such that the points
AA', BB', CC'	$a \cap a', b \cap b', c \cap c'$
are concurrent in the point V	are collinear on the line v
then, the points	then, the lines
$L = BC \cap B'C'$,	$\ell = \langle b \cap c, b' \cap c' \rangle$,
$M = AC \cap A'C'$,	$m = \langle a \cap c, a' \cap c' \rangle$,
$N = AB \cap A'B'$	$n = \langle a \cap b, a' \cap b' \rangle$
are collinear	are concurrent
on the line v	in the point V



By the Principle of Duality, if Desargues′ Theorem is valid in the EEP, so is its dual.

Exercise 2.1

1. Recall that the affine plane $\mathbb{C}^2$ contains the Euclidean plane $\mathbb{R}^2$ as a *subplane*: the points of the Euclidean plane $\mathbb{R}^2$ are points of the affine plane $\mathbb{C}^2$, and lines of the Euclidean plane $\mathbb{R}^2$ are sublines of lines of the affine plane $\mathbb{C}^2$. Using Definition 2.5 as a model, define the **Extended Plane** $\mathbb{C}^2$ by adding *points at infinity*, and *a line* ℓ_∞^* *at infinity* to the affine plane $\mathbb{C}^2$. Explain carefully the following concepts:
   (a) The lines of EEP are *sublines* of the Extended Plane $\mathbb{C}^2$.
   (b) The EEP is a *subplane* of the Extended Plane $\mathbb{C}^2$.



2. Let $ABCD$ be a quadrangle in the EEP.

   Let $X = AB \cap CD, Y = BD \cap CA, Z = AD \cap BC$. The triangle XYZ is called the **diagonal triangle**. Draw the dual configuration (the quadrilateral and the *diagonal trilateral*).

3. Assume that Desargues' Theorem is valid in the EEP.
   (a) State the dual of Desargues' Theorem.
   (b) Draw the dual Desargues' configuration.
   (c) State the converse of Desargues' Theorem.
   (d) Compare your statements in (a) and (c).
   (e) Deduce that the converse of Desargues' Theorem is also valid in the EEP.

4. (a) Dualise Pappus' Theorem.
   (b) Draw the dual Pappus' configuration.

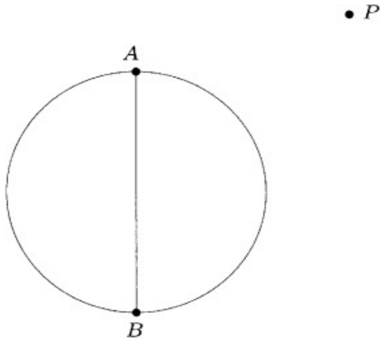
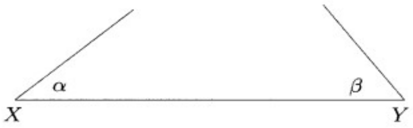
12. Construct a triangle given the foot F of an altitude, the orthocenter H, and the center N of the 9-point circle.

13. Given a diameter $\overline{AB}$ of a circle and a point P as shown, construct a perpendicular from P to $\overleftrightarrow{AB}$, *with a straightedge alone*.



14. (a) List all the regular n-gons with $n \leq 100$ sides that are constructible with a straightedge and compass.
    (b) Use Gauss' Theorem to prove that an angle of $20°$ is not constructible.
    (c) Use Gauss' Theorem to decide whether or not an angle of $6°$ is constructible.

15. Construct $\triangle ABC$ given a line segment $\overline{XY}$ and two adjacent angles, as in the figure, where the length of the perimeter is XY, $\alpha = \angle B$, and $\beta = \angle C$.



16. Construct triangle ABC given the location of its circumcenter S, the location of its orthocenter H, and the foot of an altitude F.

17. Construct a triangle given the foot F of an altitude, the circumcenter S, and the center N of the 9-point circle.

18. Construct triangle ABC given the location of vertex A, the location of its circumcenter S, and the center N of the 9-point circle.

19. Show that the incenter of a triangle is the Nagel point of its medial triangle.

"   -256-   -   -*   ! -   !   ! 7   "
L   7   3   5 ! &   "   1!   9   " ="   1"

7   1"
('$ 7!   !   ! 3   " !   !   /B

constructible. The only known primes of this form, called Fermat primes, are 3, 5, 17, 257, and 65,536. Gauss actually constructed a regular 17-gon in 1796. He conjectured and Pierre Wantzel proved in 1837 that no other regular polygons are constructible by straightedge and compass alone.

1.2.14. Assume that congruent figures have the same area.

(a) Given $\triangle ABC$ construct, as in Figure 1.23, midpoints D and E of sides $\overline{AB}$ and $\overline{AC}$, respectively, and perpendiculars $\overline{AF}$, $\overline{BG}$, and $\overline{CH}$ to $\overleftrightarrow{DE}$. Show that $\triangle ABC$ has the same area as the quadrilateral $BCHG$. (You may assume that the order of the points on $\overleftrightarrow{DE}$ is as shown in Figure 1.23.)

(b) What orderings of the points D, E, F, G, and H are possible, other than the order in Figure 1.23? Draw some of them. It is a fact that in all cases the areas of $\triangle ABC$ and of $BCHG$ are equal.

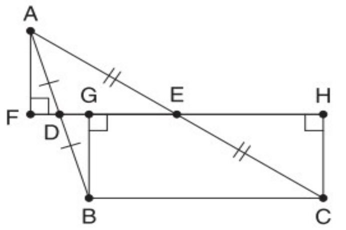

Figure 1.23

*1.2.15. Let $\triangle ABC$ be a triangle and G be the intersection of the perpendicular bisector $\overline{GD}$ of $\overline{AB}$ and the perpendicular bisector $\overline{GE}$ of $\overline{BC}$. (See Figure 1.24.)

(a) Prove that $\overline{AG}$, $\overline{BG}$, and $\overline{CG}$ are congruent. (Thus G is called the *circumcenter*, the center of the *circumscribed* circle of the triangle.)

(b) Let F be the midpoint of $\overline{AC}$. Prove that $\overline{GF}$ is the perpendicular bisector of $\overline{AC}$. (Thus the perpendicular bisectors of a triangle are *concurrent*, that is, they meet in a common point.)

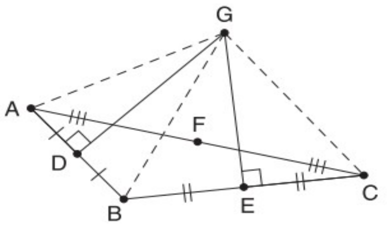

Figure 1.24 G is the circumcenter of $\triangle ABC$.

needed an essentially inborn understanding of geometry and space before we could experience anything in space. (Studies of blind people and people with recovered sight indicate that Kant's argument is incorrect; sight is essential to develop the usual conception of space. See Sacks [13, 124].) Kant also thought that geometry had to be Euclidean.

In the eighteenth century, the Age of Enlightenment, mathematicians and philosophers built on the perceived absolute truth of mathematics in a second way. The astounding success of Newton's calculus and physics convinced his successors that mathematics wasn't just true in some metaphysical sense, but also in a tangible sense. The ideal world of mathematics, it seemed, was the real world. The physical meaning of much of the mathematics developed in the eighteenth century was so convincing that the rigorous deductive methods of Greek geometry seemed superfluous. The shock of the radically different mathematical results of the nineteenth century, starting with non-Euclidean geometries, forced mathematicians to reintroduce careful proofs.

The first person to break from the world view of Euclidean geometry, its unquestionable truth, and its applicability to the physical world was Carl Friedrich Gauss (1777–1855). Despite his fame, Gauss never published anything on non-Euclidean geometries because he feared ridicule. Nicolai Lobachevsky (1793–1856) and János Bolyai (1802–1860), the two young mathematicians who did publish on non-Euclidean geometry, were greeted with silence for years after their publications in 1829 and 1832, respectively. Indeed, only with the publication of Gauss's notes after his death did the wider community of mathematicians start investigating non-Euclidean geometries.

4.1.1 The Advent of Hyperbolic Geometry

Hyperbolic geometry, the non-Euclidean geometry that Gauss, Lobachevsky, and Bolyai developed, retains Euclid's first four postulates and changes the fifth postulate to the following axiom. In Sections 4.2, 4.3, and 4.4, we investigate hyperbolic geometry in much the same way that they did. However, to make the process clearer, we make explicit certain logically necessary assumptions, overlooked until the end of the nineteenth century. (See Sections 2.1 and 2.2.) Hyperbolic geometry is sometimes called Lobachevskian geometry to honor Lobachevsky's priority in publishing. Felix Klein called the geometry *hyperbolic* in his classification of geometries, which we discuss in Section 7.5.

Characteristic Axiom of Hyperbolic Geometry Given a line k and a point P not on k, there are at least two lines on P that do not intersect k (See Figure 4.1).

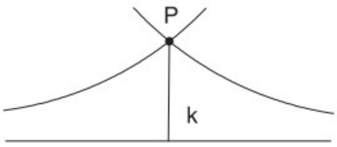

Figure 4.1 The characteristic axiom of hyperbolic geometry.

Various consequences follow from this change, including the many that Saccheri found. The most startling is the theorem that the measures of the angles of a triangle do not add up to π (or 180°), as they do in Euclidean geometry. The goal in our study of hyperbolic geometry, Theorem 4.1.1, goes even further, relating the angle sum to the area of the triangle. Figure 4.2 illustrates that the greater the area of the triangle is, the smaller its angle sum is. (We state the theorem using radians to emphasize the analogy with Theorem 1.5.3. Otherwise we will measure angles in degrees.) Consequently, there is a constant k so that each triangle's area is less than k. Since the sides of triangles can become indefinitely long, this consequence seems paradoxical.

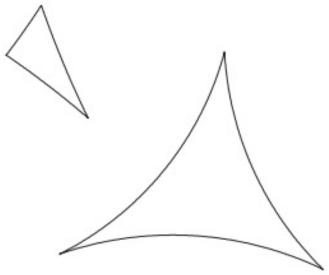

Figure 4.2 The angle sum of a hyperbolic triangle depends on its area.

Theorem 4.1.1. *In hyperbolic geometry the difference,* $\pi - (m\angle A + m\angle B + m\angle C)$, *between* π *and the angle sum of a triangle is proportional to the area of the triangle.*

Exercise 4.1.1.* Compare Theorem 4.1.1 with Theorem 1.5.3. Restate the theorem using degrees.

Theorem 4.1.1 suggests that we could decide which geometry is true by measuring real triangles. Since at least 1890, mathematicians and physicists have realized the futility of empirically deciding which geometry is correct because physical assumptions must be made to test mathematical relations. For example, we would have to assume that the path of a light ray is a straight line to measure even a moderately large triangle.

The first notable response to the advent of hyperbolic geometry came in 1854 when Georg Riemann (1826–1866) gave his introductory lecture to the faculty at Göttingen University. Only Riemann's mentor, the aging Gauss, apparently caught its point, entitled "On the Hypotheses which underlie Geometry." However, the talk, published after Riemann's death, focused geometric thought on a new field, differential geometry, and spurred an active debate on non-Euclidean geometries. Riemann had realized that the work of Gauss, Lobachevsky, and Bolyai was more than playing abstractly with a postulate. He recognized that the revised postulate implied that space had to be shaped differently than what Euclid's fifth postulate implied. He then articulated how infinitely many different geometries could be created, each with its own shape.

Differential geometry, the field pioneered by Riemann, Gauss, and others, investigates geometries by looking at how they behave in small regions and, in particular, how they curve. Gauss had shown how to measure the curvature of surfaces. Where the flat Euclidean geometry had zero curvature and a sphere had positive curvature, hyperbolic geometry has a uniform negative curvature, similar to the saddle shape of Figure 4.3. Riemann defined curvature in higher dimensions and envisioned geometries in any number of dimensions with changing curvatures throughout. The general theory of relativity builds on Riemann's work on the curvature of space. Einstein used a four-dimensional geometry (three spatial dimensions interacting with time) curved by the gravitational forces. Light waves travel along *geodesics*, paths of shortest length following the curvature of the surrounding space. Einstein's theory settled the nineteenth century question of the empirical truth of Euclidean and hyperbolic geometries in a surprising way: both are false! (See Chapter 9 as well as do Carmo [3], Kline [8], McCleary [9], Rucker [12], and Weeks [16] for further information.)

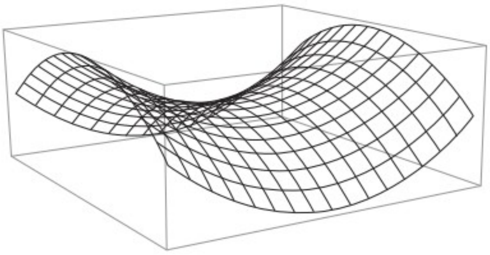

Figure 4.3 A saddle shape with negative curvature.

The abstraction throughout mathematics and the strangeness of the new geometries led mathematicians to search again for certainty in their mathematical arguments. No longer could they rely on an intuitive model to reveal the essential idea behind an argument. They examined the axioms for geometry, culminating in the modern axioms for Euclidean geometry, including Hilbert's (see Section 2.2). Hilbert also obtained an axiomatic system for hyperbolic geometry by replacing Playfair's axiom with the characteristic axiom above. (See Bonola [1] and Kline [8, Chapter 36] for further historical information.)

4.1.2 Models of Hyperbolic Geometry

In the latter part of the nineteenth century, various mathematicians developed models of hyperbolic geometry. We partially treat some of them here. Each has disadvantages, but they all help give a feel for the geometry. They are based in part on a Euclidean plane or space, with suitable interpretations of the undefined terms. For the Poincaré model, we first need a definition: Two (Euclidean) circles are *orthogonal* if and only if their radii at the circles' points of intersection are perpendicular, illustrated in Figure 4.4. In all the models the terms *on* and *between* have their usual meaning. In the language of Section 2.3, the formal models show the relative consistency of hyperbolic geometry based on Euclidean geometry.

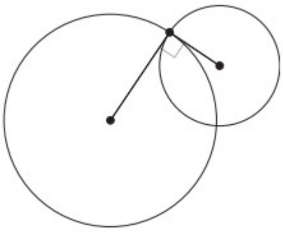

Figure 4.4 Orthogonal circles.

Informal Models. A saddle shape, as in Figure 4.3, provides a direct feel for a small part of hyperbolic geometry, although the negative curvature of actual saddles varies considerably from point to point. A physical version of this model has the advantage of facilitating actual measurements on its surface. Crocheted surfaces, as in Figure 4.5, developed by Daina Taimina, provide a more extended realization of approximately constant negatively curved surfaces. (See Henderson and Taimina [6, 49 ff].) The *pseudosphere*, represented in Figure 4.6 and discussed below, has constant negative curvature except on its "equator." In all the models, *lines* are interpreted as geodesics—intuitively shortest paths along the surface. Distances are measured along them and angles are measured using tangents to them where they meet. The surfaces give direct insight into hyperbolic geometry, at least in the region where the curvature is a constant negative.

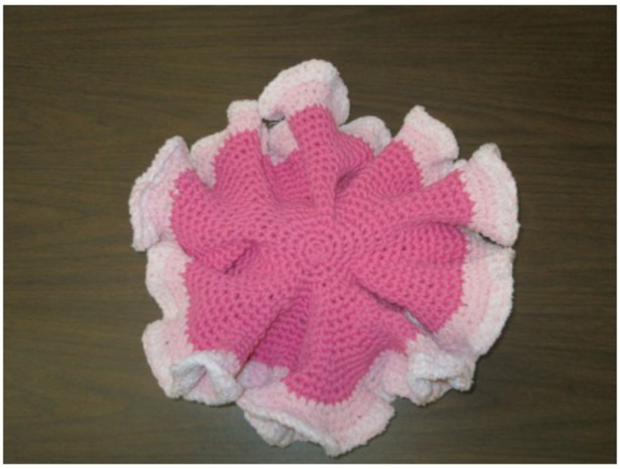

Figure 4.5 An extended crocheted surface with negative curvature.

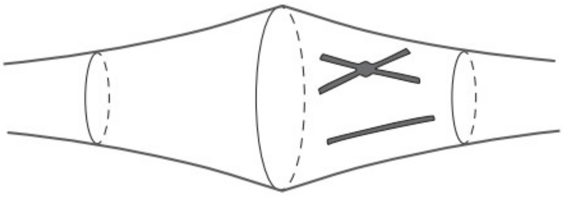

Figure 4.6 "pseudosphere" illustrating the characteristic axiom.

The Pseudosphere (1868). Ferdinand Minding (1806–1885) investigated this surface of constant negative curvature, shown in Figure 4.6, as early as 1840. Eugenio Beltrami (1835–1899) was the first to realize that it and all other surfaces of constant negative curvature provide (local) models of hyperbolic geometry. Beltrami's work suggested the relative consistency of hyperbolic geometry for the first time. The models now named for Felix Klein (1849–1925) and Henri Poincaré (1854–1912) resolved logical concerns about this geometry.

The Klein Model (1868). *Point* means a point in the interior of a Euclidean circle. *Line* means the portion of a Euclidean line in its interior. Figure 4.7 illustrates that the characteristic axiom holds in the model. Its biggest advantage is the matrix representation of its transformations, considered in Chapter 7. However, distances and angle measures are distorted and complicated in it.

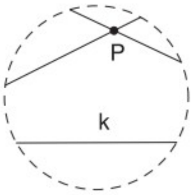

Figure 4.7 The characteristic axiom in the Klein model.

The Poincaré Model (1882). *Point* means a point in the interior of a Euclidean circle. *Line* means the portion interior to the circle of one of its diameters or of a Euclidean circle orthogonal to it. The chief advantage of this model is that angles are measured as they would be for curves in Euclidean geometry. In Figure 4.8 the curved sides of the triangle in bold show visually that the angle sum is less than 180°. The picture at the beginning of this chapter uses the Poincaré model. Because the angle measures are Euclidean, the repeated objects in this design are recognizably the same, although somewhat distorted to our eyes. Their hyperbolic size is the same, which gives a sense of how distances are measured using the same complicated formula as the Klein model. In Section 5.6 we consider transformations for this model and their connections with complex numbers. There are software programs, such as NonEuclid, that facilitate constructions in this model.

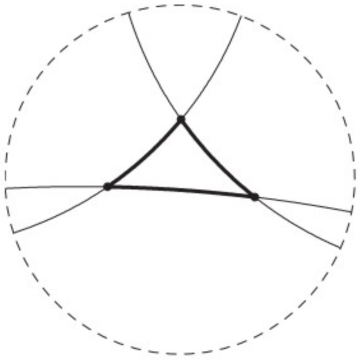

Figure 4.8 A triangle in the Poincaré model.

The Half-Plane Model (1882). *Point* means a point in the upper half of the Euclidean plane; that is, points (x, y) with $y > 0$. *Line* means the portion above the x-axis of either a vertical line or a circle with its center on the x-axis. In Figure 4.9, $\triangle ABC$ has an angle sum less than 180°, although that fact may not be as clear as in Figure 4.8. Henri Poincaré developed the model and the closely related Poincaré model at the same time. It measures angles as Euclidean angles and, in addition, its lines have equations that are easy to find. However, distances appear even more distorted than in the previous two models.

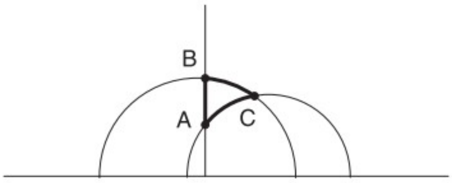

Figure 4.9 A triangle in the half plane model.

Unless explicitly stated, the figures in the rest of this chapter are not based on any of the models. This will encourage thinking of the geometry as an entire system, not an isolated exercise applying only to an artificial model. Many of the lines drawn in the figures will be curved so that they will not appear to intersect. This corresponds to one of the findings of Saccheri, mentioned earlier, that lines can approach one another in this geometry without intersecting.

4.1.3 Exercises for Section 4.1

Throughout the problems "line" refers to a hyperbolic line in the relevant model. Euclidean objects are identified as Euclidean.

4.1.2. Use a physical saddle-shaped surface, as in Figure 4.3, to explore basic properties of hyperbolic geometry. (The curves shown in that figure are not geodesics; they are the intersections of the surface with vertical planes to convey the three-dimensional curving.) An L-shaped piece of flexible plastic with straight sides and a right angle will lie on the surface closely enough to draw approximate perpendicular hyperbolic lines (geodesics). Use the protractor of Figure 2.16 to find the approximate measure of angles.

(a) Construct different sized triangles on the surface and measure their angle sums. Verify Theorem 4.1.1.

(b) Construct a quadrilateral $ABCD$ with right angles at A and B and with sides $\overline{AD}$ and $\overline{BC}$ congruent. Measure the angles at B and C. What can you say about them? Compare the lengths of $\overline{AB}$ and $\overline{CD}$.

(c) Make a large right triangle. Measure the lengths of its sides. Compare the squares of their lengths with the equation of the Pythagorean theorem (Theorem 1.1.2).

(d) Draw lines on the surface to illustrate the characteristic axiom of hyperbolic geometry.

*4.1.3 Use the Klein model of hyperbolic geometry to investigate how many lines through a point P do not intersect a line k that is not on P. Explain your answer.

4.1.4. Use the points inside the Euclidean unit circle $x^2 + y^2 = 1$ for the Poincaré model.

*(a) Show that the circle $C : (x - 1.25)^2 + y^2 = (0.75)^2$ is orthogonal to the unit circle. Graph the unit circle and the part of C in the unit circle on the same axes.

(b) We form a hyperbolic triangle with vertices $P = (0, 0)$, Q the intersection of the circle C with $y = (9/13)x$ (inside the unit circle), and R the intersection of the circle C with $y = -(9/13)x$ (inside the unit circle). Assume that $x > 0$. Verify that Q and R have x-coordinate 0.65. Find their y-coordinates. Include $\triangle PQR$ in the graph for part (a).

(c) Verify visually that the angle sum of the triangle in part (b) is less than 180°.

*(d) Find the measures of the angles of the triangle in part (b) and verify that their sum is less than 180°. Hints: The angle made by a Euclidean line and a Euclidean circle is the angle made by the Euclidean line and the tangent to the circle at their intersection. The slope of a Euclidean line equals $\tan\alpha$, where α is the angle that line makes with the x-axis. The arctangent function converts slopes to angles.

*4.1.5 Although three-dimensional Euclidean space satisfies the characteristic axiom, it doesn't satisfy all the axioms of plane geometry. Find which of Hilbert's axioms in Appendix C fail when we interpret a *plane* as three-dimensional Euclidean space and a *line* as a Euclidean line.

4.1.6. Use the half-plane model of hyperbolic geometry.

*(a) Find the equation of the line (Euclidean half circle) that is on the points $(1, 1)$ and $(4, 2)$.

(b) Explain why the equations of lines in the model are either $x = c$ or $y = \sqrt{r^2 - (x - c)^2}$, for appropriate constants c and r.

(c) Use a Euclidean argument about Euclidean circles and lines to explain why every two points in this model have one (hyperbolic) line that is on both of them.

*(d) Verify that the point $(-4, 10)$ is not on the line $y = \sqrt{25 - (x + 4)^2}$. Find the equations of two lines on $(-4, 10)$ that do not intersect $y = \sqrt{25 - (x + 4)^2}$. Graph the lines.

(e) Use a Euclidean argument to explain why the characteristic axiom always holds in this model. Hint: Consider the two kinds of lines separately.

*(f) Verify that the lines $y = \sqrt{25 - x^2}$ and $y = \sqrt{16 - (x - 1)^2}$ do not have a point of the model in common, although they intersect in a Euclidean point as curves in the Euclidean plane. Find the Euclidean point. We will call these lines *sensed parallels*.

*(g) Describe the type of intersection of the lines in part (f).

(h) Verify that every point in the model has at least one line that is a sensed parallel to the line $y = \sqrt{25 - x^2}$ in the sense that the only Euclidean intersection of the line with $y = \sqrt{25 - x^2}$ is the Euclidean point you found in part (f). Explain why, for a hyperbolic line k represented by a semicircle, that there are exactly two sensed parallels to k through a point not on k. How can we interpret sensed parallels so this property remains correct if a vertical line represents k?

4.1.7. (Calculus) In the half-plane model of hyperbolic geometry, consider the triangle formed by the lines $y = \sqrt{5 - (x - 3)^2}$, $y = \sqrt{10 - (x - 4)^2}$, and $x = 4$. Find the vertices of the triangle and graph it. Use the method of Exercise 4.1.4(d) to find the measures of the angles of this triangle. Hint: Use calculus and trigonometry. The angle sum is approximately 161.6°.

4.1.8. *(a) In the half plane model, verify that the line $y = \sqrt{16 - x^2}$ is perpendicular to the lines $y = \sqrt{9 - (x - 5)^2}$ and $y = \sqrt{9 - (x + 5)^2}$ at their points of intersection.

*(b) Find the intersections the line $y = \sqrt{34 - x^2}$makes with the lines $y = \sqrt{9 - (x \pm 5)^2}$ and the angles it makes with them. (See Exercise 4.1.4(d) and 4.1.7 for finding the angles.)

(c) Compare the angles in part (b) with Exercise 4.1.2(b).

4.1.9. A curious property of hyperbolic geometry is that two lines that do not intersect and are not sensed parallels (described informally in Exercise 4.1.6) have a common perpendicular. Use the half-plane model of hyperbolic geometry to illustrate this property with the lines $y = \sqrt{1 - x^2}$ and $x = 2$. Graph the lines first. Then use relevant Euclidean concepts, including orthogonal circles, to find the hyperbolic line perpendicular to both of them.

4.1.4 Carl Friedrich Gauss

Carl Friedrich Gauss (1777–1855) dominated mathematics during the first half of the nineteenth century, making fundamental contributions to virtually every area of mathematics. The prince of his small German state sponsored his education after learning of his prodigious abilities as a child. By age five he had found an arithmetic error in his father's accounts. In another story his grade school teacher made the class add the numbers from one to one hundred. After some thought Gauss found a formula and simply wrote down the correct answer, whereas his classmates toiled and made mistakes.

Gauss soon won acclaim as a mathematician. At 18 he developed the method of least squares, which is used extensively in statistics. A year later he constructed with straightedge and compass a regular 17-sided polygon and later characterized all constructible regular polygons, the first such advances since the ancient Greeks. He earned his Ph.D. at 22 by giving the first proof of the fundamental theorem of algebra, which says that every nth degree polynomial with real or complex coefficients has n roots, counting repetitions and these roots are all complex numbers. Two years later, he published his first major treatise on number theory, rejuvenating that ancient area. That same year, 1801, Gauss astonished astronomers by determining the orbit of the first asteroid, Ceres, based on only a few observations and after it had been lost from view owing to weather conditions. To do so he had to generalize his method of least squares. Gauss subsequently became a professor of astronomy and director of the observatory in Göttingen.

By 1800 Gauss had become convinced that Euclid's parallel postulate could not be proven, and in installments he developed what he called non-Euclidean geometry. Although none of this work was published until after his death, he did correspond with a number of mathematicians about it. Gauss also made seminal contributions to differential geometry, including the curvature of a surface and geodesics. He showed that Gaussian curvature determined all the properties of a surface not related to how it is placed in a surrounding space.

Gauss's contributions on complex numbers persuaded mathematicians that complex numbers were essential in mathematics. He represented complex numbers geometrically, as some others before him had. Additionally, he extended number theory to complex integers, and contributed fundamentally to what is now called complex analysis. He advanced knowledge in astronomy, magnetism, optics, and other applied fields.

Gauss's contemporaries revered him as the "Prince of Mathematicians," and he is widely considered the greatest mathematician since Newton. He was also one of the last who could claim to know all the mathematics in existence at his time. Gauss's work can be seen both as crowning the great expansion of mathematics in the sixteenth and seventeenth centuries and as igniting the explosion of specialized, abstract mathematics since then.

4.2 Properties of Lines and Omega Triangles

We develop hyperbolic geometry following the path of Saccheri, Gauss, Lobachevsky, and Bolyai, but add a modern foundation, due to Hilbert and others. We can thus accentuate the geometric intuition of earlier work while having the logical basis required to avoid the flaws discovered later.

Our undefined terms are *point*, *line, on, between,* and *congruent*. Our axioms are Hilbert's axioms for plane geometry (see Appendix C), with the exception of axiom IV-1 (Playfair's axiom), which we replace with the characteristic axiom of hyperbolic geometry. (See Section 4.1.) We also avail ourselves of Euclid's first 28 propositions, the ones he proved without using the parallel postulate. (See Appendix A.) They historically provided the key properties about lines and triangles needed to development of hyperbolic geometry. They are provable in Hilbert's axiomatic system without either Axiom IV-1 or the characteristic axiom. We will also make use of some of the SMSG postulates that hold in hyperbolic geometry. We assume the SMSG postulates in Appendix B, except 16, 20, 21, and 22. (They are false in hyperbolic geometry.)

Like the developers of hyperbolic geometry, we use proofs by contradiction for many theorems in this chapter, including Theorem 4.2.1. Until 1868, when Beltrami built the first model of hyperbolic geometry, mathematicians wondered whether the characteristic axiom itself was potentially a contradiction. The heavy use of proofs by contradiction increased mathematicians' unease before Beltrami's model. A rigorous proof of even Theorem 4.2.1 requires considerable development from Hilbert's axioms. For example, in Figure 4.10 we would need to show that B can always be chosen so that the line m enters $\triangle ABC$ at P. (By "enter" we mean that the line through P also has a point inside of the triangle on it, following Pasch's axiom.) The use of real numbers from the SMSG postulates does simplify the proof. Moise [10, Chapter 24] gives a careful development of the basics from Hilbert's axioms, including the justification of right- and left-sensed parallels in the definition below.

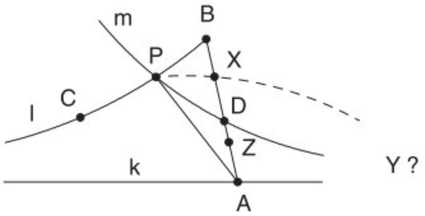

Figure 4.10 Constructing non-intersecting lines.

Theorem 4.2.1. *Given a point P not on a line k, there are infinitely many lines on P that have no points on k.*

Proof. Let the two lines indicated by the characteristic axiom be l and m. Pick points A on k and B and C on l such that line m enters $\triangle ABC$ at P. By Pasch's axiom, m intersects the triangle on another side, without loss of generality at D on $\overline{AB}$. SMSG postulate 3 permits us to match the points on $\overleftrightarrow{AB}$ with the real numbers, with 0 at B and 1 at D. Now, for every point X on the segment $\overline{BD}$, we can draw $\overleftrightarrow{PX}$. (See Figure 4.10.)

We claim that $\overleftrightarrow{PX}$ does not intersect k. Suppose, for a contradiction, that $\overleftrightarrow{PX}$ and k had the point Y in common. Then the line m would enter triangle $\triangle XYA$ at D, and by Pasch's axiom m would have to intersect the triangle again on $\overline{XY}$ or on $\overline{YA}$. However, m already intersects $\overleftrightarrow{PX}$ at P, eliminating $\overline{XY}$. Furthermore, $\overline{YA}$ is part of k, which has no point in common with m, which is a contradiction. The points X between B and D match with numbers between 0 and 1. Since there are infinitely many such numbers, there are infinitely many lines $\overleftrightarrow{PX}$ that have no point in common with k. ■

For the same k and P as in the preceding proof, the lines through P split into two categories, those that intersect k and those that do not. In Figure 4.10, for Z on the segment $\overline{AD}$, some of the lines $\overleftrightarrow{PZ}$, such as $\overleftrightarrow{PA}$, intersect k, but others don't, such as $\overleftrightarrow{PD}$. The points Z match with numbers greater than 1, but less than the number matched with A. By the continuity of the real numbers, some number ω must separate the numbers of points with lines intersecting k from those not intersecting k. Let W be the point matching ω, so W must separate these lines. Does $\overleftrightarrow{PW}$ intersect k? Draw a figure illustrating the following argument by contradiction showing that $\overleftrightarrow{PW}$ cannot intersect k. If T is the supposed intersection of $\overleftrightarrow{PW}$ and k, consider a point S on k with T between A and S. Now draw $\overleftrightarrow{PS}$, which clearly intersects k at S. Therefore $\overleftrightarrow{PW}$ would not be the last line, contradicting the assumption about W. A similar situation occurs on the left side of Figure 4.10.

Definition. Given a point P not on line k, the first line on P in each direction that does not intersect k is the (*right-* or *left-*) *sensed parallel* to k at P. Other lines on P that do not intersect k are called *ultraparallel* to k. Let A be on k with $\overline{AP} \perp k$. Call the smaller of the angles a sensed parallel makes with $\overline{AP}$ the *angle of parallelism at P*. (If the angles are equal, either is the angle of parallelism.)

The goal of this section has two parts. First, we start building inequalities leading to the big inequality in Theorem 4.1.1 about the angle sum of a triangle. Corollary 4.2.3, on the angle of parallelism, provides the starting point. Theorems 4.2.8 and 4.2.9 accomplish the other goal, showing that the angle of parallelism depends only on the length of the segment $\overline{AP}$.

Theorem 4.2.2. *If l and m are the two sensed parallels to k at P, they have the same angle of parallelism.*

Proof. As shown in Figure 4.11, let $\overline{AP} \perp k$ and $\overleftrightarrow{PB}$ and $\overleftrightarrow{PC}$ be the sensed parallels to k at P. For a contradiction, let the angles of parallelism differ, say, $m\angle APB < m\angle APC$. Construct inside $\angle APC$ a new angle $\angle APD \cong \angle APB$. Because $\overleftrightarrow{PC}$ is a sensed parallel, $\overleftrightarrow{PD}$ intersects k, say at E, giving a triangle $\triangle APE$. Let F be on k with $\overline{AF} \cong \overline{AE}$. Then $\triangle APF \cong \triangle APE$ by SAS (Euclid I-4). But $\angle APF \cong \angle APD \cong \angle APB$, which means that $\overleftrightarrow{PF}$ and $\overleftrightarrow{PB}$ are the same line by Hilbert's axiom III-4. However, $\overleftrightarrow{PB}$ is a sensed parallel to k, so it cannot intersect k at F, which is a contradiction. Hence the angles of parallelism must be the same. ■

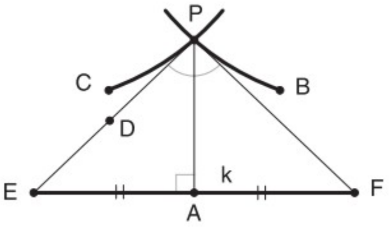

Figure 4.11 Angles of parallelism.

The proof of Theorem 4.2.2 may seem on first reading overly complicated. However, in order to use the Euclidean proposition SAS, we need "ordinary" triangles.

Corollary 4.2.3. *All angles of parallelism are less than a right angle. Two lines with a common perpendicular are ultraparallel.*

Proof. See Exercise 4.2.5. ■

Theorem 4.2.4. *Let P be a point not on k and let m be a sensed parallel to k at P. If S is any other point on m, then m also is a sensed parallel to k at S.*

Proof. Without loss of generality, let m be a right-sensed parallel to k at P.

Case 1. Suppose that S is on m to the left of P and U is on m with S between P and U. Because m and k do not intersect, m is either the right-sensed parallel to k at S or m is ultraparallel to k at S. For a contradiction, suppose that l, not m, is the right-sensed parallel to k at S, as in Figure 4.12. Pick T on l and on the opposite side of m from k. Then $\overleftrightarrow{TP}$ crosses m at

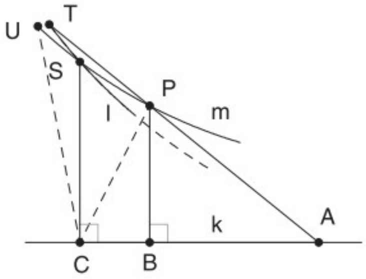

Figure 4.12 The sensed parallel to k at P is also sensed parallel at S.

P. As m is the right-sensed parallel to k at P, $\overleftrightarrow{TP}$ must intersect k, say at A. Let U be on m with S between P and U and C on k with $\overline{SC} \perp k$. Now l enters $\triangle UPC$ at S. Since l is right-sensed parallel, it must exit on $\overline{PC}$, rather than $\overline{UC}$. In turn l enters $\triangle CPB$ on $\overline{CP}$ and, by Pasch's axiom, l would need to intersect either $\overline{CB}$ or $\overline{PB}$. But l is a right-sensed parallel of $k = \overleftrightarrow{CB}$, so l intersects $\overline{PB}$. Finally l enters $\triangle PBA$. Again by Pasch's axiom, either l intersects $\overline{BA}$, which is k, or it intersects $\overline{PA}$. As before, k can't intersect l. However, l already intersected $\overline{PA}$ at T, so that also is impossible. We thus have a contradiction from assuming l was the right-sensed parallel. Hence m is the right-sensed parallel to k at S.

Case 2. Let S be on m to the right of P. (See Exercise 4.2.6.) ■

4.2.1 Omega Triangles

In both the Klein model (Figure 4.13) and the Poincaré model (Figure 4.14) of hyperbolic geometry m and n, the sensed parallels to k at P, "meet" k on the circular boundary. Only points interior to the boundary qualify as points in these models. Following the historical development, we say that two sensed parallels meet at an imaginary point called an *omega point*. Although the originators of hyperbolic geometry didn't have models in the modern sense, they benefited greatly from thinking of sensed parallels "meeting at infinity." They used *omega triangles*, which have one omega point, to prove theorems about ordinary triangles. They first showed, as do we here, that omega triangles share some key properties with regular triangles. Figures 4.15 and 4.16 illustrate an omega triangle in the Klein and Poincaré models with one vertex (labelled Π)

Differential Geometry

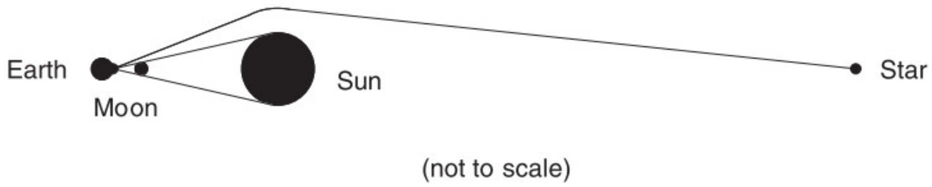

Figure 9.0 In 1919 Sir Arthur Eddington (1882–1944) spectacularly confirmed a key prediction of Einstein's general theory of relativity during a solar eclipse. Astronomers had determined that the sun should have blocked a starlight's path if it followed a Euclidean straight line from the star to earth. Instead because the sun's gravity distorted the shape of space, Eddington saw the star when the moon blocked the sun's light during the eclipse. The figure greatly distorts sizes to illustrate the setting of this famous experiment. In the language of differential geometry, the light from the star followed a geodesic—a locally shortest path. The gravitational field of the sun induced enough curvature to space to make an observable difference between the geodesic and a Euclidean line. While relativity theory is beyond the level of this chapter, we will investigate curvature and geodesics.

9.1 Overview and History

A plane flying from Tokyo to Los Angeles flies far north of either city, depicted in Figure 9.1. However, the two cities lie at virtually the same latitude. Why don't planes fly straight east from Tokyo to Los Angeles? Actual airline routes minimize the distance on the curved surface of the earth. A straight eastward route follows a circle of latitude, which doesn't minimize distances (except the equator). Differential geometry provides the language and theory to understand the geometry of curved surfaces. We will investigate how to find the curvature of a surface and geodesics, which are the locally straight paths on them.

Intuitively, Euclidean straight lines do not bend at all, while circles bend at constant rates depending on their radii. (See Figure 9.2.) The ancient Greeks realized that other curves, such as the parabola in Figure 9.3, bend more at some points (for example, A) than others (such as B or C). However, real advances in defining and measuring curvature, the amount of bending, needed the language of calculus. By 1671 Sir Isaac Newton (1642–1727), one of the originators of calculus, had already figured out the correct formulation for the curvature of a plane curve. (See Theorem 9.2.1.) However, Newton delayed publishing that work and much else for decades. By that time Gottlieb Wilhelm Leibniz (1646–1716), the other founder of calculus, and his followers

had published on many of the same topics, including curvature. Jakob Bernoulli (1654–1705), a follower of Leibniz, determined geodesics on surfaces of revolution in 1698.

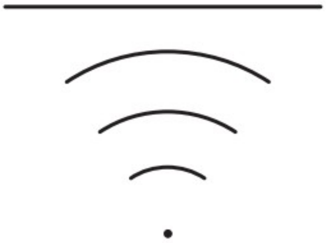

Figure 9.2

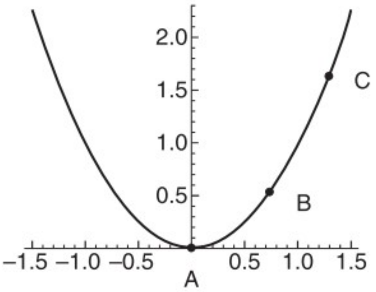

Figure 9.3 Curvature on a parabola.

In the 1730s Alexis-Claude Clairaut (1713–1765) and Leonhard Euler (1707–1783) considered space curves, such as the helix of Figure 9.4. They analyzed how much such curves twisted out of a plane, now called the *torsion* of a curve. (See Project 1.) More central to our focus, they and others investigated general surfaces and geodesics.

The inherent distortions of a flat map of portions of a curved earth motivated many mathematicians from Euler to Carl Friedrich Gauss (1777–1855). In fact, as part of his employment, Gauss spent some years surveying the state of Hanover, which spurred his profound investigations in differential geometry. His major paper in 1827 shaped the direction of this subject. Gauss studied a space on its own terms, not dependent on how it is embedded in Euclidean space. For example, measurements of a portion of the surface of the earth could determine its curvature there. One of his profound theorems (Theorem 9.4.3) generalizes Theorem 1.5.3 and Theorem 4.1.1. They link the area of a triangle in spherical and hyperbolic geometry to their angle sums. In the generalization Gauss used geodesics for the sides of the triangles. Then, as

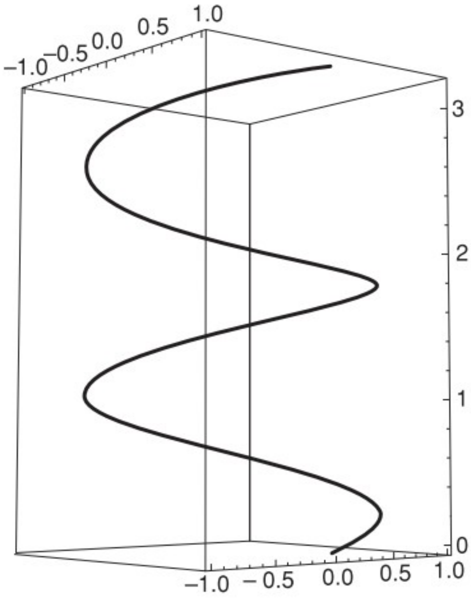

Figure 9.4 A helix.

he proved, the difference between the angle sum of the triangle and π was determined by the area of the triangle and the curvature within it. The sphere has constant positive curvature and the hyperbolic plane has constant negative curvature, accounting for the difference in Theorems 1.5.3 and 4.1.1.

In 1854 Georg Riemann (1826–1866) generalized Gauss's results to any number of dimensions and so transformed differential geometry again. Many mathematicians developed Riemann's insights into rigorous mathematics with computational methods. Albert Einstein (1879–1955) built on Riemann's profound insights to revolutionize physics with the general theory of relativity. Einstein needed a four-dimensional space built from three spatial dimensions and time, all with varying curvature corresponding to the strength of gravitational fields at different points.

9.1.1 Exercises for Section 9.1

*9.1.1. Use a computer graphing capability to find the circle best approximating the bend of $y = x^2$ at $x = 0$ as follows.

(a) Explain why the circle should have a common tangent with $y = x^2$ at $x = 0$. On what line does the center of the circle lie? Use your answers to simplify the general equation of a circle: $(x - a)^2 + (y - b)^2 = r^2$.

(b) Solve the equation in part (a) for y and graph the bottom half along with $y = x^2$ for various radii. Which center and radius appear to give the best fit?

9.1.2. *(a) Repeat Exercise 9.1.1 for the function $y = \cos(x)$ at $x = 0$.

(b) Repeat Exercise 9.1.1 for the function $y = x^4$ at $x = 0$.

9.3 Surfaces and Curvature

The bulging of a sphere makes the angle sum of spherical triangles greater than 180°. Indeed, the excess of the angle sum over 180° depends on the area of the triangle, as Theorem 1.5.3 makes precise. The angle sum of a hyperbolic triangle also depends on the triangle's area. But, as proven in Theorem 4.1.1, the angle sum is less than 180°. What kind of anti-bulging would a surface need to have to match hyperbolic geometry? Carl Friedrich Gauss, one of the founders of hyperbolic geometry, answered that question with differential geometry, although it is unclear whether he saw the connection. From Gauss's definition of curvature, a sphere has constant positive curvature and a Euclidean plane has 0 curvature. Eugenio Beltrami (1835–1900) realized that a surface with constant negative Gaussian curvature gave a model of (part of) hyperbolic geometry. In this section we investigate surfaces and their curvatures. To simplify the theory and calculations we will use parametric equations to embed the surfaces in $\mathbb{R}^3$, Euclidean 3-dimensional space. (Gauss showed how to study the geometry of a surface independently of embedding it in $\mathbb{R}^3$.) We focus on surfaces of revolution, further easing our work. We often use the formula $\cos^2(\theta) + \sin^2(\theta) = 1$ to simplify formulas for surfaces of revolution.

9.3.1 Surfaces

Example 1. We can represent the surface of a sphere of radius R in more than one way. The pair of functions $z = \pm\sqrt{R^2 - x^2 - y^2}$ determine the upper and lower hemispheres. The computer drawing in Figure 9.15 uses the curves determined from them by holding one of x or y fixed and varying the other. The familiar and more useful longitude and latitude coordinates, depicted in Figure 9.16, fit with the parametric equations $x(u, v) = R\cos(u)\cos(v)$, $y(u, v) = R\sin(u)\cos(v)$, and $z(u, v) = R\sin(v)$, where $-\pi < u \leq \pi$ and $-\frac{\pi}{2} \leq v \leq \frac{\pi}{2}$. Here u gives the longitude and v gives the latitude. The equations come from rotating the circle $\overrightarrow{c(v)} = (R\cos(v), R\sin(v))$ around the z-axis. If we restrict v to $-\frac{\pi}{2} < v < \frac{\pi}{2}$, they map the points (u, v) in a rectangle to the points $(x(u, v), y(u, v), z(u, v))$ on the sphere, minus the north and south poles. The latitudes and longitudes in Figure 9.16 come from holding v or u fixed and varying the other. This parameterization doesn't work well at the north and south poles, which are the images of infinitely many points $(u, \frac{\pi}{2})$ and $(u, -\frac{\pi}{2})$, respectively. Both representations of the sphere present difficulties at the edges of the domain—where $z = 0$ for the first one and where $u = \pm\pi$ or $v = \pm\frac{\pi}{2}$ for the second one. A more rigorous development of differential geometry covers a surface with overlapping patches, each with its own parameterization. (See Do Carmo [1, 55–57].) ◊

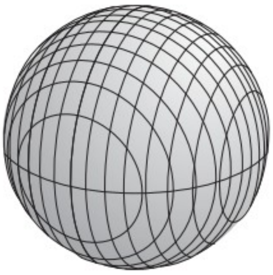

Figure 9.15 A sphere represented using cross sections.

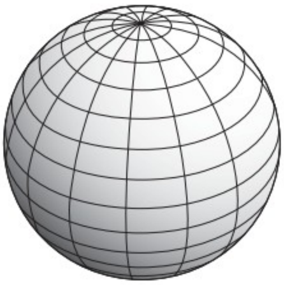

Figure 9.16 Longitude and latitude lines on a sphere.

Exercise 9.3.1. Replace x and y in the first form for the sphere with their parametric formulas and reduce the expression to $z(u, v)$ to verify that the representations of a sphere match.

Exercise 9.3.2. Most texts parameterize the sphere as $x(u, v) = R\cos(u)\sin(v)$, $y(u, v) = R\sin(u)\sin(v)$, and $z(u, v) = R\cos(v)$, where $0 < u \leq 2\pi$ and $0 \leq v \leq \pi$. Convert it to the second one in Example 1.

Example 2. We generate a *torus*, or more informally an inner tube, by rotating the circle $(y - R)^2 + z^2 = r^2$ in the yz-plane around the z-axis. (See Figures 9.17 and 9.18.) The rotation replaces the y-value in the equation with corresponding points (x, y). The distance of (x, y) from the origin, $\sqrt{x^2 + y^2}$, takes the place of y, giving the formula $z = \pm\sqrt{r^2 - (\sqrt{x^2 + y^2} - R)^2}$.

Figure 9.19 depicts the torus as a surface of revolution using cross sections from the parametric form $((r\cos(v) + R)\cos(u), (r\cos(v) + R)\sin(u), r\sin(v))$, for $0 \leq u < 2\pi$ and $-\frac{\pi}{2} \leq v < \frac{3\pi}{2}$.

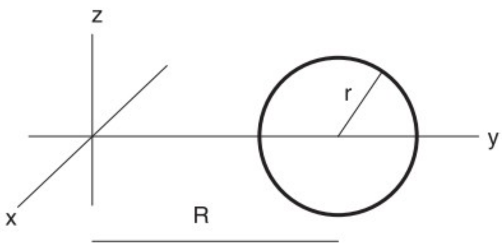

Figure 9.17

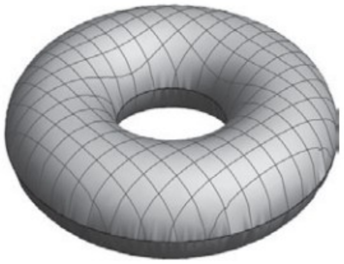

Figure 9.18

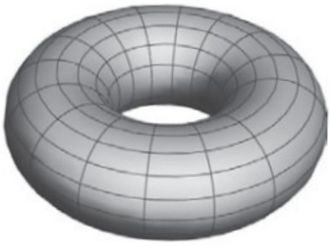

Figure 9.19

Points on the bulging outside surface of the torus, where $-\frac{\pi}{2} < v < \frac{\pi}{2}$, have positive curvature. Points on the inside surface, where $\frac{\pi}{2} < v < \frac{3\pi}{2}$, have negative curvature. For them the surface has a saddle-like shape, curving inward for the horizontal cross section and outward for the vertical cross section. Consider the two circles of points when $v = \pm\frac{\pi}{2}$, between the bulging points and the saddle points. Although the torus may not appear flat at them, its curvature can't be positive or negative, and so must be 0. The situation is analogous to Example 3 of Section 9.2, where $y = x^4$ had a curvature of 0 at $x = 0$. ◊

Exercise 9.3.3. Replace x and y in the first form for the torus with the parametric formulas and reduce the expression to $z(u, v)$ to verify that the two representations of a torus match.

In general, a surface is a function $\mathbf{s}$ from a region of $\mathbb{R}^2$ to $\mathbb{R}^3$ that we represent using parametric equations: $\mathbf{s}(u, v) = (x(u, t),\ y(u, v),\ z(u, v))$. There are many conditions on them to make the patches smooth enough and able to fit together. We'll avoid the technical details and say $\mathbf{s}$ is a *smooth surface* provided it satisfies the conditions found in Oprea [7, 71–73].

9.3.2 Curvature

The curvature of a surface at a point is more subtle than the curvature of curves. We use curves on the surface and through the point, in particular the cross sections, as discussed in Examples 1 and 2, to lead us to a definition of surface curvature. When we fix v, the values of $\mathbf{s}(u, v)$ vary with u and so the cross section curve has tangent vectors $\mathbf{s}_u = (\frac{\partial x}{\partial u}, \frac{\partial y}{\partial u}, \frac{\partial z}{\partial u})$. Similarly, when we fix u, the tangent vectors are $\mathbf{s}_v = (\frac{\partial x}{\partial v}, \frac{\partial y}{\partial v}, \frac{\partial z}{\partial v})$. From multivariable calculus other tangent vectors to the surface at this point are linear combinations of them and so form a plane. However, it is easier to keep track of the *unit normal*, a unit vector orthogonal to the tangent plane. The cross product $\mathbf{s}_u \times \mathbf{s}_v$ gives us a vector orthogonal to both tangent vectors and so it is orthogonal to the entire tangent plane. The definition of $N(u, v)$ divides the cross product by its length to get a unit vector. We'll use the change of the unit normal to determine how the surface bends. This is analogous to (9.4) which gave the curvature of a curve in terms of the change of the unit tangent vector.

Definition. For a smooth surface $\mathbf{s}(u, v)$, the *unit normal* is $N(u, v) = \frac{\mathbf{s}_u \times \mathbf{s}_v}{\|\mathbf{s}_u \times \mathbf{s}_v\|}$.

Example 3. For the sphere of Example 1, $\mathbf{s}(u, v) = (R\cos(u)\cos(v),\ R\sin(u)\cos(v),\ R\sin(v))$. Then

$$\begin{aligned} \mathbf{s}_u &= (-R\sin(u)\cos(v),\ R\cos(u)\cos(v), 0) \\ \text{and } \mathbf{s}_v &= (-R\cos(u)\sin(v),\ -R\sin(u)\sin(v),\ R\cos(v)). \end{aligned}$$

We find

$$\mathbf{s}_u \times \mathbf{s}_v = R^2(\cos(u)\cos^2(v),\ \sin(u)\cos^2(v),\ \cos(v)\sin(v)).$$

From the fact that $\cos(v) > 0$ for $-\frac{\pi}{2} < v < \frac{\pi}{2}$ we find

$$\begin{aligned} \|\mathbf{s}_u \times \mathbf{s}_v\| &= R^2\sqrt{\cos^2(u)\cos^4(v) + \sin^2(u)\cos^4(v) + \cos^2(v)\sin^2(v)} \\ &= R^2\sqrt{\cos^4(v) + \cos^2(v)\sin^2(v)} = R^2\sqrt{\cos^2(v)} = R^2\cos(v). \end{aligned}$$

Thus $N(u, v) = (\cos(u)\cos(v), \sin(u)\cos(v), \sin(v))$. The vectors point directly out from the sphere at each point $\mathbf{s}(u, v)$. ◊

Exercise 9.3.4.* Find $N_u = \frac{\partial N}{\partial u}$ and $N_v = \frac{\partial N}{\partial v}$ and verify that $N_u = \frac{1}{R}\mathbf{s}_u$ and $N_v = \frac{1}{R}\mathbf{s}_v$.

Example 4. Exercise 9.3.16 shows that the normal to the torus in Example 2 is $N(u, v) = (\cos(u)\cos(v), \sin(u)\cos(v), \sin(v))$. To determine the curvature of the surface at a point (a, b) we need to know more than the normal. We need to know how it is changing as (u, v) approaches (a, b) along the cross sections. Exercise 9.3.16 gives formulas for N_u and N_v and shows that $N_u = \frac{\cos(v)}{R + r\cos(v)}\mathbf{s}_u$ and $N_v = \frac{1}{r}\mathbf{s}_v$. The ratios indicate how quickly the normal is changing in the u and v directions. We can find the curvature of the curves of the cross sections from them. ◊

In a more complicated but analogous manner to Theorem 9.2.2 the partial derivatives N_u and N_v are linear combinations of $\mathbf{s}_u$ and $\mathbf{s}_v$. That is, there is a 2×2 matrix M with entries possibly dependent on u and v so that $M\begin{bmatrix} \mathbf{s}_u \\ \mathbf{s}_v \end{bmatrix} = \begin{bmatrix} N_u \\ N_v \end{bmatrix}$. In Example 3, $M = \begin{bmatrix} 1/R & 0 \\ 0 & 1/R \end{bmatrix}$ and in Example 4, $M = \begin{bmatrix} \frac{\cos(v)}{R+r\cos(v)} & 0 \\ 0 & \frac{1}{r} \end{bmatrix}$. For a surface $\mathbf{s}(u, v)$, M is called the *shape operator*. While the terms of M depend on the parameterization of the surface, the Gaussian curvature defined below is independent of it. (See Oprea [7, 83–105] for a more extensive exposition of shape operators and their connection with curvature.)

Definition. For a point (p, q) on the surface $\mathbf{s}(u, v)$, the *Gaussian curvature* is $\kappa(p, q) = \det M$, where M is the shape operator of $\mathbf{s}(u, v)$ at (p, q).

Exercise 9.3.5. Use Exercise 9.3.4 to verify that at a point on a sphere of radius R the curvature is $1/R^2$.

Example 5. The curvature of the torus of Examples 2 and 4 is $\kappa(u, v) = \det M = \frac{\cos(v)}{r(R+r\cos(v))}$. For $-\frac{\pi}{2} < v < \frac{\pi}{2}$ the torus bulges out and so should have a positive curvature, matching $\cos(v) > 0$ and $\kappa(u, v) > 0$ for these values. For $v = 0$, $\kappa(u, 0) = \frac{1}{r(R+r)}$, the product of the curvatures of the circles that are the cross sections for fixed u and v. Similarly, for $\frac{\pi}{2} < v < \frac{3\pi}{2}$, the torus has a saddle shape and negative curvature, matching the negative value of $\cos(v)$ and so $\kappa(u, v)$. Also $\kappa(u, \pi) = \frac{-1}{r(R-r)}$, which is the negative of the product of the curvatures of the cross sections for fixed u and v. Finally, $\cos(\pm\frac{\pi}{2}) = 0$, giving a curvature $\kappa(u, \pm\frac{\pi}{2}) = 0$, as discussed in Example 2. ♢

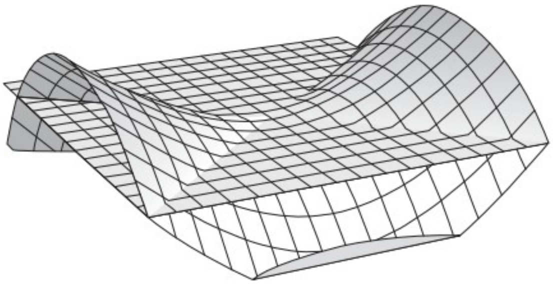

Figure 9.20 A tangent plane at a saddle point.

We can interpret the curvature of a surface in terms of "signed curvatures" for certain cross sections, generalizing Example 5. As noted in that example, the curvature of the torus at (u, π) is negative. As Figure 9.20 indicates, at a saddle point, the tangent plane cuts through the surface. Thus the osculating circles for the cross sections fixing u and v have centers on opposite sides of the tangent plane at (u, π). We pick one side of the tangent plane to carry a positive sign for curvature of curves and the other side to carry a negative sign. For points in the inside, saddle shaped part, the product of the signed curvatures will be negative. For points where the torus bulges outward, the signed curvatures have the same sign and so the product is positive. Euler noticed this relationship using the cross sections to a smooth surface through the normal at a point. Gauss proved that his definition of curvature at a point of a surface was the product of the maximum and minimum (signed) curvatures for curves formed from the cross sections.

9.3.3 Surfaces of Revolution

We derive the general equation of a surface of revolution and verify its curvature formula. Given a parametric curve $(f(v), g(v))$, as in Figure 9.21, we rotate it around the axis of the second coordinate (z) to get a surface of revolution, depicted in Figure 9.22. The radius $f(v)$ is split into its x and y components: $x = f(v)\cos(u)$ and $y = f(v)\sin(u)$. (Since $f(v)$ is a radius, we assume that $f(v) \geq 0$.) Thus the surface is $\mathbf{s}(u, v) = (f(v)\cos(u), f(v)\sin(u), g(v))$.

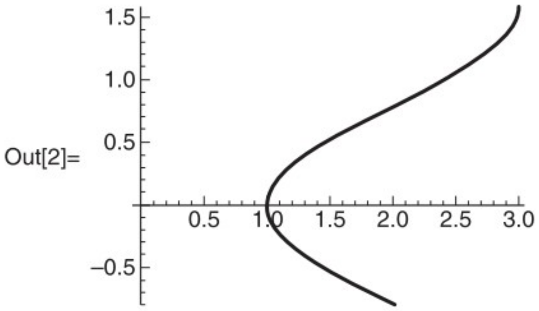

Figure 9.21 A parametric curve.

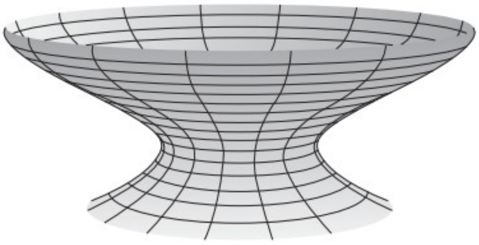

Figure 9.22 The corresponding surface of revolution.

Exercise 9.3.6. Verify the following calculations.

$$\mathbf{s}_u = (-f(v)\sin(u), f(v)\cos(u), 0)$$

$$\mathbf{s}_v = (f'(v)\cos(u), f'(v)\sin(u), g'(v))$$

$$\mathbf{s}_u \times \mathbf{s}_v = (f(v)g'(v)\cos(u),\ f(v)g'(v)\sin(u),\ -f(v)f'(v))$$

$$\|\mathbf{s}_u \times \mathbf{s}_v\| = f(v)\sqrt{f'(v)^2 + g'(v)^2}$$

$$N(u, v) = \left(\frac{g'(v)\cos(u)}{\sqrt{f'(v)^2 + g'(v)^2}}, \frac{g'(v)\sin(u)}{\sqrt{f'(v)^2 + g'(v)^2}}, \frac{-f'(v)}{\sqrt{f'(v)^2 + g'(v)^2}}\right)$$

$$N_u = \left(\frac{-g'(v)\sin(u)}{\sqrt{f'(v)^2 + g'(v)^2}}, \frac{g'(v)\cos(u)}{\sqrt{f'(v)^2 + g'(v)^2}}, 0\right) \quad N_u = \left(\frac{g'(v)}{f(v)\sqrt{f'(v)^2 + g'(v)^2}}\right)\mathbf{s}_u.$$

In addition to the computations of Exercise 9.3.6, we also need N_v to determine the curvature of a surface of revolution. We can simplify the complicated expression for N_v using the substitution $K = \frac{g''(v)f'(v)-g'(v)f''(v)}{(f'(v)^2+g'(v)^2)^{3/2}}$. In (9.3) K is the signed curvature of the parametric curve $(f(v), g(v))$, the curve we are revolving to make the surface.

Exercise 9.3.7. Verify $\left(\frac{g'(v)}{\sqrt{f'(v)^2+g'(v)^2}}\right)' = f'(v)K$ and $\left(\frac{-f'(v)}{\sqrt{f'(v)^2+g'(v)^2}}\right)' = g'(v)K$.

From Exercise 9.3.7, $N_v = K(f'(v)\cos(u), f'(v)\sin(u), g'(v)) = K\mathbf{s}_v$. The preceding work shows that the shape operator for a surface of revolution is $M = \left[\begin{smallmatrix} J & 0 \\ 0 & K \end{smallmatrix}\right]$, where $J = \frac{g'(v)}{f(v)\sqrt{f'(v)^2+g'(v)^2}}$ and K is given above. Now the proof of Theorem 9.3.1 only requires multiplying J and K.

Theorem 9.3.1. *Suppose the surface of revolution* $\mathbf{s}(u, v) = (f(v)\cos(u), f(v)\sin(u), g(v))$ *is a smooth surface. Then the curvature of* $\mathbf{s}(u, v)$ *is* $\kappa(u, v) = \frac{g'(v)(g''(v)f'(v)-g'(v)f''(v))}{f(v)(f'(v)^2+g'(v)^2)^2}$.

Exercise 9.3.8. Verify that $\mathbf{s}_u$ and $\mathbf{s}_v$ are orthogonal for surfaces of revolution.

9.3.4 Exercises for Section 9.3

Use computer software to make the requested graphs.

9.3.9. *(a) Explain why $\mathbf{s}(u, v) = (R\cos(u), R\sin(u), v)$ is a cylinder. Explain what curve is rotated around the z-axis to generate it.

(b) Find its curvature. Explain why the formula is reasonable.

(c) Verify that the helices of Example 6 of Section 9.2 are curves on the surface of the cylinder.

9.3.10. *(a) From Example 1 we can represent the sphere as $\mathbf{s}(x, y) = (x, y, \pm\sqrt{R^2 - x^2 - y^2})$. Find $\mathbf{s}_x$, $\mathbf{s}_y$, and $N(x, y)$. Are $\mathbf{s}_x$ and $\mathbf{s}_y$ orthogonal? Are N_x and N_y linear combinations of $\mathbf{s}_x$ and $\mathbf{s}_y$? This part illustrates some advantages of surfaces of revolution.

(b) Graph the surface $\mathbf{s}(u, v) = (u, v, u^2 - v^2)$ for $-2 \le u \le 2$ and $-2 \le v \le 2$. Describe what you think the curvature of this surface is at various points.

(c) At $(0, 0)$ the curvature of the surface of part (b) is the negative of the product of the curvatures of the cross sections when $u = 0$ and when $v = 0$. Find the curvatures of the cross sections and so the curvature of the surface at $(0, 0)$. What does the value tell you about the curvature of the surface at other points?

9.3.11. *(a) Graph the surface $(u, v, \cos(u)\cos(v))$ for $-\pi \le u \le \pi$ and $-\pi \le v \le \pi$. Describe what you think the curvature of this surface is at various points.

(b) At points $(p\pi, q\pi)$ the curvature of the surface of part (a) is the product of the curvatures of the cross sections when $u = p\pi$ and when $v = q\pi$, for integers p and q. Find the curvatures of the cross sections and so the curvature of the surface at $(p\pi, q\pi)$.

(c) Verify that the curvatures of the cross sections $u = \frac{\pi}{2}$ and $v = \frac{\pi}{2}$ are 0. Explain from the graph of part (a) why the curvature at $(\frac{\pi}{2}, \frac{\pi}{2})$ is not 0.

(d) The biggest (positive and negative signed) curvatures at $(\frac{\pi}{2}, \frac{\pi}{2})$ occur in cross sections bisecting the angles between $u = \frac{\pi}{2}$ and $v = \frac{\pi}{2}$. Explain why the cross sections have equations $z = \cos^2(u)$ and $z = -\cos^2(u)$. Find their curvatures and so the curvature of the surface in part (c) at $(\frac{\pi}{2}, \frac{\pi}{2})$.

9.3.12. The surface of a paraboloid results from rotating a parabola about its axis. The parametric form is $\mathbf{s}(u, v) = (v\cos(u), v\sin(u), bv^2)$.

(a) Explain how to derive the parametric form of the paraboloid from the equation of a parabola.

(b) Graph the paraboloid with $b = 1$. How does increasing the value of b affect its shape? Decreasing b?

(c) Verify that the curvature of a paraboloid is $\kappa(u, v) = \frac{4b}{4b^2v^4+1}$. For $b = 1$ graph the osculating sphere at $v = 0$ with the graph in part (b).

(d) Another way to represent a paraboloid is $\mathbf{s}(x, y) = (x, y, bx^2 + by^2)$. Find $\mathbf{s}_x$, $\mathbf{s}_y$, and $N(x, y)$. Are $\mathbf{s}_x$ and $\mathbf{s}_y$ orthogonal? Are N_x and N_y linear combinations of $\mathbf{s}_x$ and $\mathbf{s}_y$? This part illustrates some advantages of surfaces of revolution.

9.3.13. (a) Graph $\mathbf{s}(u, v) = (v\cos(u), v\sin(v), v^4 - 2v^2)$ for $0 \le u \le 2\pi$ and $0 \le v \le \sqrt{2}$.

(b) Describe the values of v for which you think the curvature of the surface in part (a) is positive. Repeat for negative curvature.

(c) Graph the cone with formula $\mathbf{c}(u, v) = (v\cos(u), v\sin(u), mv)$ for $0 \le u \le 2\pi$ and $0 \le v \le \sqrt{2}$. Explain why the surface is not smooth when $v = 0$.

(d) Assume $v > 0$ and find the curvature of the surface in part (c). Explain why this curvature is reasonable. What happens at $v = 0$?

9.3.14. (a) Write the equations for the surface of revolution for the curve $\overrightarrow{c(t)} = (t, \cos(t))$.

(b) Graph the surface in part (a) with $0 \le u \le 2\pi$ and $0 \le v \le 3\pi$. For which values of v does the curvature appear positive? negative?

(c) Assume that the curvature of the surface in part (a) is $\kappa(u, v) = \frac{\sin(v)\cos(v)}{v(1+\sin^2(v))^2}$ for $v > 0$. Use a limit to determine $\kappa(u, 0)$. For which values of v is $\kappa(u, v) > 0$? Repeat for $\kappa(u, v) < 0$. Compare the values with your answers in part (b).

(d) At $t = 0$, $cos(t)$ has a derivative of 0, so the surface of revolution is smooth when $v = 0$. Investigate as in parts (a) and (b) the surface $\mathbf{g}(u, v)$ made by rotating $(t, \sin(t))$. What happens when $v = 0$? Graph the surface $\mathbf{g}(u, v)$ for $0 \le u \le 2\pi$ and $0 \le v \le 2\pi$.

9.3.15. Figure 9.23 depicts an ellipse, which has parametric form $\overrightarrow{c(t)} = (\cos(t), a\sin(t))$. When we rotate the ellipse around the vertical axis, we get a *spheroid*. When $a > 1$, we call it a *prolate* spheroid, like a rounded football. When $a < 1$, as the ellipse in Figure 9.23, the spheroid is *oblate*. The earth is, as Newton predicted, slightly oblate, with the diameter at the equator less than 1% bigger than the distance between the poles.

*(a) Find the parametric form for the surface $\mathbf{s}(u, v)$ of a spheroid. Graph the spheroid with $a = 2$. Repeat with $a = \frac{1}{2}$.

*(b) Find $\mathbf{s}_u$, $\mathbf{s}_v$, and $\mathbf{s}_u \times \mathbf{s}_v$.

(c) Verify that $\|\mathbf{s}_u \times \mathbf{s}_v\| = \cos(v)\sqrt{a^2\cos^2(v)+\sin^2(v)}$ and $N(u,v) = \left(\frac{a\cos(u)\cos(v)}{\sqrt{a^2\cos^2(v)+\sin^2(v)}}, \frac{a\sin(u)\cos(v)}{\sqrt{a^2\cos^2(v)+\sin^2(v)}}, \frac{\sin(v)}{\sqrt{a^2\cos^2(v)+\sin^2(v)}}\right)$.

*(d) Find N_u and write N_u as a multiple of $\mathbf{s}_u$.

(e) Use a computer algebra system to find and simplify N_v. Verify that $N_v = \frac{a}{(\sin^2(v)+a^2\cos^2(v))^{3/2}}\mathbf{s}_v$ and so the curvature of a spheroid is $\kappa(u,v) = \frac{a^2}{(\sin^2(v)+a^2\cos^2(v))^2}$.

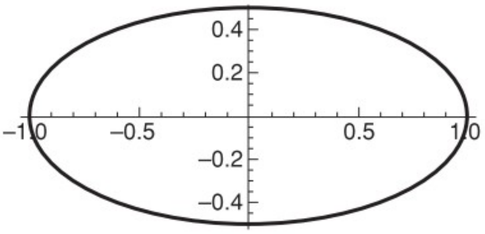

Figure 9.23 An ellipse.

9.3.16. Let $\mathbf{s}(u,v) = ((r\cos(v)+R)\cos(u), (r\cos(v)+R)\sin(u), r\sin(v))$, a parametric representation of the torus.

*(a) Find $\mathbf{s}_u$ and $\mathbf{s}_v$.

(b) Verify that

$$\mathbf{s}_u \times \mathbf{s}_v = (r\cos(u)\cos(v)(R+r\cos(v))$$

$$r\sin(u)\cos(v)(R+r\cos(v)),\ \ r\sin(v)(R+r\cos(v)).$$

(c) Verify that $\|\mathbf{s}_u \times \mathbf{s}_v\| = r(R+r\cos(v))$.

(d) Find $N(u,v)$, N_u, and N_v.

(e) Verify that $N_u = \frac{\cos(v)}{R+r\cos(v)}\mathbf{s}_u$ and $N_v = \frac{1}{r}\mathbf{s}_v$.

9.3.17. Define the hyperbolic trigonometry functions $\tanh(x) = \frac{e^x-e^{-x}}{e^x+e^{-x}}$ and $\operatorname{sech}(x) = \frac{2}{e^e+e^{-x}}$.

(a) Verify that $\tanh^2(x)+\operatorname{sech}^2(x) = 1$, $\tanh(x)' = \operatorname{sech}^2(x)$, $\operatorname{sech}(x)' = -\tanh(x)\operatorname{sech}(x)$, and $\operatorname{sech}(x)'' = -\operatorname{sech}^3(x)+\tanh^2(x)\operatorname{sech}(x)$.

(b) Verify that the pseudosphere $\mathbf{s}(u,v) = (\cos(u)\operatorname{sech}(v), \sin(u)\operatorname{sech}(v), v-\tanh(v))$ is a surface of constant negative curvature for $v \neq 0$.

(c) Graph the plane curve $\overrightarrow{c(t)} = (\operatorname{sech}(t), t-\tanh(t))$. Explain why we need to require $v \neq 0$ in part (b) both visually and from the definition of a curve in Section 9.2.

(Sir Isaac Newton, among others in the early days of calculus, studied the curve $\overrightarrow{c(t)} = (\operatorname{sech}(t), t-\tanh(t))$, called the *tractrix*. Revolved it generates the pseudosphere. Beltrami realized in 1868 that the pseudosphere gave a model of hyperbolic geometry.)

9.3.18. Figure 9.24 depicts one branch of the hyperbola $x^2 - v^2 = 1$, for $x > 0$. When we rotate it around the vertical axis, as in Example 2, we get a hyperboloid of one sheet.

*(a) Find the parametric form for it and graph it.

(b) Use a computer algebra system to verify that the curvature of the surface in part (b) is $\kappa(u,v) = \frac{-1}{(1+2v^2)^2}$.

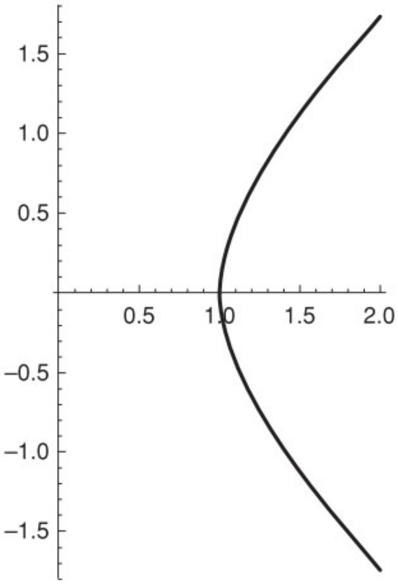

Figure 9.24 A branch of a hyperbola.

*(c) Repeat part (a) for the hyperboloid of two sheets obtained from $v^2 - x^2 = 1$, for $x > 0$ and $v \geq 1$. From the graph what can you say about its curvature?

9.4 Geodesics and the Geometry of Surfaces

9.4.1 Geodesics

Imagine driving a car in hilly terrain. You can easily distinguish when the car goes straight versus turning to the right or left, independently of the curvature of the hills. Intuitively, a straight path following the terrain is a *geodesic*. It is a locally shortest path on the surface. Geodesics are the natural generalization to surfaces of Euclidean lines. Great circles are geodesics on a sphere, discussed in Section 1.5. And on a sphere, the shortest path between any two points follows a great circle. On a surface of constant negative curvature the geodesics become the lines of hyperbolic geometry, discussed in Chapter 4. On a torus the geodesics are more complicated. Figure 9.25 depicts some geodesics on a torus that are indeed shortest paths between two points on them. As the figure illustrates, the curvature can be positive or negative and still the geodesic can be the shortest path. The solid curve $\overrightarrow{g}$ between points A and B in Figure 9.26 gives a geodesic, even though the curve $\overrightarrow{c}$ seems to provide a shorter path. Curve $\overrightarrow{g}$ would, however, feel straight to someone traveling along it, unlike $\overrightarrow{c}$. For nearby points on $\overrightarrow{g}$, it is locally a shortest path. In this section we investigate geodesics on surfaces and their relationship to curvature. In addition we explore more deeply the geometry of a surface, leading to some profound insights of Gauss. The ideas extend to higher dimensions, which we consider briefly.

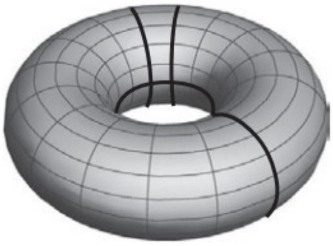

Figure 9.25 Geodesics on a torus that are shortest paths.

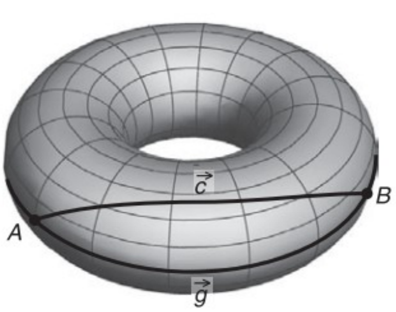

Figure 9.26 A geodesic that is not a shortest path globally.

Imagine attaching a unit tangent vector $T(t)$ to a point (or the car of the previous paragraph) moving along a curve on a surface. In Figure 9.27, the point is "going straight up" the surface. Here the acceleration vector $T'(t)$ is perpendicular to the tangent. In this case the curve is a geodesic, following the surface. In contrast, the plane curve in Figure 9.28 is not a geodesic and here $T'(t)$ is in the plane, which is the tangent plane.

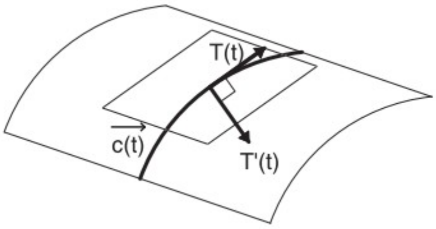

Figure 9.27 A geodesic.

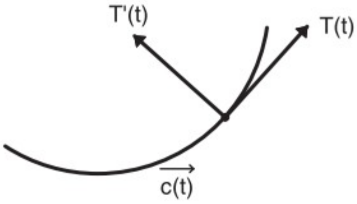

Figure 9.28 A non-geodesic.

Suppose $\overrightarrow{c(t)}$ is a curve in the surface $\mathbf{s}(u, v)$. At a point $\overrightarrow{c(t_0)} = \mathbf{s}(u_0, v_0)$ the unit tangent vector $T(t_0)$ to the curve and the unit normal $N(u_0, v_0) = N(t_0)$ are perpendicular to each other. The tangent plane at this point is determined by $T(t_0)$ and the cross product $T(t_0) \times N(t_0) = B(t_0)$, which is called the *binormal* to the curve. The vectors $T(t_0)$, $N(t_0)$, and $B(t_0)$, form a basis of $\mathbb{R}^3$. So every vector from this point on the curve can be written uniquely as a linear combination of them, in particular, the acceleration vector $T'(t_0)$. By Theorem 9.2.2, T' is orthogonal to T, so T' is a linear combination of the normal and binormal vectors. The binormal component indicates the amount of turning of the curve in the tangent plane and so the deviation from the geodesic. In Figure 9.27, $T'(t_0)$ is a scalar multiple of the binormal, whereas in Figure 9.28 it is a scalar multiple of the normal. The difference motivates our definition of a geodesic. For simplicity, whenever possible we make the curve move at unit velocity so that $\overrightarrow{c'(t_0)} = T(t_0)$ and $\overrightarrow{c''(t_0)} = T'(t_0)$.

Definition. A curve $\overrightarrow{c(t)}$ on a surface $\mathbf{s}(u, v)$ is a *geodesic* if and only if for every value t, there is a scalar $\alpha(t)$ so that $T'(t) = \alpha(t)N(t)$.

Example 1. The lines of longitude on a sphere run through the north and south pole and are, as proved here, geodesics. (See Figure 9.29.) A line of longitude has the form

$$\overrightarrow{c(t)} = \left(R\cos(u_0)\cos\left(\frac{t}{R}\right), R\sin(u_0)\cos\left(\frac{t}{R}\right), R\sin\left(\frac{t}{R}\right)\right) \quad \text{for a fixed } u_0$$

and the sphere is

$$\mathbf{s}(u, v) = (R\cos(u)\cos(v), R\sin(u)\cos(v), R\sin(v)).$$

By Exercise 9.2.13 and Example 3 of Section 9.3 we have

$$\overrightarrow{c'(t)} = T(t) = \left(-\cos(u_0)\sin\left(\frac{t}{R}\right), -\sin(u_0)\sin\left(\frac{t}{R}\right), \cos\left(\frac{t}{R}\right)\right),$$
$$\overrightarrow{c''(t)} = T'(t) = \left(-\frac{1}{R}\cos(u_0)\cos\left(\frac{t}{R}\right), -\frac{1}{R}\sin(u_0)\cos\left(\frac{t}{R}\right), -\frac{1}{R}\sin\left(\frac{t}{R}\right)\right),$$

and

$$N\left(u_0, \frac{t}{R}\right) = \left(\cos(u_0)\cos\left(\frac{t}{R}\right), \sin(u_0)\cos\left(\frac{t}{R}\right), \sin\left(\frac{t}{R}\right)\right).$$

Then for every value of t we have $T'(t) = -\frac{1}{R}N(u_0, \frac{t}{R})$. Hence these curves are geodesics.

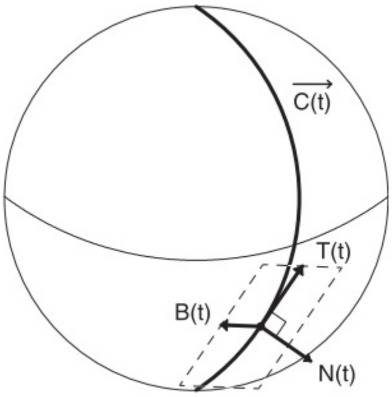

Figure 9.29 Longitude lines are geodesics.

In contrast we show that the circles of latitude, depicted in Figure 9.30, are not geodesics, except the equator (when $v_0 = 0$). Thus we consider values v_0 strictly between $-\frac{\pi}{2}$ and $\frac{\pi}{2}$, other than 0. (The north and south poles, where $v_0 = \pm\frac{\pi}{2}$, are points, not curves.) Here

$$\overrightarrow{c(t)} = (R\cos(t)\cos(v_0), R\sin(t)\cos(v_0), R\sin(v_0))$$

for a fixed v_0. Then

$$\overrightarrow{c'(t)} = (-R\sin(t)\cos(v_0), R\cos(t)\cos(v_0), 0),$$

which is generally not a unit vector. For v_0 other than $\pm\frac{\pi}{2}$, we can divide $\overrightarrow{c'(t)}$ by $R\cos(v_0)$ to find

$$T(t) = (-\sin(t), \cos(t), 0) \qquad \text{and}$$
$$T'(t) = (-\cos(t), -\sin(t), 0).$$

However,

$$N(t) = N(t, v_0) = (\cos(t)\cos(v_0), \sin(t)\cos(v_0), \sin(v_0))$$

and $T'(t)$ is not a scalar multiple of just $N(t)$. That is, circles of latitude are generally not geodesics. Exercise 9.4.5 asks you to show that the equator is a geodesic. ◊

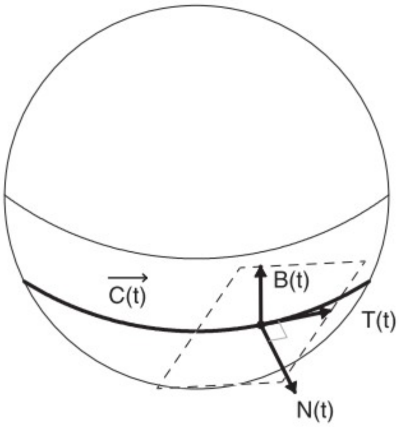

Figure 9.30 Latitude lines generally are not geodesics.

Exercise 9.4.8 asks you to verify that great circles besides longitudes are geodesics.

9.4.2 Geodesics on Surfaces of Revolution

Example 1 generalizes to a surface of revolution $\mathbf{s}(u, v) = (f(v)\cos(u), f(v)\sin(u), g(v))$. Curves with u_0 fixed are geodesics, as Theorem 9.4.1 shows, but curves with v_0 fixed generally are not. Surfaces of revolution have geodesics in other directions, but they can be quite difficult to determine. We add the assumption $f'(v)^2 + g'(v)^2 = 1$ in Theorem 9.4.1 only to simplify the proof. It ensures that $\overrightarrow{c'(t)}$ will have unit length. However, the result remains correct with different parameterizations of the curve. (See Do Carmo [1, 255–258 and 356].)

Exercise 9.4.1. Verify that $f'(v)^2 + g'(v)^2 = 1$ holds in Example 1.

Theorem 9.4.1. *Let* $\mathbf{s}(u, v) = (f(v)\cos(u), f(v)\sin(u), g(v))$ *be a smooth surface of revolution with* $f'(v)^2 + g'(v)^2 = 1$ *for all* v. *Then for all fixed* u_0, *the curves* $\overrightarrow{c(t)} = (f(t)\cos(u_0), f(t)\sin(u_0), g(t))$ *are geodesics.*

Proof. From the assumptions,

$$\overrightarrow{c'(t)} = T(t) = (f'(t)\cos(u_0),\, f'(t)\sin(u_0), g'(t))$$
$$\text{and } T'(t) = (f''(t)\cos(u_0),\, f''(t)\sin(u_0), g''(t)).$$

By Theorem 9.2.2, $T(t) \cdot T'(t) = 0$. That is,

$$f'(t)f''(t)\cos^2(u_0) + f'(t)f''(t)\sin^2(u_0) + g'(t)g''(t) = 0 \qquad \text{or}$$
$$f'(t)f''(t) + g'(t)g''(t) = 0.$$

For now assume that $f'(t) \neq 0$ and rewrite the last equality as $f''(t) = \frac{-g'(t)g''(t)}{f'(t)}$. From subsection 9.3.3

$$N(t) = (g'(t)\cos(u_0), g'(t)\sin(u_0), -f'(t)).$$

For $\overrightarrow{c(t)}$ to be a geodesic, $T'(t)$ must be a scalar multiple of $N(t)$ and so the third coordinates must match. That is, we need

$$g''(t) = \alpha(t)(-f'(t)) \quad \text{or} \quad \alpha(t) = \frac{-g''(t)}{f'(t)}.$$

Now

$$\begin{aligned}\alpha(t)N(t) &= \frac{-g''(t)}{f'(t)}(g'(t)\cos(u_0), g'(t)\sin(u_0), -f'(t)) \\ &= \left(\frac{-g'(t)g''(t)}{f'(t)}\cos(u_0), \frac{-g'(t)g''(t)}{f'(t)}\sin(u_0), g''(t)\right) \\ &= (f''(t)\cos(u_0),\, f''(t)\sin(u_0), g''(t)) = T'(t).\end{aligned}$$

Thus $\overrightarrow{c(t)}$ is a geodesic. Exercise 9.4.9 considers the case $f'(t) = 0$. ■

9.4.3 Arc Length on Surfaces

Figure 9.31 depicts a straight line and a right triangle on a flat piece of paper. When we roll the paper into a cylinder, as in Figure 9.32, the line becomes a helix, which by Exercise 9.4.10 is a geodesic of the cylinder. Distances on the surface of the cylinder work just like Euclidean distance, as long as we don't go too far around it. That is, in Figure 9.32 we can use the Pythagorean theorem and the lengths a and b to find c, provided the triangle is made from geodesic segments on the cylinder. In this sense, the cylinder remains flat, in spite of the bending of the paper. And, as found in Exercise 9.3.9, the cylinder has 0 curvature everywhere. The length of a curve on a surface with nonzero curvature requires a more sophisticated approach.

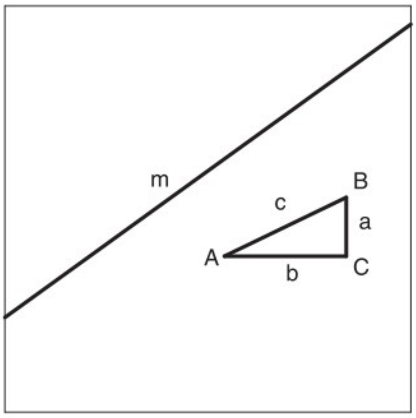

Figure 9.31 Shapes in the plane.

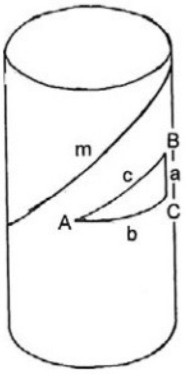

Figure 9.32 Corresponding shapes on a cylinder.

Gauss generalized the Pythagorean theorem to curved surfaces. Since general surfaces vary from point to point, his approach had to be local. He used the language of differentials, which we still use. For a surface $\mathbf{s}(u, v)$, Gauss expressed the distance along a geodesic in terms of the distance along the cross section curves. In Figure 9.33 we want to determine the differential (infinitesimal distance) ds along the geodesic from (u_0, v_0) to (u_1, v_1) in terms of the differentials du and dv. Gauss found the following amazing formula, now called the first fundamental form. (See Do Carmo [1, 92].)

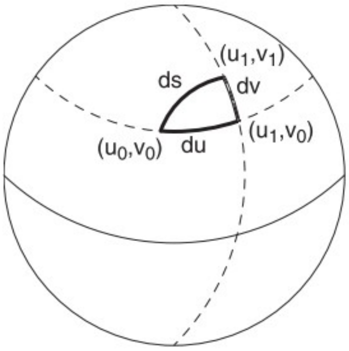

Figure 9.33 A differential on a surface.

$$ds^2 = Edu^2 + 2Fdudv + Gdv^2, \tag{9.5}$$

where $E = \mathbf{s}_u \cdot \mathbf{s}_u$, $F = \mathbf{s}_u \cdot \mathbf{s}_v$, and $G = \mathbf{s}_v \cdot \mathbf{s}_v$.

Exercise 9.4.2.* For the cylinder $\mathbf{s}(u, v) = (R\cos(\frac{u}{R}), R\sin(\frac{u}{R}), v)$ find E, F, and G from equation 9.5. Explain why the values validate the text's assertion about distances on the surface of the cylinder.

(9.5) generalizes the distance formulas of exercises 3.1.9 and 3.1.10 when the scales of the axes differ and are at an angle to one another. In linear algebra terms, for each point of the surface (9.5) determines an inner product for the tangent plane. From Exercise 9.3.8, for surfaces of revolution $\mathbf{s}_u$ and $\mathbf{s}_v$ are orthogonal, and so F is always 0.

Exercise 9.4.3.* For a surface of revolution as in Theorem 9.4.1 find $E(u,v)$ and $G(u,v)$ to verify that $ds^2 = f(v)^2du^2 + dv^2$.

Theorem 9.4.2 uses (9.5) to find the length along a curve on a surface. Calculus texts derive the arc length of a plane curve through approximation with the lengths Δs_i of line segments, as in Figure 9.34. A larger number of segments can improve the approximation. The plane curve $\overrightarrow{c(t)} = (x(t), y(t))$ has arc length $s = \int_a^b \sqrt{x'(t)^2 + y'(t)^2}dt$ for $a \leq t \leq b$. On a surface we similarly approximate the length of a curve $\overrightarrow{c(t)}$ using geodesic segments, as in Figure 9.35, giving $s \approx \sum \Delta s_i$. In the limit we get an integral: $s = \int_a^b ds = \int_a^b \sqrt{Edu^2 + 2Fdudv + Gdv^2}$. From calculus $du = u'(t)dt$ and $dv = v'(t)dt$. The reasoning of this paragraph gives us Theorem 9.4.2.

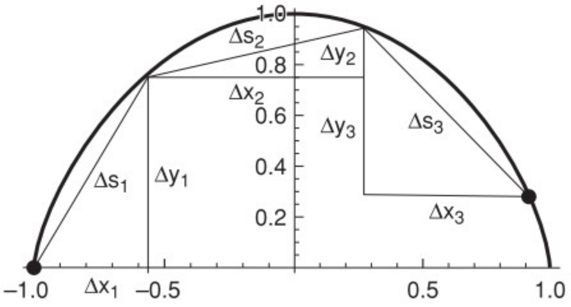

Figure 9.34 Arc length of a plane curve.

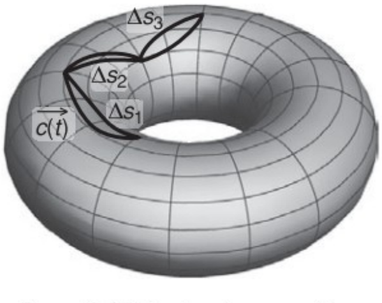

Figure 9.35 Arc length on a surface.

Theorem 9.4.2. *On a smooth surface* $\mathbf{s}(u,v)$, *the length of a curve* $\overrightarrow{c(t)}$ *from* $t = a$ *to* $t = b$ *is*

$$s = \int_a^b \sqrt{E(t)u'(t)^2 + 2F(t)u'(t)v'(t) + G(t)v'(t)^2}dt. \tag{9.6}$$

Example 2. For the sphere of radius R, $\mathbf{s}(u, v) = (R\cos(u)\cos(\frac{v}{R}), R\sin(u)\cos(\frac{v}{R}), R\sin(\frac{v}{R}))$. From Exercise 9.4.3, $E(u, v) = R^2\cos^2(\frac{v}{R})$, $F = 0$, and $G = 1$. A circle of latitude with $v = v_0$ has $\overrightarrow{c(t)} = (R\cos(t)\cos(\frac{v_0}{R}), R\sin(t)\cos(\frac{v_0}{R}), R\sin(\frac{v_0}{R}))$ for $0 \leq t \leq 2\pi$. Here $u(t) = t$ and $v(t) = v_0$. We can substitute these values into (9.6) to obtain

$$s = \int_0^{2\pi} \sqrt{R^2\cos^2\left(\frac{v_0}{R}\right) \cdot 1 + 0 + 0}\,dt = \int_0^{2\pi} R\left|\cos\left(\frac{v_0}{R}\right)\right| dt = 2\pi R\left|\cos\left(\frac{v_0}{R}\right)\right|,$$

the circumference of a circle with radius $R\cos(\frac{v_0}{R})$. ♢

9.4.4 The Gauss-Bonnet Theorem

Gauss coupled his insights on curvature and geodesics to relate areas of triangles and curvature. The proof of Theorem 9.4.3 goes beyond the level of this text. However, its statement unites Theorem 1.5.3 and Theorem 4.1.1 and so shows the unity of spherical and hyperbolic geometries. The notation $d\sigma$ in the theorem is a shorthand for the differential of area taking into account the values of E, F, and G in (9.5).

Theorem 9.4.3 (Gauss part of Gauss-Bonnet Theorem, 1827). *Suppose a triangular region T of a smooth surface is bounded by geodesics and the measures of the angles made by the geodesics are α, β, and γ. Assume that T can be shrunk continuously to a point on the surface. Then $\alpha + \beta + \gamma - \pi = \int\int_T \kappa(u, v)d\sigma$, where $\kappa(u, v)$ is the curvature at (u, v).*

Proof. See Do Carmo [1, 264–270]. ■

Example 3. A sphere of radius R has constant curvature $\frac{1}{R^2}$. Then $\int\int_T \kappa(u, v)d\sigma = \frac{1}{R^2}$ area(T). Thus we can rearrange the equation of Theorem 9.4.3 to give Theorem 1.5.3 for spherical triangles: $R^2(\alpha + \beta + \gamma - \pi) = \text{area}(T)$. In Chapter 1 we called $\alpha + \beta + \gamma - \pi$ the spherical excess. Analogously, Theorem 4.1.1 tells us about the area of triangles in hyperbolic geometry. The hyperbolic plane has constant negative curvature, say $-\frac{1}{k}$. (See Exercise 9.3.17.) The minus sign changes Gauss's formula to $-k(\alpha + \beta + \gamma - \pi) = k(\pi - (\alpha + \beta + \gamma)) = \text{area}(T)$. We called $\pi - (\alpha + \beta + \gamma)$ the defect of a triangle. In between spherical and hyperbolic geometries is Euclidean geometry, where the curvature is 0. In the Euclidean case, Theorem 9.4.3 reduces to Theorem 1.1.1, and the angle sum of a Euclidean triangle is π or 180°. ♢

Pierre Ossian Bonnet (1819–1892) generalized Gauss's result in 1848 to regions bounded by curves, whether or not they are geodesics. (See Do Carmo [1, 264–270].) He also considered regions that can't be shrunk to a point. For example, the shaded band on the torus in Figure 9.36 can't be shrunk continuously on the surface to a point. The general Gauss-Bonnet theorem needs to take into account the topological type of the surface, using the Euler characteristic. (See Project 9. Also, Project 12 of Chapter 1 considers the generalized Euler's formula, which relates to the Euler characteristic.)

9.4.5 Higher Dimensions

Bernhard Riemann (1826–1866) boldly extended Gauss's vision from two-dimensional surfaces to what are called n-dimensional *manifolds*. All our work has embedded curves and surfaces

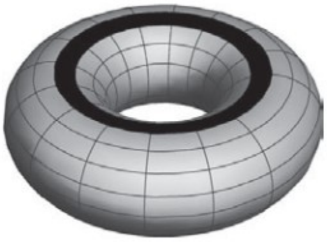

Figure 9.36 A band on a torus.

in 2- and 3-dimensional Euclidean space. While the embedding simplified our presentation, it would have made Riemann's advances impossible. For example, we heavily used the cross product, which is defined only in $\mathbb{R}^3$. Riemann needed the results Gauss proved about surfaces independent of whether they were embedded in a space. Riemann generalized the concepts of curvature, geodesics, and more. For example, a 3-dimensional manifold $\mathbf{m}(u, v, w)$ has lengths generalizing the 3-dimensional Pythagorean theorem. Riemann's version of (9.5) for the 3-manifold $\mathbf{m}(u, v, w)$ is

$$ds^2 = Edu^2 + 2Fdudv + Gdv^2 + 2Hdudw + 2Idvdw + Jdw^2,$$

where

$$E = \mathbf{m}_u \cdot \mathbf{m}_u,\ F = \mathbf{m}_u \cdot \mathbf{m}_v,\ G = \mathbf{m}_v \cdot \mathbf{m}_v,\ H = \mathbf{m}_u \cdot \mathbf{m}_w,$$
$$I = \mathbf{m}_v \cdot \mathbf{m}_w, \quad \text{and} \quad J = \mathbf{m}_w \cdot \mathbf{m}_w \tag{9.7}$$

Exercise 9.4.4. Verify that the three-dimensional Pythagorean theorem (Exercise 1.5.11) corresponds to a 3-dimensional manifold with $E = G = J = 1$ and $F = H = I = 0$.

Einstein's general theory of relativity is related to 4-dimensional manifolds since physics uses three spatial dimensions and one time dimension. The values of the parameters in the formula analogous to (9.5) and (9.6) depend on the gravitational field. (However, the value corresponding to ds^2 can come out negative, so the space isn't Riemannian. See the discussions in Section 5.5 and 6.6.) Alternatively, we could take the curvature of the manifold as determining what gravity is at each point. In any case, light travels on geodesics of it and so bends from a Euclidean straight line. In 1919 Sir Arthur Eddington provided the most well known confirmation of this bending of light, mentioned in the introduction to Chapter 9. The general theory of relativity has everyday effects as well. The calculations for global positioning systems need to compensate for relativistic effects. The effects include the difference of the earth's gravitational field around the satellites compared with the field on the earth's surface where we use devices to find position. The gravitational differences modify how fast the highly accurate atomic clocks on the satellites run compared to earth clocks. Hence GPS systems must compensate for relativistic effects to avoid significant errors. (See Love [5].)

Differential geometry has provided profound understanding in mathematics and physics. At the heart of its insights are the geometric concepts of curvature and geodesics.

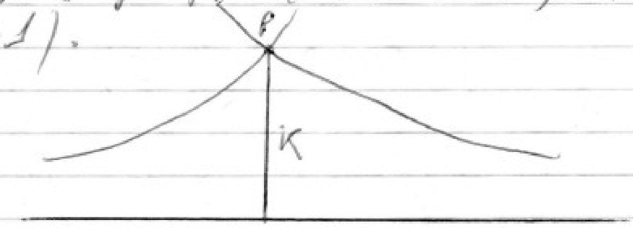
The Advent of Hyperbolic Geometry

(%

Characteristic Axiom of Hyperbolic Geometry

Given a line K and a point P not on K, there are at least two lines on P that do not intersect K (Fig 4.1).



Various consequences from this change, including the many that Saccheri found.

The most startling is the theorem that the measures of the angles of a triangle do not add up to

π (or 180°), as they do in Euclidean geometry.

Pag 154 (179) theorem 4.1.1

In hyperbolic geometry the difference,

$\pi - (m\angle A + m\angle B + m\angle C)$

between π and the angle sum of a triangle is proportional to the area of triangle.

(%

Pág. 160 (185) 4.1.4

Carl Friedrich Gauss

Gauss → regular 17-sided polygon

Obs: Exercises 4.1.9.

A curious property of hyperbolic geometry is that two lines do not intersect and are not sensed parallel (described informally in Exercise 4.1.6) have a common perpendicular.

2º By 1800 Gauss had become convinced that Euclid's parallel postulate could not be proven, and in installments he developed what he called non-Euclidean geometry.

IMPORTANT:

Pág. 410 (435)

Gauss → they link the area of a triangle in spherical and hyperbolic geometry to their angle sums.

In the generalization, Gauss used geodesics for the sides of the triangles. Then, as he proved, the difference

(%

Pag. 411 (436) cont.

between the angle sum of the triangle and π was determined by the area of the triangle and the curvature within it.

The sphere has constant positive curvature and the hyperbolic plane has constant negative curvature, accounting for the difference in theorems 1.5.3 and 4.1.1.

Einstein
Riemann
Gauss

In 1854, Georg Riemann (1826–1866) generalized Gauss's results to any number of dimensions and so transformed differential geometry again.

Many mathematicians developed Riemann's insights into rigorous mathematics with computational methods.

Albert Einstein (1879–1955) built on Riemann's profound insights to revolutionize physics with the general theory of relativity.

Einstein needed a four-dimensional space built from three dimensions and time, all with varying CURVATURE corresponding to the strength of gravitational fields.

Lemma 9.6.1. *Let B be the closed ball centered at a point $\boldsymbol{P}$ and with radius $R > 0$. The flux of the vector field $\boldsymbol{F}$ across ∂B is*

$$-4\pi GMm.$$

Proof. The unit normal vector to ∂B at a point $(x,y,z) \in \partial B$, pointing to the *exterior* of B, is given by

$$\boldsymbol{N} = \frac{\boldsymbol{r}}{\| \boldsymbol{r} \|}.$$

Hence, for

$$\boldsymbol{F} = -\frac{GMm}{\| \boldsymbol{r} \|^3}\,\boldsymbol{r},$$

it turns out that

$$\langle \boldsymbol{F},\boldsymbol{N} \rangle = -GMm\frac{1}{\| \boldsymbol{r} \|^2} = -GMm\frac{1}{R^2}.$$

That is, $\langle \boldsymbol{F},\boldsymbol{N} \rangle$ is constant on the sphere. Consequently, the flux of the vector field $\boldsymbol{F}$ across ∂B coincides with the product of such a constant with the area of ∂B. That is,

$$\text{Flux} \;=\; -4\pi GMm.$$

□

Theorem 9.6.1 (Gauss's law). *Let U be a regular 3-surface with boundary of class C^2 in $\mathbb{R}^3$ and assume that*

$$S := \partial U$$

is a compact regular surface that is oriented according to the normal vector pointing to the exterior of U.

(1) If $\boldsymbol{P} \notin U$, then the flux of $\boldsymbol{F}$ across S is zero.
(2) If $\boldsymbol{P} \in U \setminus S$, then the flux of $\boldsymbol{F}$ across S is $-4\pi GMm$.

Proof. We first suppose that $\boldsymbol{P} \notin U$. In this case, $\boldsymbol{F}$ is a vector field of class C^1 on a neighborhood of U, and by the divergence theorem, the flux of $\boldsymbol{F}$ across S coincides with

$$\iiint_U \operatorname{Div}\boldsymbol{F}(x,y,z)\;\mathrm{d}(x,y,z) = 0.$$

Next, suppose that $\boldsymbol{P} \in U \setminus S$. This time, it is not so easy to apply the divergence theorem, because $\boldsymbol{F}$ is not defined at the point $\boldsymbol{P} \in U$. To avoid this complication, take $R > 0$ small enough that the closed ball B centered at $\boldsymbol{P}$ and with radius R is contained in the interior of U (Fig. 9.6). Now consider

$$\Omega = \{(x,y,z) \in U \;:\, \| (x-x_0, y-y_0, z-z_0) \| \geq R\},$$

which is a regular 3-surface with boundary

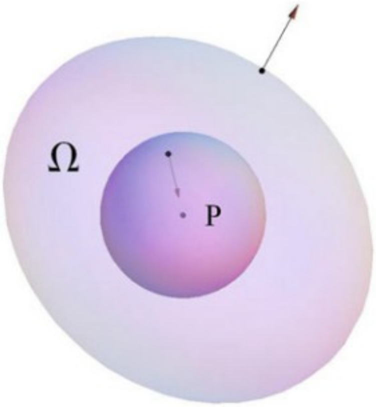

Fig. 9.6 Illustration of the proof of Theorem 9.6.1

$$\partial\Omega = S \cup \partial B.$$

As usual, the boundary of Ω is oriented according the normal vector exterior to Ω. This means that the orientation of $\partial\Omega$ at the points of S is given by the normal vector to S that points to the exterior of U, and the orientation of $\partial\Omega$ at points of ∂B is given by the normal vectors to the sphere that point to the *interior* of the ball.

So, if we consider in ∂B the orientation according to the normal vector *exterior* to the ball, then

$$\int_{\partial\Omega} \langle \boldsymbol{F}, \boldsymbol{N} \rangle \ \mathrm{d}S = \int_{S} \langle \boldsymbol{F}, \boldsymbol{N} \rangle \ \mathrm{d}S - \int_{\partial B} \langle \boldsymbol{F}, \boldsymbol{N} \rangle \ \mathrm{d}S.$$

On the other hand, since $\boldsymbol{F}$ is a vector field of class C^1 on Ω, we can apply the divergence theorem to conclude that

$$\int_{\partial\Omega} \langle \boldsymbol{F}, \boldsymbol{N} \rangle \ \mathrm{d}S = \iiint_{\Omega} \mathrm{Div}\boldsymbol{F}(x,y,z) \ \mathrm{d}(x,y,z) = 0.$$

Consequently, from the previous lemma,

$$\int_{S} \langle \boldsymbol{F}, \boldsymbol{N} \rangle \ \mathrm{d}S = \int_{\partial B} \langle \boldsymbol{F}, \boldsymbol{N} \rangle \ \mathrm{d}S = -4\pi GMm.$$

□

It should be noted that Gauss's law is usually formulated in terms of the electrical field generated by a point charge.

In what follows, we assume for simplicity that $m = 1$. Note that the flux of the gravitational field generated by a point mass M located at $\boldsymbol{P}$ in the interior of U depends only on M and not on the position $\boldsymbol{P}$. If we consider a series of point masses

$M_1, M_2, \ldots$ in the interior of U, the resulting vector field $\boldsymbol{F}$ is the sum of the vector fields generated by each one of the point masses, and the flux of $\boldsymbol{F}$ across S is given by

$$\sum_j -4\pi G M_j = -4\pi G M,$$

where

$$M = \sum_j M_j$$

is the total mass. Therefore, it is no surprise that *if $\boldsymbol{F}$ is the gravitational field generated by an object of total mass M located in the interior of U, then the flux of $\boldsymbol{F}$ across $S = \partial U$ equals $-4\pi GM$*. (see [11]).

(B %B $

Clearly, $\det(A) = 0$ unless P is a full permutation matrix. Furthermore, we have the following proposition.

Proposition 5.10. *If $A = LPDU$ is nonsingular, then*

$$\det(A) = \det(P)\det(D) = \pm\det(D).$$

Thus, up to sign, the determinant of an invertible matrix is the product of its pivots. If $A = LDU$, then $\det(A) = \det(D)$.

Proof. Just use the product rule and the fact that $\det(L) = \det(U) = 1$, since L and U are triangular and have ones on their diagonals. ☐

Recall from Proposition 4.17 that an invertible $A \in \mathbb{F}^{n\times n}$ has an LDU decomposition if and only if each A_k is also invertible, where A_k is the $k \times k$ submatrix in the upper left-hand corner of A, and that the pivots of A are the diagonal entries of D. Let $d_1, \dots, d_n$ be these pivots. Then $A_k = L_k D_k U_k$, so

$$\det(A_k) = \det(D_k) = d_1 \cdots d_k.$$

This gives us the following result.

Proposition 5.11. *If $A \in \mathbb{F}^{n\times n}$ satisfies the condition that each A_k, $1 \le k \le n$, is invertible, then A has an LDU decomposition, and the kth pivot of A in its LDU decomposition is*

$$d_k = \frac{\det(A_k)}{\det(A_{k-1})}. \tag{5.10}$$

5.2.7 A beautiful formula: Lewis Carroll's identity

The theory of determinants is a remarkably rich topic, and we have barely scratched its surface. Many of the foremost mathematicians of the nineteenth century, among them Gauss, Laplace, Lagrange, Cayley, Sylvester, and Jacobi, discovered some of its important properties and applications. An example is the Jacobian of a mapping and the change of variables formula. In this section, we will consider a determinantal curiosity from the nineteenth century that has recently been found to have connections to contemporary mathematics. The formula $\det\begin{pmatrix} a & b \\ c & d \end{pmatrix} = ad - bc$ turns out to have a generalization to $n \times n$ matrices that was discovered by Charles Dodgson, a professor of mathematics at Oxford who, as is well known, wrote *Alice's Adventures in Wonderland* and *Through the Looking Glass* under the pseudonym Lewis Carroll. Dodgson found an identity involving the determinant of an $n \times n$ matrix A that is analogous to the formula in the 2×2 case. Let A_C be the

$(n-2) \times (n-2)$ submatrix of A obtained by deleting the first and last rows and the first and last columns. If $n = 2$, put $\det(A_C) = 1$. Also, let A_{NW} denote the $(n-1) \times (n-1)$ submatrix in the upper left-hand corner of A, and define A_{NE}, A_{SW}, and A_{SE} to be the $(n-1) \times (n-1)$ submatrices in the other three corners of A. Dodgson's formula asserts that

$$\det(A_C)\det(A) = \det(A_{NW})\det(A_{SE}) - \det(A_{NE})\det(A_{SW}) \qquad (5.11)$$

(see C.L. Dodgson, *Proc. Royal Soc. London* **17**, 555–560 (1860)). If $\det(A_C) \neq 0$, this substantially cuts down on the difficulty of finding $\det(A)$. Of course, if $\det(A_C) = 0$, then the identity says nothing about $\det(A)$, although it does say something about the four determinants at the corners. This formula is referred to as Dodgson condensation. Dodgson himself supplied the term condensation. In the 1980s, it was noticed that Dodgson condensation is related to the problem of counting alternating sign matrices (ASMs). Eventually, the problem of enumerating the ASMs was given an elegant solution using statistical mechanics.

CHAPTER 3

Curve Sketching

3.1 INTRODUCTION

Curve sketching is a procedure to obtain an approximate shape of the curve without plotting a large number of points on it. The graph of a given function is helpful in giving a visual presentation of the behaviour of the function involving a study of symmetries, asymptotes, the interval of rising up or falling down and of the concavity upwards and downwards, etc. Before drawing curves, we will study monotonic functions, concavity and convexity of a curve and points of inflection.

3.2 MONOTONIC FUNCTIONS

A function $f(x)$ is called *monotonic increasing* if

(i) $f(x)$ is continuous in the closed interval $[a, b]$,
(ii) $f(x)$ is differentiable in the open interval (a, b) and
(iii) $f'(x) \geq 0$ throughout the interval (a, b).
If $f'(x) > 0$, the function is called *strictly increasing*.

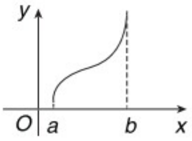

Fig. 3.1

A function $f(x)$ is called *monotonic decreasing* if

(i) $f(x)$ is continuous in the closed interval $[a, b]$,
(ii) $f(x)$ is differentiable in the open interval (a, b) and
(iii) $f'(x) \leq 0$ throughout the interval (a, b).
If $f'(x) < 0$, the function is called *strictly decreasing*.

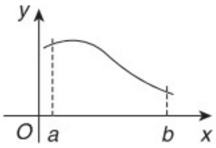

Fig. 3.2

A function is called monotonic in the interval $[a, b]$, if it is increasing or decreasing in the interval $[a, b]$.

3.3 CONCAVITY, CONVEXITY AND POINTS OF INFLECTION OF A CURVE

A function $f(x)$ is concave upwards (convex downwards) if

(i) $f(x)$ is continuous in the closed interval $[a, b]$,
(ii) $f(x)$ is differentiable in the open interval (a, b), and
(iii) $f''(x) > 0$ throughout the interval (a, b).

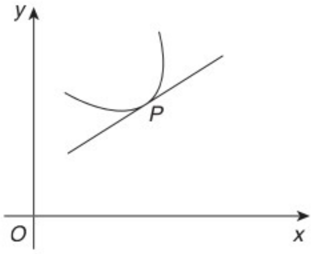

Fig. 3.3

A function $f(x)$ is concave downwards (convex upwards) if

(i) $f(x)$ is continuous in the closed interval $[a, b]$,
(ii) $f(x)$ is differentiable in the open interval (a, b), and
(iii) $f''(x) < 0$ throughout the interval (a, b).

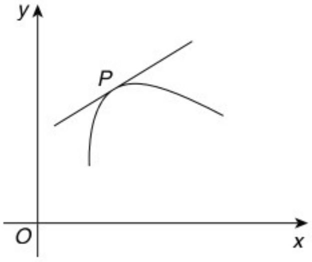

Fig. 3.4

A point at which $f''(x) = 0$ is known as point of inflection where the function changes the direction of concavity from downwards to upwards or vice versa.

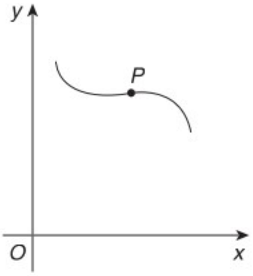

Fig. 3.5

3.4 MAXIMA AND MINIMA

Maxima and minima are largest and smallest value respectively that a function takes either within a given neighbourhood or on the entire function domain.

First Derivative Test for Local Extremum

(a) $f(x)$ has a local maximum at $x = a$, if $f'(a) = 0$ and $f'(x)$ changes sign from positive to negative at $x = a$.

(b) $f(x)$ has a local minimum at $x = a$, if $f'(a) = 0$ and $f'(x)$ changes sign from negative to positive at $x = a$.

Second Derivative Test for Local Extremum

(a) $f(x)$ has a local maximum at $x = a$, if $f'(a) = 0$ and $f''(a) < 0$.
(b) $f(x)$ has a local minimum at $x = a$, if $f'(a) = 0$ and $f''(a) > 0$.
(c) The test fails if $f'(a) = 0$ and $f''(a) = 0$. $f(x)$ may have a local maximum, a local minimum or neither.

Example 1

Discuss the function $f(x) = x^4 - 4x^3$ with respect to increasing or decreasing nature, concavity, points of inflection and local maxima and minima.

Solution

$$f(x) = x^4 - 4x^3$$
$$f'(x) = 4x^3 - 12x^2 = 4x^2 (x - 3)$$
$$f''(x) = 12x^2 - 24x = 12x (x - 2)$$

(*i*) *Increasing or decreasing function*

(a) $f(x)$ is an increasing function if $f'(x) > 0$ i.e. $4x^2(x - 3) > 0$, i.e. $x^2(x - 3) > 0$, i.e. $x - 3 > 0$ since $x^2 > 0$ i.e. $x > 3$.
Hence, $f(x)$ is increasing in the interval $(3, \infty)$.

(b) $f(x)$ is a decreasing function if $f'(x) < 0$, i.e. $4x^2(x - 3) < 0$, i.e. $x^2(x - 3) < 0$, i.e. $x - 3 < 0$ since $x^2 > 0$, i.e. $x < 3$.

Hence, $f(x)$ is decreasing in the interval $(-\infty, 3)$.

(*ii*) *Concavity*

(a) $f(x)$ is concave upwards if $f''(x) > 0$, i.e. $12x(x - 2) > 0$, i.e. $x(x - 2) > 0$.
Now, $x(x - 2) > 0$ if

Case (I) $x > 0$ and $x - 2 > 0$, i.e. $x > 0$ and $x > 2$, i.e. $x > 2$.
Case (II) $x < 0$ and $x - 2 < 0$, i.e. $x < 0$ and $x < 2$, i.e. $x < 0$

Hence, $f''(x) > 0$ in the intervals $(-\infty, 0)$ and $(2, \infty)$ and the function $f(x)$ is concave upwards in these intervals.

(b) $f(x)$ is concave downwards if $f''(x) < 0$, i.e. $12x(x - 2) < 0$, i.e. $x(x - 2) < 0$ i.e. $x(x - 2) < 0$
Now, $x(x - 2) < 0$ if

Case (I) $x > 0$ and $x-2 < 0$, i.e. $x > 0$ and $x < 2$, i.e. $0 < x < 2$.
Case (II) $x < 0$ and $x-2 > 0$, i.e. $x < 0$ and $x > 2$ but this is not possible.

Hence, $f''(x) < 0$ in the interval $(0, 2)$ and the function $f(x)$ is concave downwards in this interval.

(*iii*) *Points of inflection*
At the points of inflection, $f''(x) = 0$, i.e. $12x(x - 2) = 0$, i.e. $x = 0, x = 2$.
At $x = 0$, $f(x) = 0$

CHAPTER 4

Applications of Definite Integrals

Chapter Outline

4.1 Introduction
4.2 Volume using Cross-sections
4.3 Length of Plane Curves
4.4 Area of Surface of Solid of Revolution

4.1 INTRODUCTION

In this chapter, we will explore few applications of definite integrals. Applications of definite integrals in finding volume by cross-sections, length of plane curves and areas of surfaces of revolution are discussed in detail.

4.2 VOLUME USING CROSS-SECTIONS

The volume of a solid of known integrable cross-section area $A(x)$ formed by a plane perpendicular to the x-axis at any point between $x = a$ to $x = b$ is

$$V = \int_a^b A(x)\mathrm{d}x$$

Note: If the cross-section $A(y)$ is perpendicular to the y-axis at any point between $y = c$ to $y = d$, then the volume of the solid is

$$V = \int_c^d A(y)\mathrm{d}y$$

Example 1

Find the volume of the solid generated by rotating the plane region bounded by $y=\dfrac{1}{x}$, $x=1$ *and* $x = 3$ *about the x-axis.*

Solution

The volume is generated by rotating the dotted region about the x-axis.

The cross-section PQ of the generated volume is a circle of radius y perpendicular to x-axis.

Area of cross-section, $A = \pi y^2$

$$= \pi\cdot\frac{1}{x^2}$$

For the region shown, x varies from 1 to 3.

Volume,
$$V = \int_1^3 \frac{\pi}{x^2}\,\mathrm{d}x$$
$$= \pi\left|-\frac{1}{x}\right|_1^3$$
$$= \pi\left(-\frac{1}{3}+1\right)$$
$$= \frac{2}{3}\pi$$

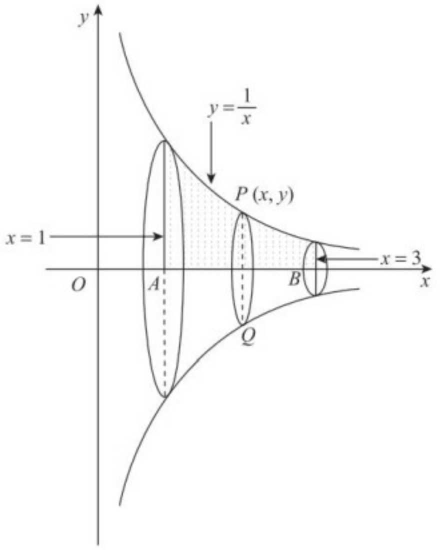

Fig. 4.1

Example 2

Find the volume of the solid that lies between planes perpendicular to the x-axis at $x = 0$ *and* $x = 4$. *The cross-sections perpendicular to the x-axis between these planes run from one side of the parabola* $x = y^2$ *to the other. The cross-sections are squares with bases in the xy-plane.*

Solution

The cross-section of the solid is a square $PQRS$ with side runs from $y=-\sqrt{x}$ to $y=\sqrt{x}$

Length $PQ = 2y = 2\sqrt{x}$

Area of cross-section, $A = (2\sqrt{x})^2 = 4x$

For the region shown, x varies from 0 to 4.

Volume, $$V = \int_0^4 4x\,dx$$

$$= 4\left|\frac{x^2}{2}\right|_0^4$$

$$= 2(16-0)$$

$$= 32$$

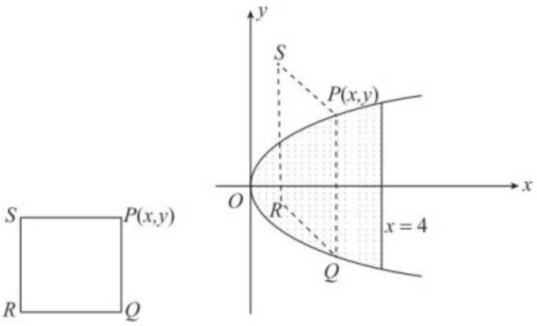

Fig. 4.2

Example 3

Find the volume of a right circular cone of base radius r and height h.

Solution

The cone is generated by rotating the line AB about the y-axis. Equation of the line AB passing through the points $A(r, 0)$ and $B\ (0, h)$ is

$$y - 0 = \frac{h-0}{0-r}(x-r)$$

$$x = r\left(1-\frac{y}{h}\right)$$

The cross-section PQ of the cone is a circle of radius x perpendicular to the y-axis.

Area of cross-section, $A = \pi x^2$

$$= \pi r^2\left(1-\frac{y}{h}\right)^2$$

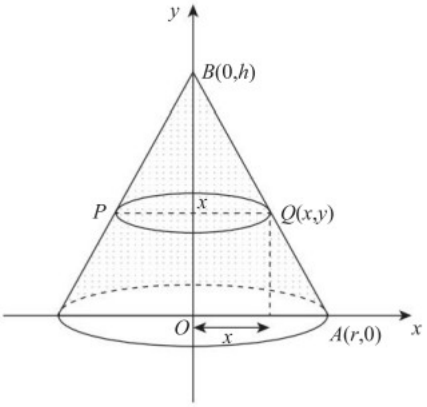

Fig. 4.3

For the region shown, y varies from 0 to h.

Volume, $$V = \int_o^h \pi r^2\left(1-\frac{y}{h}\right)^2 dy$$

$$= \pi r^2\left|\frac{\left(1-\frac{y}{h}\right)^3}{3\left(-\frac{1}{h}\right)}\right|_o^h$$

$$= -\frac{\pi r^2 h}{3}(0-1)$$

$$= \frac{1}{3}\pi r^2 h$$

Example 4

Find the volume of the solid with a circular base of radius 5 and whose cross-sections perpendicular to the base and parallel to the x-axis are equilateral triangles.

Solution

Equation of the circular base of radius 5 is,

$$x^2 + y^2 = 25 \qquad \ldots(1)$$

The cross-section of the solid is an equilateral triangle PQR with base $2x$.

Area of cross-section,
$$\begin{aligned} A &= \frac{1}{2} \times (\text{base}) \times (\text{height}) \\ &= \frac{1}{2}(2x)(h) \\ &= \frac{1}{2}(2x)(x \tan 60^\circ) \\ &= x^2\sqrt{3} \\ &= (25 - y^2)\sqrt{3} \qquad \text{[from Eq. (1)]} \end{aligned}$$

For the region shown, y varies from −5 to 5.

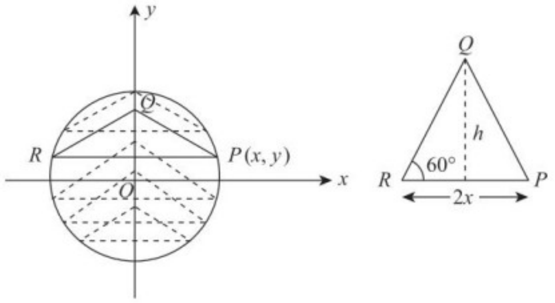

Fig. 4.4

Volume,
$$\begin{aligned} V &= \int_{-5}^{5} \sqrt{3}(25 - y^2)\,dy \\ &= 2\int_{0}^{5} \sqrt{3}(25 - y^2)\,dy \\ &= 2\sqrt{3}\left|25y - \frac{y^3}{3}\right|_0^5 \\ &= 2\sqrt{3}\left(125 - \frac{125}{3}\right) \\ &= \frac{500\sqrt{3}}{3} \end{aligned}$$

Example 5

Use the method of slicing to find the volume of solid with semicircular base defined by $y = 5\sqrt{\cos x}$ *on the interval* $\left[-\frac{\pi}{2}, \frac{\pi}{2}\right]$. *The cross-sections of the solid are squares perpendicular to the x-axis with base running from x-axis to the curve.* **[Winter 2015]**

Solution

The cross-section of the solid is a square with side runs from $y = 0$ (x-axis) to $y = 5\sqrt{\cos x}$.

Length of one side of the square = $5\sqrt{\cos x}$

Area of cross-section, $A = \left(5\sqrt{\cos x}\right)^2$

$= 25\cos^2 x$

In the given interval $\left[-\frac{\pi}{2}, \frac{\pi}{2}\right]$, x varies from $-\frac{\pi}{2}$ to $\frac{\pi}{2}$.

Volume,

$$V = \int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} 25\cos^2 x\,dx$$

$$= 25\int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} \left(\frac{1+\cos 2x}{2}\right)dx$$

$$= \frac{25}{2}\left|x + \frac{\sin 2x}{2}\right|_{-\frac{\pi}{2}}^{\frac{\pi}{2}}$$

$$= \frac{25}{2}\left[\left(\frac{\pi}{2} + \frac{\pi}{2}\right) + 0\right] \quad [\because \sin\pi = 0]$$

$$= \frac{25}{2}\pi$$

EXERCISE 4.1

---

1. Find the volume of the solid that lies between planes perpendicular to the y-axis at $y = 0$ and $y = 2$. The cross-sections perpendicular to the

y-axis are circular disks with diameters running from the y-axis to the parabola $x = \sqrt{5}y^2$.

[Ans.: 8π]

2. Find the volume of the solid that lies between the planes perpendicular to the x-axis at $x = -1$ and $x = 1$. The cross-sections perpendicular to the x-axis are circular disks whose diameters run from the parabola $y = x^2$ to the parabola $y = 2 - x^2$.

$\left[\textbf{Ans.: } \frac{16}{15}\pi\right]$

3. Show that the volume of a sphere of radius r is $\frac{4}{3}\pi r^3$.

4. Find the volume of the solid whose base is the region bounded between the curves $y = x$ and $y = x^2$, and whose cross-sections perpendicular to the x-axis are squares.

$\left[\textbf{Ans.: } \frac{1}{30}\right]$

5. Find the volume of the solid whose base is a triangle with vertices (0, 0), (2, 0) and (0, 2) and whose cross-sections perpendicular to the base and parallel to the y-axis are semicircles.

$\left[\textbf{Ans.: } \frac{\pi}{3}\right]$

4.3 LENGTH OF PLANE CURVES

The process of determining the length of an arc of a plane curve is known as rectification of curves.

4.3.1 Length of Arc in Cartesian Form

We know from differential calculus that for the curve $y = f(x)$,

$$\frac{ds}{dx} = \sqrt{1 + \left(\frac{dy}{dx}\right)^2}$$

The length of the arc of the curve $y = f(x)$ between $x = a$ and $x = b$ is given by,

$$s = \int_a^b \frac{ds}{dx}\,dx$$

$$= \int_a^b \sqrt{1 + \left(\frac{dy}{dx}\right)^2}\,dx$$

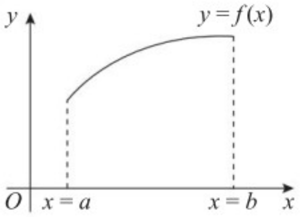

Fig. 4.5

Similarly, the length of the arc of the curve $x = f(y)$ between $y = c$ and $y = d$ is given by,

$$s = \int_c^d \frac{\mathrm{d}s}{\mathrm{d}y}\mathrm{d}y$$
$$= \int_c^d \sqrt{1+\left(\frac{\mathrm{d}x}{\mathrm{d}y}\right)^2}\,\mathrm{d}y$$

Example 1

Show that the length of the arc of the curve $4ax = y^2 - 2a^2\log\frac{y}{a} - a^2$ *from* $(0, a)$ *to any point* (x, y) *is given by* $\frac{y^2}{2a} - \frac{a}{2} - x$.

Solution

$$4ax = y^2 - 2a^2\log\frac{y}{a} - a^2 \qquad \ldots (1)$$
$$4a\frac{\mathrm{d}x}{\mathrm{d}y} = 2y - 2a^2\cdot\frac{a}{y}\cdot\frac{1}{a}$$
$$\frac{\mathrm{d}x}{\mathrm{d}y} = \frac{y}{2a} - \frac{a}{2y} = \frac{y^2-a^2}{2ay}$$

For the required arc, y varies from a to y.

Length of the arc, $$s = \int_a^y \sqrt{1+\left(\frac{\mathrm{d}x}{\mathrm{d}y}\right)^2}\,\mathrm{d}y$$
$$= \int_a^y \sqrt{1+\left(\frac{y^2-a^2}{2ay}\right)^2}\,\mathrm{d}y$$
$$= \int_a^y \sqrt{\frac{(y^2+a^2)^2}{(2ay)^2}}\,\mathrm{d}y$$
$$= \frac{1}{2a}\int_a^y \frac{y^2+a^2}{y}\mathrm{d}y$$
$$= \frac{1}{2a}\left(\int_a^y y\,\mathrm{d}y + a^2\int_a^y \frac{1}{y}\mathrm{d}y\right)$$
$$= \frac{1}{2a}\left|\frac{y^2}{2} + a^2\log y\right|_a^y$$

$$= \frac{1}{2a}\left(\frac{y^2}{2} + a^2 \log\frac{y}{a} - \frac{a^2}{2}\right)$$

$$= \frac{1}{2a}\left[\frac{y^2}{2} + \left(\frac{y^2}{2} - 2ax - \frac{a^2}{2}\right) - \frac{a^2}{2}\right] \qquad \text{… [From Eq. (1)]}$$

$$= \frac{1}{2a}(y^2 - 2ax - a^2)$$

$$= \frac{y^2}{2a} - x - \frac{a}{2}$$

$$= \frac{y^2}{2a} - \frac{a}{2} - x$$

Example 2

Find the length of the arc of the curve y = e^x from the point (0, 1) *to* (1, *e*).

Solution

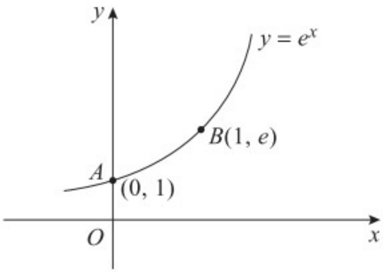

Fig. 4.6

$$y = e^x$$

$$\frac{dy}{dx} = e^x$$

For the required arc, x varies from 0 to 1.

Length of the arc AB, $$s = \int_0^1 \sqrt{1 + \left(\frac{dy}{dx}\right)^2}\, dx$$

$$= \int_0^1 \sqrt{1 + e^{2x}}\, dx$$

Putting $1 + e^{2x} = t^2$,

$$2e^{2x} dx = 2t\, dt$$

$$dx = \frac{t}{t^2 - 1} dt$$

When $x = 0, \quad t = \sqrt{2}$

When $x = 1, \quad t = \sqrt{1 + e^2}$

Length of the arc, $$s = \int_{\sqrt{2}}^{\sqrt{1+e^2}} t \cdot \frac{t}{t^2 - 1} dt$$

$$= \int_{\sqrt{2}}^{\sqrt{1+e^2}} \frac{t^2 - 1 + 1}{t^2 - 1} dt$$

$$= \int_{\sqrt{2}}^{\sqrt{1+e^2}} \left(1 + \frac{1}{t^2 - 1}\right) dt$$

$$= \left| t + \frac{1}{2}\log\frac{t-1}{t+1} \right|_{\sqrt{2}}^{\sqrt{1+e^2}}$$

$$= \sqrt{1+e^2} - \sqrt{2} + \frac{1}{2}\left(\log\frac{\sqrt{1+e^2}-1}{\sqrt{1+e^2}+1} - \log\frac{\sqrt{2}-1}{\sqrt{2}+1} \right)$$

$$= \sqrt{1+e^2} - \sqrt{2} + \frac{1}{2}\left[\log\left\{ \frac{\left(\sqrt{1+e^2}-1\right)^2}{1+e^2-1} \right\} - \log\left\{ \frac{\left(\sqrt{2}-1\right)^2}{2-1} \right\} \right]$$

$$= \sqrt{1+e^2} - \sqrt{2} + \log\left(\sqrt{1+e^2}-1\right) - \frac{1}{2}\log e^2 - \log\left(\sqrt{2}-1\right)$$

$$= \sqrt{1+e^2} - \sqrt{2} + \log\left(\sqrt{1+e^2}-1\right) - 1 - \log\left(\sqrt{2}-1\right)$$

$[\because \log e^2 = 2 \log e = 2]$

Example 3

Find the length of the arc of the curve $y = \log \sec x$ *from* $x = 0$ *to* $x = \frac{\pi}{3}$.

Solution

$$y = \log \sec x$$

$$\frac{dy}{dx} = \frac{1}{\sec x} \cdot \sec x \tan x = \tan x$$

For the required arc, x varies from 0 to $\frac{\pi}{3}$.

Length of the arc, $s = \int_0^{\frac{\pi}{3}} \sqrt{1 + \left(\frac{dy}{dx}\right)^2}\, dx$

$$= \int_0^{\frac{\pi}{3}} \sqrt{1 + \tan^2 x}\, dx$$

$$= \int_0^{\frac{\pi}{3}} \sec x\, dx$$

$$= \left| \log(\sec x + \tan x) \right|_0^{\frac{\pi}{3}}$$

$$= \log\left(2 + \sqrt{3}\right)$$

Example 4

Find the length of the arc of the curve $y = \log\left(\frac{e^x-1}{e^x+1}\right)$ *from* $x = 1$ *to* $x = 2$.

Important:

The geometric meaning of differentials is shown in Figure 5. Let $P(x, f(x))$ and $Q(x + \Delta x, f(x + \Delta x))$ be points on the graph of f and let $dx = \Delta x$. The corresponding change in y is

$$\Delta y = f(x + \Delta x) - f(x)$$

The slope of the tangent line PR is the derivative $f'(x)$. Thus the directed distance from S to R is $f'(x)\,dx = dy$. Therefore dy represents the amount that the tangent line rises or falls (the change in the linearization), whereas Δy represents the amount that the curve $y = f(x)$ rises or falls when x changes by an amount dx.

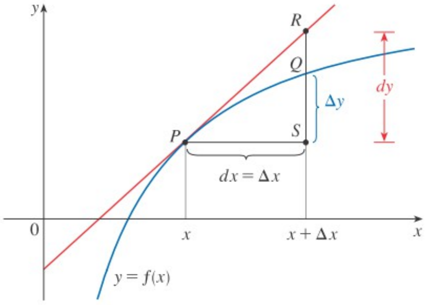

FIGURE 5

EXAMPLE 3 Compare the values of Δy and dy if $y = f(x) = x^3 + x^2 - 2x + 1$ and x changes (a) from 2 to 2.05 and (b) from 2 to 2.01.

SOLUTION

(a) We have

$$f(2) = 2^3 + 2^2 - 2(2) + 1 = 9$$

$$f(2.05) = (2.05)^3 + (2.05)^2 - 2(2.05) + 1 = 9.717625$$

$$\Delta y = f(2.05) - f(2) = 0.717625$$

Figure 6 shows the function in Example 3 and a comparison of dy and Δy when $a = 2$. The viewing rectangle is $[1.8, 2.5]$ by $[6, 18]$.

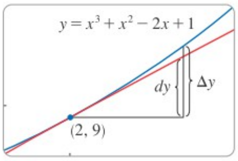

FIGURE 6

In general, $dy = f'(x)\,dx = (3x^2 + 2x - 2)\,dx$

When $x = 2$ and $dx = \Delta x = 0.05$, this becomes

$$dy = [3(2)^2 + 2(2) - 2]0.05 = 0.7$$

(b) $$f(2.01) = (2.01)^3 + (2.01)^2 - 2(2.01) + 1 = 9.140701$$

$$\Delta y = f(2.01) - f(2) = 0.140701$$

When $dx = \Delta x = 0.01$,

$$dy = [3(2)^2 + 2(2) - 2]0.01 = 0.14$$ ■

Notice that the approximation $\Delta y \approx dy$ becomes better as Δx becomes smaller in Example 3. Notice also that dy was easier to compute than Δy.

In the notation of differentials, the linear approximation $f(x) \approx f(a) + f'(a)(x - a)$ can be written as

$$f(a + dx) \approx f(a) + dy$$

the sequence has a limit. What can you say about the value of the limit?

78–84 Determine whether the sequence is increasing, decreasing, or not monotonic. Is the sequence bounded?

78. $a_n = \cos n$

79. $a_n = \dfrac{1}{2n + 3}$

80. $a_n = \dfrac{1 - n}{2 + n}$

81. $a_n = n(-1)^n$

82. $a_n = 2 + \dfrac{(-1)^n}{n}$

83. $a_n = 3 - 2ne^{-n}$

84. $a_n = n^3 - 3n + 3$

---

85. Find the limit of the sequence

$$\left\{\sqrt{2}, \sqrt{2\sqrt{2}}, \sqrt{2\sqrt{2\sqrt{2}}}, \ldots\right\}$$

86. A sequence $\{a_n\}$ is given by $a_1 = \sqrt{2}$, $a_{n+1} = \sqrt{2 + a_n}$.

(a) By induction or otherwise, show that $\{a_n\}$ is increasing and bounded above by 3. Apply the Monotonic Sequence Theorem to show that $\lim_{n\to\infty} a_n$ exists.

(b) Find $\lim_{n\to\infty} a_n$.

87. Show that the sequence defined by

$$a_1 = 1 \qquad a_{n+1} = 3 - \frac{1}{a_n}$$

is increasing and $a_n < 3$ for all n. Deduce that $\{a_n\}$ is convergent and find its limit.

88. Show that the sequence defined by

$$a_1 = 2 \qquad a_{n+1} = \frac{1}{3 - a_n}$$

satisfies $0 < a_n \leqslant 2$ and is decreasing. Deduce that the sequence is convergent and find its limit.

89. (a) Fibonacci posed the following problem:

> Suppose that rabbits live forever and that every month each pair produces a new pair which becomes productive at age 2 months. If we start with one newborn pair, how many pairs of rabbits will we have in the nth month?

Show that the answer is f_n, where $\{f_n\}$ is the Fibonacci sequence defined in Example 3(c).

(b) Let $a_n = f_{n+1}/f_n$ and show that $a_{n-1} = 1 + 1/a_{n-2}$. Assuming that $\{a_n\}$ is convergent, find its limit.

90. (a) Let $a_1 = a$, $a_2 = f(a)$, $a_3 = f(a_2) = f(f(a))$, . . . , $a_{n+1} = f(a_n)$, where f is a continuous function. If $\lim_{n\to\infty} a_n = L$, show that $f(L) = L$.

(b) Illustrate part (a) by taking $f(x) = \cos x$, $a = 1$, and estimating the value of L to five decimal places.

91. (a) Use a graph to guess the value of the limit

$$\lim_{n\to\infty} \frac{n^5}{n!}$$

(b) Use a graph of the sequence in part (a) to find the smallest values of N that correspond to $\varepsilon = 0.1$ and $\varepsilon = 0.001$ in Definition 2.

92. Use Definition 2 directly to prove that $\lim_{n\to\infty} r^n = 0$ when $|r| < 1$.

93. Prove Theorem 6.
[*Hint:* Use either Definition 2 or the Squeeze Theorem.]

94. Use Theorem 7 to prove the Power Law:

$$\lim_{n\to\infty} a_n^p = \left[\lim_{n\to\infty} a_n\right]^p \qquad \text{if } p > 0 \text{ and } a_n > 0$$

95. Prove that if $\lim_{n\to\infty} a_n = 0$ and $\{b_n\}$ is bounded, then $\lim_{n\to\infty} (a_n b_n) = 0$.

96. Let $a_n = (1 + 1/n)^n$.

(a) Show that if $0 \leqslant a < b$, then

$$\frac{b^{n+1} - a^{n+1}}{b - a} < (n + 1)b^n$$

(b) Deduce that $b^n[(n + 1)a - nb] < a^{n+1}$.

(c) Use $a = 1 + 1/(n + 1)$ and $b = 1 + 1/n$ in part (b) to show that $\{a_n\}$ is increasing.

(d) Use $a = 1$ and $b = 1 + 1/(2n)$ in part (b) to show that $a_{2n} < 4$.

(e) Use parts (c) and (d) to show that $a_n < 4$ for all n.

(f) Use Theorem 12 to show that $\lim_{n\to\infty} (1 + 1/n)^n$ exists. (The limit is e. See Equation 3.6.6.)

97. Let a and b be positive numbers with $a > b$. Let a_1 be their arithmetic mean and b_1 their geometric mean:

$$a_1 = \frac{a + b}{2} \qquad b_1 = \sqrt{ab}$$

Repeat this process so that, in general,

$$a_{n+1} = \frac{a_n + b_n}{2} \qquad b_{n+1} = \sqrt{a_n b_n}$$

(a) Use mathematical induction to show that

$$a_n > a_{n+1} > b_{n+1} > b_n$$

(b) Deduce that both $\{a_n\}$ and $\{b_n\}$ are convergent.

(c) Show that $\lim_{n\to\infty} a_n = \lim_{n\to\infty} b_n$. Gauss called the common value of these limits the **arithmetic-geometric mean** of the numbers a and b.

98. (a) Show that if $\lim_{n\to\infty} a_{2n} = L$ and $\lim_{n\to\infty} a_{2n+1} = L$, then $\{a_n\}$ is convergent and $\lim_{n\to\infty} a_n = L$.

(b) If $a_1 = 1$ and

$$a_{n+1} = 1 + \frac{1}{1 + a_n}$$

find the first eight terms of the sequence $\{a_n\}$. Then use

WRITING PROJECT | HOW NEWTON DISCOVERED THE BINOMIAL SERIES

The Binomial Theorem, which gives the expansion of $(a + b)^k$, was known to Chinese mathematicians many centuries before the time of Newton for the case where the exponent k is a positive integer. In 1665, when he was 22, Newton was the first to discover the infinite series expansion of $(a + b)^k$ when k is a fractional exponent (positive or negative). He didn't publish his discovery, but he stated it and gave examples of how to use it in a letter (now called the *epistola prior*) dated June 13, 1676, that he sent to Henry Oldenburg, secretary of the Royal Society of London, to transmit to Leibniz. When Leibniz replied, he asked how Newton had discovered the binomial series. Newton wrote a second letter, the *epistola posterior* of October 24, 1676, in which he explained in great detail how he arrived at his discovery by a very indirect route. He was investigating the areas under the curves $y = (1 - x^2)^{n/2}$ from 0 to x for $n = 0, 1, 2, 3, 4, \ldots$. These are easy to calculate if n is even. By observing patterns and interpolating, Newton was able to guess the answers for odd values of n. Then he realized he could get the same answers by expressing $(1 - x^2)^{n/2}$ as an infinite series.

Write an essay on Newton's discovery of the binomial series. Start by giving the statement of the binomial series in Newton's notation (see the *epistola prior* on page 285 of [4] or page 402 of [2]). Explain why Newton's version is equivalent to Theorem 11.10.17. Then read Newton's *epistola posterior* (page 287 in [4] or page 404 in [2]) and explain the patterns that Newton discovered in the areas under the curves $y = (1 - x^2)^{n/2}$. Show how he was able to guess the areas under the remaining curves and how he verified his answers. Finally, explain how these discoveries led to the binomial series. The books by Edwards [1] and Katz [3] contain commentaries on Newton's letters.

11.11 Applications of Taylor Polynomials

In this section we explore two types of applications of Taylor polynomials. First we look at how they are used to approximate functions—computer scientists employ them because polynomials are the simplest of functions. Then we investigate how physicists and engineers use them in such fields as relativity, optics, blackbody radiation, electric dipoles, the velocity of water waves, and building highways across a desert.

■ Approximating Functions by Polynomials

Suppose that $f(x)$ is equal to the sum of its Taylor series at a:

$$f(x) = \sum_{n=0}^{\infty} \frac{f^{(n)}(a)}{n!} (x - a)^n$$

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

In Section 11.10 we introduced the notation $T_n(x)$ for the nth partial sum of this series and called it the nth-degree Taylor polynomial of f at a. Thus

$$T_n(x) = \sum_{i=0}^{n} \frac{f^{(i)}(a)}{i!}(x-a)^i$$

$$= f(a) + \frac{f'(a)}{1!}(x-a) + \frac{f''(a)}{2!}(x-a)^2 + \cdots + \frac{f^{(n)}(a)}{n!}(x-a)^n$$

Since f is the sum of its Taylor series, we know that $T_n(x) \to f(x)$ as $n \to \infty$ and so T_n can be used as an approximation to f: $f(x) \approx T_n(x)$.

Notice that the first-degree Taylor polynomial

$$T_1(x) = f(a) + f'(a)(x-a)$$

is the same as the linearization of f at a that we discussed in Section 3.10. Notice also that T_1 and its derivative have the same values at a that f and f' have. In general, it can be shown that the derivatives of T_n at a agree with those of f up to and including derivatives of order n.

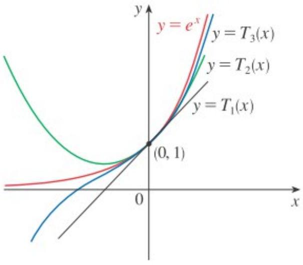

FIGURE 1

	$x = 0.2$	$x = 3.0$
$T_2(x)$	1.220000	8.500000
$T_4(x)$	1.221400	16.375000
$T_6(x)$	1.221403	19.412500
$T_8(x)$	1.221403	20.009152
$T_{10}(x)$	1.221403	20.079665
e^x	1.221403	20.085537

To illustrate these ideas let's take another look at the graphs of $y = e^x$ and its first few Taylor polynomials, as shown in Figure 1. The graph of T_1 is the tangent line to $y = e^x$ at $(0, 1)$; this tangent line is the best linear approximation to e^x near $(0, 1)$. The graph of T_2 is the parabola $y = 1 + x + x^2/2$, and the graph of T_3 is the cubic curve $y = 1 + x + x^2/2 + x^3/6$, which is a closer fit to the exponential curve $y = e^x$ than T_2. The next Taylor polynomial T_4 would be an even better approximation, and so on.

The values in the table give a numerical demonstration of the convergence of the Taylor polynomials $T_n(x)$ to the function $y = e^x$. We see that when $x = 0.2$ the convergence is very rapid, but when $x = 3$ it is somewhat slower. In fact, the farther x is from 0, the more slowly $T_n(x)$ converges to e^x.

When using a Taylor polynomial T_n to approximate a function f, we have to ask the questions: How good an approximation is it? How large should we take n to be in order to achieve a desired accuracy? To answer these questions we need to look at the absolute value of the remainder:

$$|R_n(x)| = |f(x) - T_n(x)|$$

There are three possible methods for estimating the size of the error:

1. We can use a calculator or computer to graph $|R_n(x)| = |f(x) - T_n(x)|$ and thereby estimate the error.
2. If the series happens to be an alternating series, we can use the Alternating Series Estimation Theorem.
3. In all cases we can use Taylor's Inequality (Theorem 11.10.9), which says that if $|f^{(n+1)}(x)| \leqslant M$, then

$$|R_n(x)| \leqslant \frac{M}{(n+1)!}|x-a|^{n+1}$$

EXAMPLE 1

(a) Approximate the function $f(x) = \sqrt[3]{x}$ by a Taylor polynomial of degree 2 at $a = 8$.
(b) How accurate is this approximation when $7 \leqslant x \leqslant 9$?

Copyright 2021 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

SOLUTION

(a)

$$\begin{aligned} f(x) &= \sqrt[3]{x} = x^{1/3} & f(8) &= 2 \\ f'(x) &= \tfrac{1}{3}x^{-2/3} & f'(8) &= \tfrac{1}{12} \\ f''(x) &= -\tfrac{2}{9}x^{-5/3} & f''(8) &= -\tfrac{1}{144} \\ f'''(x) &= \tfrac{10}{27}x^{-8/3} \end{aligned}$$

Thus the second-degree Taylor polynomial is

$$\begin{aligned} T_2(x) &= f(8) + \frac{f'(8)}{1!}(x-8) + \frac{f''(8)}{2!}(x-8)^2 \\ &= 2 + \tfrac{1}{12}(x-8) - \tfrac{1}{288}(x-8)^2 \end{aligned}$$

The desired approximation is

$$\sqrt[3]{x} \approx T_2(x) = 2 + \tfrac{1}{12}(x-8) - \tfrac{1}{288}(x-8)^2$$

(b) The Taylor series is not alternating when $x < 8$, so we can't use the Alternating Series Estimation Theorem in this example. But we can use Taylor's Inequality with $n = 2$ and $a = 8$:

$$|R_2(x)| \leqslant \frac{M}{3!}|x-8|^3$$

where $|f'''(x)| \leqslant M$. Because $x \geqslant 7$, we have $x^{8/3} \geqslant 7^{8/3}$ and so

$$f'''(x) = \frac{10}{27} \cdot \frac{1}{x^{8/3}} \leqslant \frac{10}{27} \cdot \frac{1}{7^{8/3}} < 0.0021$$

Therefore we can take $M = 0.0021$. Also $7 \leqslant x \leqslant 9$, so $-1 \leqslant x - 8 \leqslant 1$ and $|x - 8| \leqslant 1$. Then Taylor's Inequality gives

$$|R_2(x)| \leqslant \frac{0.0021}{3!} \cdot 1^3 = \frac{0.0021}{6} < 0.0004$$

Thus, if $7 \leqslant x \leqslant 9$, the approximation in part (a) is accurate to within 0.0004. ■

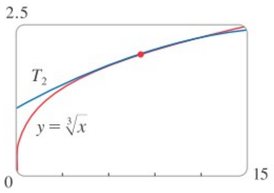

FIGURE 2

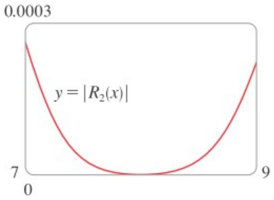

FIGURE 3

Let's check the calculation in Example 1 graphically. Figure 2 shows that the graphs of $y = \sqrt[3]{x}$ and $y = T_2(x)$ are very close to each other when x is near 8. Figure 3 shows the graph of $|R_2(x)|$ computed from the expression

$$|R_2(x)| = |\sqrt[3]{x} - T_2(x)|$$

We see from the graph that

$$|R_2(x)| < 0.0003$$

when $7 \leqslant x \leqslant 9$. Thus the error estimate from graphical methods is slightly better than the error estimate from Taylor's Inequality in this case.

EXAMPLE 2

(a) What is the maximum error possible in using the approximation

$$\sin x \approx x - \frac{x^3}{3!} + \frac{x^5}{5!}$$

when $-0.3 \leqslant x \leqslant 0.3$? Use this approximation to find sin 12° correct to six decimal places.

(b) For what values of x is this approximation accurate to within 0.00005?

Copyright 2021 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

SOLUTION

(a) Notice that the Maclaurin series

$$\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \cdots$$

is alternating for all nonzero values of x, and the successive terms decrease in size because $|x| < 1$, so we can use the Alternating Series Estimation Theorem. The error in approximating $\sin x$ by the first three terms of its Maclaurin series is at most

$$\left| \frac{x^7}{7!} \right| = \frac{|x|^7}{5040}$$

If $-0.3 \leqslant x \leqslant 0.3$, then $|x| \leqslant 0.3$, so the error is smaller than

$$\frac{(0.3)^7}{5040} \approx 4.3 \times 10^{-8}$$

To find sin 12° we first convert to radian measure:

$$\begin{aligned} \sin 12° &= \sin\left(\frac{12\pi}{180}\right) = \sin\left(\frac{\pi}{15}\right) \\ &\approx \frac{\pi}{15} - \left(\frac{\pi}{15}\right)^3 \frac{1}{3!} + \left(\frac{\pi}{15}\right)^5 \frac{1}{5!} \approx 0.20791169 \end{aligned}$$

Thus, correct to six decimal places, $\sin 12° \approx 0.207912$.

(b) The error will be smaller than 0.00005 if

$$\frac{|x|^7}{5040} < 0.00005$$

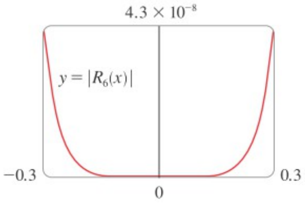

FIGURE 4

Solving this inequality for x, we get

$$|x|^7 < 0.252 \qquad \text{or} \qquad |x| < (0.252)^{1/7} \approx 0.821$$

So the given approximation is accurate to within 0.00005 when $|x| < 0.82$. ■

What if we use Taylor's Inequality to solve Example 2? Since $f^{(7)}(x) = -\cos x$, we have $|f^{(7)}(x)| \leqslant 1$ and so

$$|R_6(x)| \leqslant \frac{1}{7!}|x|^7$$

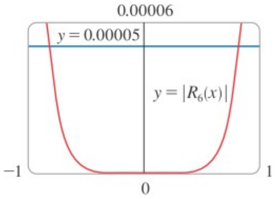

FIGURE 5

So we get the same estimates as with the Alternating Series Estimation Theorem.

What about graphical methods? Figure 4 shows the graph of

$$|R_6(x)| = \left|\sin x - \left(x - \tfrac{1}{6}x^3 + \tfrac{1}{120}x^5\right)\right|$$

and we see from it that $|R_6(x)| < 4.3 \times 10^{-8}$ when $|x| \leqslant 0.3$. This is the same estimate that we obtained in Example 2. For part (b) we want $|R_6(x)| < 0.00005$, so we graph both $y = |R_6(x)|$ and $y = 0.00005$ in Figure 5. From the coordinates of the right intersection point we find that the inequality is satisfied when $|x| < 0.82$. Again this is the same estimate that we obtained in the solution to Example 2.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

If we had been asked to approximate sin 72° instead of sin 12° in Example 2, it would have been wise to use the Taylor polynomials at $a = \pi/3$ (instead of $a = 0$) because they are better approximations to $\sin x$ for values of x close to $\pi/3$. Notice that 72° is close to 60° (or $\pi/3$ radians) and the derivatives of $\sin x$ are easy to compute at $\pi/3$.

Figure 6 shows the graphs of the Maclaurin polynomial approximations

$$T_1(x) = x \qquad\qquad T_3(x) = x - \frac{x^3}{3!}$$

$$T_5(x) = x - \frac{x^3}{3!} + \frac{x^5}{5!} \qquad\qquad T_7(x) = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!}$$

to the sine curve. You can see that as n increases, $T_n(x)$ is a good approximation to $\sin x$ on a larger and larger interval.

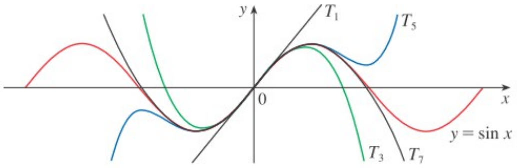

FIGURE 6

One use of the type of calculation done in Examples 1 and 2 occurs in calculators and computers. For instance, when you press the sin or e^x key on your calculator, or when a computer programmer uses a subroutine for a trigonometric or exponential or Bessel function, in many machines a polynomial approximation is calculated. The polynomial is often a Taylor polynomial that has been modified so that the error is spread more evenly throughout an interval.

Applications to Physics

Taylor polynomials are also used frequently in physics. In order to gain insight into an equation, a physicist often simplifies a function by considering only the first two or three terms in its Taylor series. In other words, the physicist uses a Taylor polynomial as an approximation to the function. Taylor's Inequality can then be used to gauge the accuracy of the approximation. The following example shows one way in which this idea is used in special relativity.

EXAMPLE 3 In Einstein's theory of special relativity the mass m of an object moving with velocity v is

$$m = \frac{m_0}{\sqrt{1 - v^2/c^2}}$$

where m_0 is the mass of the object when at rest and c is the speed of light. The kinetic energy k of the object is the difference between its total energy and its energy at rest:

$$K = mc^2 - m_0c^2$$

(a) Show that when v is very small compared with c, this expression for K agrees with classical Newtonian physics: $K = \frac{1}{2}m_0v^2$.

Copyright 2021 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

(b) Use Taylor's Inequality to estimate the difference in these expressions for K when $|v| \leqslant 100$ m/s.

SOLUTION

(a) Using the expressions given for K and m, we get

$$K = mc^2 - m_0c^2 = \frac{m_0c^2}{\sqrt{1 - v^2/c^2}} - m_0c^2 = m_0c^2\left[\left(1 - \frac{v^2}{c^2}\right)^{-1/2} - 1\right]$$

With $x = -v^2/c^2$, the Maclaurin series for $(1 + x)^{-1/2}$ is most easily computed as a binomial series with $k = -\frac{1}{2}$. (Notice that $|x| < 1$ because $v < c$.) Therefore we have

The upper curve in Figure 7 is the graph of the expression for the kinetic energy K of an object with velocity v in special relativity. The lower curve shows the function used for K in classical Newtonian physics. When v is much smaller than the speed of light, the curves are practically identical.

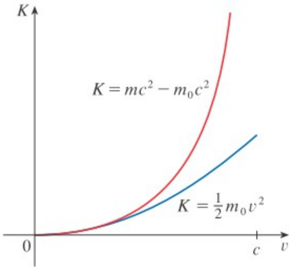

FIGURE 7

$$\begin{aligned}(1 + x)^{-1/2} &= 1 - \tfrac{1}{2}x + \frac{\left(-\frac{1}{2}\right)\left(-\frac{3}{2}\right)}{2!}x^2 + \frac{\left(-\frac{1}{2}\right)\left(-\frac{3}{2}\right)\left(-\frac{5}{2}\right)}{3!}x^3 + \cdots \\ &= 1 - \tfrac{1}{2}x + \tfrac{3}{8}x^2 - \tfrac{5}{16}x^3 + \cdots\end{aligned}$$

and

$$\begin{aligned}K &= m_0c^2\left[\left(1 + \frac{1}{2}\frac{v^2}{c^2} + \frac{3}{8}\frac{v^4}{c^4} + \frac{5}{16}\frac{v^6}{c^6} + \cdots\right) - 1\right] \\ &= m_0c^2\left(\frac{1}{2}\frac{v^2}{c^2} + \frac{3}{8}\frac{v^4}{c^4} + \frac{5}{16}\frac{v^6}{c^6} + \cdots\right)\end{aligned}$$

If v is much smaller than c, then all terms after the first are very small when compared with the first term. If we omit them, we get

$$K \approx m_0c^2\left(\frac{1}{2}\frac{v^2}{c^2}\right) = \tfrac{1}{2}m_0v^2$$

(b) If $x = -v^2/c^2$, $f(x) = m_0c^2[(1 + x)^{-1/2} - 1]$, and M is a number such that $|f''(x)| \leqslant M$, then we can use Taylor's Inequality to write

$$|R_1(x)| \leqslant \frac{M}{2!}x^2$$

We have $f''(x) = \frac{3}{4}m_0c^2(1 + x)^{-5/2}$ and we are given that $|v| \leqslant 100$ m/s, so

$$|f''(x)| = \frac{3m_0c^2}{4(1 - v^2/c^2)^{5/2}} \leqslant \frac{3m_0c^2}{4(1 - 100^2/c^2)^{5/2}} \quad (=M)$$

Thus, with $c = 3 \times 10^8$ m/s,

$$|R_1(x)| \leqslant \frac{1}{2} \cdot \frac{3m_0c^2}{4(1 - 100^2/c^2)^{5/2}} \cdot \frac{100^4}{c^4} < (4.17 \times 10^{-10})m_0$$

So when $|v| \leqslant 100$ m/s, the magnitude of the error in using the Newtonian expression for kinetic energy is at most $(4.2 \times 10^{-10})m_0$. ■

Another application to physics occurs in optics. Figure 8 depicts a wave from the point source S meeting a spherical interface of radius R centered at C. The ray SA is refracted toward P.

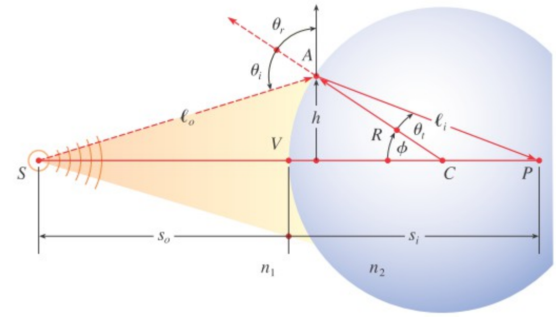

FIGURE 8
Refraction at a spherical interface

Using Fermat's principle that light travels so as to minimize the time taken, one can derive the equation

$$\boxed{1} \qquad \frac{n_1}{\ell_o} + \frac{n_2}{\ell_i} = \frac{1}{R}\left(\frac{n_2 s_i}{\ell_i} - \frac{n_1 s_o}{\ell_o}\right)$$

where n_1 and n_2 are indexes of refraction and ℓ_o, ℓ_i, s_o, and s_i are the distances indicated in Figure 8. By the Law of Cosines, applied to triangles ACS and ACP, we have

$$\boxed{2} \qquad \ell_o = \sqrt{R^2 + (s_o + R)^2 - 2R(s_o + R)\cos\phi}$$

$$\ell_i = \sqrt{R^2 + (s_i - R)^2 + 2R(s_i - R)\cos\phi}$$

Here we use the identity

$$\cos(\pi - \phi) = -\cos\phi$$

Because Equation 1 is cumbersome to work with, Gauss, in 1841, simplified it by using the linear approximation $\cos\phi \approx 1$ for small values of ϕ. (This amounts to using the Taylor polynomial of degree 1.) Then Equation 1 becomes the following simpler equation [as you are asked to show in Exercise 34(a)]:

$$\boxed{3} \qquad \frac{n_1}{s_o} + \frac{n_2}{s_i} = \frac{n_2 - n_1}{R}$$

The resulting optical theory is known as *Gaussian optics*, or *first-order optics*, and has become the basic theoretical tool used to design lenses.

A more accurate theory is obtained by approximating $\cos\phi$ by its Taylor polynomial of degree 3 (which is the same as the Taylor polynomial of degree 2). This takes into account rays for which ϕ is not so small, that is, rays that strike the surface at greater distances h above the axis. In Exercise 34(b) you are asked to use this approximation to derive the more accurate equation

$$\boxed{4} \qquad \frac{n_1}{s_o} + \frac{n_2}{s_i} = \frac{n_2 - n_1}{R} + h^2\left[\frac{n_1}{2s_o}\left(\frac{1}{s_o} + \frac{1}{R}\right)^2 + \frac{n_2}{2s_i}\left(\frac{1}{R} - \frac{1}{s_i}\right)^2\right]$$

The resulting optical theory is known as *third-order optics.*

Other applications of Taylor polynomials to physics and engineering are explored in Exercises 32, 33, 35, 36, 37, and 38, and in the Applied Project following this section.

(xi) *f is $\mathbb{C}$-differentiable in $S := [0,1] \times [0,1]$ and ε is positive. By an ε-*decomposition *of S is meant a decomposition into finitely many closed squares S_j whose sides are parallel to the coordinate axes and whose interiors are disjoint, such that each S_j contains a point z_j satisfying*

$$(6.j) \qquad |f(z) - [f(z_j) + f'(z_j)(z - z_j)]| \le \varepsilon |z - z_j| \qquad \forall z \in S_j.$$

Prove that S has such a decomposition (Goursat [1900]).

Hints: If not, then when S is divided into four congruent subsquares, at least one will have no ε-decomposition. Proceed inductively to get a decreasing sequence of closed squares S_n having side-length 2^{-n} and no ε-decomposition. The finite-intersection property of compacta supplies a point $z_0 \in \cap S_n$. As S_n has no ε-decomposition and $z_0 \in S_n$, there must be $z_n \in S_n \setminus \{z_0\}$ with

$$|f(z_n) - [f(z_0) + f'(z_0)\ (z_n - z_0)]| > \varepsilon |z_n - z_0|.$$

Division by $z_n - z_0$ then contradicts differentiability of f at z_0, since $z_n \to z_0$.

(xii) *With f and S_j, having side-length ℓ_j, as in* (xi), *show that*

$$(7.j) \qquad \left| \int_{\partial S_j} f \right| \le 4\varepsilon \ell_j \cdot \sup_{z \in S_j} |z - z_j| \le 8\varepsilon \ell_j^2.$$

Hints: Since the bracketed expression in (6.j) integrates to 0 [2.10(ii)], we have $\int_{\partial S_j} f = \int_{\partial S_j} (f(z) - [f(z_j) + f'(z_j)(z - z_j)]dz$, and because of inequality (6.j) and 2.9(ii), the latter integral is majorized as claimed.

(xiii) *Continuing with* (xii), *show that $\sum_j |\int_{\partial S_j} f| \le 8\varepsilon$.*

Hint: Since the S_j lie in S and have disjoint interiors, $\sum_j \ell_j^2 = \sum_j \text{area}(S_j) \le \text{area}(S)$.

(xiv) *For f, S as in* (xi), *does* (xiii) *justify the conclusion $\int_{\partial S} f = 0$?* (Cf. de la Vallée Poussin [1914].)

Hint: Although the details are a combinatorial headache, one can *prove* the (obvious?) equality $\int_{\partial S} f = \sum_j \int_{\partial S_j} f$. *Granted this*, it follows from (xiii) that $|\int_{\partial S} f| \le 8\varepsilon$, an inequality that holds for every $\varepsilon > 0$.

Remarks: As will be seen, $\int_{\partial R} f = 0$ (gotten as in (v) by Cauchy in 1846) leads to the remarkable fact that f is infinitely often differentiable and even (3.6) of power-series type in R. Cauchy suspected that the continuity hypothesis in (v) was unnecessary, but this was only confirmed in 1900, 43 years after his death. Modulo a (non-)trivial detail, the argument in 2.19(xiv) proves this. A combinatorially simpler proof, also featuring the method of descent, will be given in 5.1 (which the reader could easily turn to right now!). Neither of these proofs involves Green. But one can adapt these arguments to prove Green under the weaker hypothesis that $D_2f - iD_1f$ merely be Riemann double-integrable over R. Evidently (v) without the continuity hypothesis is a corollary of this improved Green's theorem. See Bochner [1955b], P. J. Cohen [1959], Craven [1964], Grunsky [1966], Acker [1996] and Greenlee [2004/05]. See also **MR** 2005e:30069.

The aforementioned power-series representation of a holomorphic function comes from expanding the kernel in a certain integral representation of the function (as in 3.8), which in turn is derived from Cauchy's Integral Theorem 2.19(v) by an ingenious idea that the next exercise sketches, but which gets a fuller treatment in chapter V. See also 3.39 and the remarks following it. It is noteworthy that by itself 2.19(v) is able to provide a brief, elegant proof of the fundamental theorem of algebra, essentially Gauss' third proof freed of reference to the transcendental functions sine and cosine (cf. also the remarks following 5.5).

Exercise 2.20 *Let $a, b, c, d \in \mathbb{R}$ with $a < b, c < d$, $R := (a, b) \times (c, d)$, $\overline{R} \subset U$ open $\subset \mathbb{C}$.*

(i) *Suppose $z_0 \in R$, $F : U \setminus \{z_0\} \mapsto \mathbb{C}$ is holomorphic, is bounded near z_0, and F' is continuous. Show that $\int_{\partial R} F = 0$.*

Hints: For $r > 0$ sufficiently small and $S_r := (-r, r) \times (-r, r)$, we have $z_0 + \overline{S}_r \subset R$. Extend the sides of the square $z_0 + S_r$ and thereby pave R as the union of this square and eight rectangles disjoint from it. To each of the latter 2.19(v) is applicable. When the integrals over the boundaries of these rectangles are written as sums of integrals over intervals and added, significant cancellation occurs, resulting in

$$0 = \int_{\partial R} F - \int_{z_0 + \partial S_r} F.$$

Since F is bounded near z_0 and $l(z_0 + \partial S_r) = 8r$, it follows from 2.9(i) that the second integral converges to 0 with r.

(ii) *Suppose f is holomorphic and f' is continuous in U. Show that*

$$f(z_0) \int_{\partial R} \frac{d\xi}{\xi - z_0} = \int_{\partial R} \frac{f(\xi)}{\xi - z_0} d\xi \qquad \forall z_0 \in R.$$

Hint: For each $z_0 \in R$ part (i) is applicable to the function defined by $F(z_0) := f'(z_0)$, $F(z) := (f(z) - f(z_0))/(z - z_0)$ for $z \in U \setminus \{z_0\}$. An alternative proof method is the Fubini argument employed in 3.39(ii).

(iii) *Using* 2.15(iii) *and the paving technique in the hints above, show that*

$$\int_{\partial R} \frac{d\xi}{\xi - z_0} = 8i \int_0^1 \frac{du}{u^2+1} \qquad \forall z_0 \in R.$$

(iv) *Combine* (ii) *and* (iii) *to prove the following weak version of* Cauchy's Integral Formula: *If f is holomorphic and f' is continuous in a neighborhood of $\overline{R}$, then*

$$f(z) = \frac{1}{2pi} \int_{\partial R} \frac{f(\xi)}{\xi - z} d\xi \qquad \forall z \in R,$$

where $p := 4\int_0^1 \frac{du}{u^2+1}$. Infer (2.14) *that f is $\mathbb{C}$-differentiable of all orders!*

(v) *Suppose P is a complex polynomial of degree n with no zeros in $\mathbb{C}$. Use the (obvious) fact that $\lim_{|z|\to\infty} zP'(z)/P(z) = n$ to deduce that*

$$\lim_{r\to\infty} \int_{\partial S_r} \frac{P'}{P} = 8n \int_0^1 \frac{1}{\gamma},$$

where $S_r := (-r, r) \times (-r, r)$ and $\gamma := [-1-i, 1-i]$.

Hints: Set $f := P'/P$. Note that $\gamma' = 2$ and $\operatorname{Im}\gamma = -1$. As in the hint to 2.15(iii), the intervals comprising the polygonal loop ∂S_r are $r\gamma$, $ir\gamma$, $-r\gamma$, $-ir\gamma$, so 2.9(ii) together with the fact $\gamma' = 2$ gives

$$\int_{\partial S_r} f = 2\sum_{k=0}^{3} \int_0^1 \frac{i^k r\gamma f \circ (i^k r\gamma)}{\gamma}.$$

Since $|\gamma| \ge |\operatorname{Im}\gamma| = 1$, we have $|r\gamma| \to \infty$ uniformly on $[0,1]$ as $r \uparrow \infty$. Consequently, $\lim_{|z|\to\infty} zf(z) = n$ implies that each integrand on the right converges to n/γ, uniformly on $[0,1]$ as $r \uparrow \infty$.

(vi) (FTA) *From* (v) *and Cauchy's theorem* 2.19(v) *infer that every nonconstant complex polynomial has a zero in* $\mathbb{C}$.

Hints: If P is a complex polynomial of degree n which has no zeros in $\mathbb{C}$, then $f := P'/P$ is holomorphic and f' is continuous in $\mathbb{C}$. Hence by 2.19(v) every integral on the left-hand side of the equality in part (v) above is 0. From that equality and the fact that $\operatorname{Im}\gamma = -1$ therefore follows

$$0 = \operatorname{Im}\left(8n \int_0^1 \frac{1}{\gamma}\right) = 8n \operatorname{Im} \int_0^1 \frac{\bar{\gamma}}{|\gamma|^2} = 8n \int_0^1 \frac{1}{|\gamma|^2},$$

not entirely trivial fact: see Minda [1973] (and 5.71 below). For more general results see Rogers and Zame [1982].

Though adumbrated by Gauss and Poisson, the idea of the complex contour integral in 2.8 was codified by Cauchy in his famous 1825 memoir. See Stäckel [1900], [1901], Ettlinger [1921–22], Yuškevič [1947] and chapter 4 of Smithies [1997]. Eighteenth-century mathematicians sometimes (but with suspicion) made an “imaginary substitution” in an integral (that is, a $\mathbb{C}$-valued change of variable, 11.33 and the generalized Fresnel integral in Remark (ii) following 11.32 being historically significant examples, and $x := it$ in $\int_{-\infty}^{\infty}(1+x^4)^{-1}dx$ being one reason for suspicion); this can be seen as foreshadowing the contour integral, and it was still the prevalent view in Cauchy’s early work. See pp. 10–23 of Smithies [1997].

Much work has gone into efforts to weaken the conditions in 2.17 and these conditions can indeed be considerably relaxed. The natural global converse of 2.16(i) is:

> *If f is continuous, D_1f, D_2f exist and satisfy* (C. R.) *throughout an open set U, then $f \in H(U)$.*

But it is not significantly easier to prove than the following:

Theorem (Looman [1923], Ridder [1930a], Wilkosz [1933], Menchoff [1936]) *If f is continuous on U, D_1f and D_2f each exist at all but countably many points of U and the equation* (C. R.) *holds almost everywhere in U (in the sense of plane Lebesgue measure), then f is holomorphic in U.*

In fact there is nothing exceptional about the horizontal and vertical directional derivatives here: Menchoff [1935] showed that if f is continuous on U and through each $z_0 \in U$ there pass two distinct lines $L_1(z_0)$, $L_2(z_0)$ such that

$$\lim_{\substack{z\to z_0\\ z\in L_1(z_0)}} \frac{f(z)-f(z_0)}{z-z_0} \quad \text{and} \quad \lim_{\substack{z\to z_0\\ z\in L_2(z_0)}} \frac{f(z)-f(z_0)}{z-z_0}$$

exist and coincide, then f is holomorphic in U. For some remarkable counterexamples when the continuity hypothesis of the theorem is absent, see Pelling [1979].

The requirement of differentiability at every point in the definition 2.1 of holomorphy can also be relaxed. 5.41, 5.42 and 9.28 are examples; here is another:

Theorem (Pompeiu [1905a], Looman [1922/1924], Ridder [1930a]) *If f is continuous in U, $\overline{\lim}_{h\to 0}\left|(f(z+h)-f(z))/h\right|$ is finite for all but countably*

(2) The group of units of $\mathbb{Z}$ is the group $U_2 = \{\pm 1\}$ under multiplication.

(3) The group of units of the matrix ring $M_n(\mathbb{Z})$ is the group $GL_n(\mathbb{Z})$ (or $\mathbb{Q}, \mathbb{R}, \mathbb{C}$).

Since not all rings are commutative, many of the facts to which you're likely accustomed are not quite the same. The following technical theorem is designed to bring these differences to light.

Theorem 12.9. *Let R be a ring.*

(1) *Let $a, b \in R$. Then $(a+b)^2 = a^2 + 2ab + b^2$ if and only if $ab = ba$.*

(2) $\left(\sum_{i=1}^{n} a_i\right)\left(\sum_{j=1}^{m} b_j\right) = \sum_{i=1}^{n}\sum_{j=1}^{m} a_i b_j$ *for all $a_i, b_j \in R$.*

(3) *If R is a commutative ring, then $(a+b)^n = \sum_{i=0}^{n} \binom{n}{i} a^{n-i} b^i$ for all integers $n \geq 1$, where $a^n b^0 = a^n$ and $a^0 b^n = b^n$.*

In general, to compute $(a_1 + a_2 + \cdots + a_k)^n$ in an arbitrary ring, list every possible ordering of products of n elements chosen from the set $\{a_1, a_2, \ldots, a_k\}$ and add those k^n elements up. The last part of Theorem 12.9 is called the **Binomial Theorem**, and it simply provides a simpler result in the case where R is commutative.

Finally, we can define subrings in the same way that we defined subgroups, with a similar condition on recognizing them, but without any special notation. But beware: your knowledge about subgroups might lead your intuition astray when it comes to subrings, as you're about to discover.

Definition 12.10. Let R be a ring and S a subset of R. Then S is a **subring** of R if and only if S is a ring under the two operations of addition and multiplication induced by those operations on R.

Theorem 12.11. *Let R be a ring and S a subset of R. Then S is a subring of R if and only if S is an additive subgroup of R and S is closed under multiplication.*

Example 12.12. There are far fewer subrings for you to know than there are for subgroups.

(1) For any nonnegative integer n, the set $n\mathbb{Z}$ is a subring of $\mathbb{Z}$. When $n \neq 1$, the ring does not have unity.

(2) As with groups, $\mathbb{Z}$ is a subring of $\mathbb{Q}$, which is a subring of $\mathbb{R}$, which is a subring of $\mathbb{C}$.

(3) The Gaussian integers $\mathbb{Z}[i]$ is a subring of $\mathbb{C}$. It has four units: ± 1 and $\pm i$.

Exercise 12.13. Be careful not to assume that everything you know about subgroups is the same for subrings. Consider the ring $R = \mathbb{Z} \times \mathbb{Z}$ and the subset $S = \mathbb{Z} \times \{0\}$. Show that R has a unity element, that S is a subring of R, that the unity element of R is not in S, and that S is a subring *with unity* (in other words, show that S has a unity element different from the unity element of R)!

The reason for this shocking exercise is to focus your attention on the nature of equations dealing with multiplication. Specifically, in a ring with unity, the equation

$ax = a$ has a solution $x = \mathbf{1}$, but it need not be the *unique* solution. This kind of example happens all the time in linear algebra: pick a noninvertible $n \times n$ matrix A, and you can always find multiple solutions to the equation $AX = A$.

Example 12.14. Your instincts in solving equations like $ax = a$ in rings will likely involve canceling the common factor of a on both sides. In group theory, that's no problem, since every element has an inverse. But elements in rings routinely lack multiplicative inverses, which means there is no general cancellation law. So, for instance:

(1) In the ring $\mathbb{Z}_{10}$, the equation $2x = 2$ has two solutions: $x = 1$ and $x = 6$.

(2) In the ring $2\mathbb{Z}$, the equation $2x = 2$ has no solutions whatsoever.

(3) In the ring $\mathbb{Z}_8$, the equation $4x = 4$ has four solutions: $x = 1, 3, 5,$ and 7.

(4) In the ring $M_2(\mathbb{R})$, the equation $\begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix} X = \begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix}$ has infinitely many solutions; any 2×2 matrix whose column sums equal 1 will work.

So, when solving equations in rings, be very careful when dealing with multiplication. It is *not* a group operation!

Let's close this section with at least one fact that does have a parallel from group theory.

Theorem 12.15. *Let R be a ring and $\mathcal{C}$ be a nonempty collection of subrings of R. Then $\bigcap_{S \in \mathcal{C}} S$ is a subring of R.*

Definition 12.16. Let R be a ring and A be any subset of R. Then the **subring generated by** A is the intersection of all subrings of R containing A. We say that A is a **generating set** for a subring S if and only if the subring generated by A is the subring S.

Theorem 12.17. *Let R be a ring and $r \in R$. Then the subring generated by r is the set*

$$\{n_0 + n_1 r + n_2 r^2 + \cdots + n_k r^k \mid k, n_i \in \mathbb{Z}, k \geq 0\}.$$

12.2 Homomorphisms

Just as we did with groups, we need to develop a notion of maps between rings that preserve structure. Now that we have two operations to deal with, those maps need to preserve both structures.

Definition 12.18. Let R and R' be rings and $\phi : R \to R'$ be a function. Then ϕ is a **(ring) homomorphism** if $\phi(a + b) = \phi(a) + \phi(b)$ and $\phi(ab) = \phi(a)\phi(b)$ for all $a, b \in R$. A ring homomorphism ϕ is an **isomorphism** if and only if ϕ is also a bijection, and a ring **automorphism** is a ring isomorphism from a ring to itself. Two rings are **isomorphic** if and only if there is a ring isomorphism from one ring to the other.

Notice that since ring homomorphisms and isomorphisms are, in fact, group homomorphisms and group isomorphisms under addition, all of the results from group theory still apply to the additive structure of a ring. On the other hand, since the multiplicative structure of a ring isn't a group structure, we don't get all of the nice multiplicative properties we might hope for. However, if you have a ring *isomorphism*, then all of the algebraic properties like commutativity, unity, and inverses are preserved, as well as unity and inverses being mapped to unity and inverses. Yet even with ring homomorphisms, we do get a few nice properties similar to our results from groups.

Theorem 12.19. *Let $\phi : R \to R'$ be a ring homomorphism.*

(1) $\phi(a^n) = \phi(a)^n$ *for all* $a \in R$ *and* $n \in \mathbb{Z}^+$.

(2) *If S is a subring of R, then $\phi(S)$ is a subring of R', and if S is commutative, then $\phi(S)$ is also commutative.*

(3) *If S' is a subring of R', then $\phi^{-1}(S')$ is a subring of R.*

Definition 12.20. Let $\phi : R \to R'$ be a homomorphism, where R, R' are rings. Then the subring $\phi^{-1}(\mathbf{0}) = \{r \in R \mid \phi(r) = \mathbf{0}\}$ is called the **kernel** of ϕ, denoted $Ker(\phi)$.

Theorem 12.21. *Let $\phi : R \to R'$ be a ring homomorphism. Then ϕ is injective if and only if $Ker(\phi) = \{\mathbf{0}\}$.*

Exercise 12.22. Which, if any, of the following functions are ring homomorphisms? Of those that are (if any), what is the kernel of the homomorphism? Are any isomorphisms?

(1) $\phi : \mathbb{Z} \to \mathbb{Z}; \quad \phi(x) = 2x.$

(2) $\phi : \mathbb{Z} \to \mathbb{Z}_5; \quad \phi(x) = r_x$, where r_x is the remainder of x when divided by 5.

(3) $\phi : \mathbb{Z}_{mn} \to \mathbb{Z}_m \times \mathbb{Z}_n; \quad \phi(x) = (r_x, s_x)$, where r_x and s_x are the remainders of x when divided by m and n, respectively.

(4) $\phi : M_n(\mathbb{R}) \to \mathbb{R}; \quad \phi(A) = \det(A).$

There's one last theorem to prove in this section. It's not hard, but it's easy to misapply this theorem.

Theorem 12.23. *Let $\phi : R \to R'$ be a ring homomorphism. If R is a ring with unity element $\mathbf{1}$ and $\phi(\mathbf{1}) \neq \mathbf{0}$, then $\phi(\mathbf{1})$ is the unity element of the subring $\phi(R)$ of R'.*

Note that it does *not* say that the unity element of R must be mapped to the unity element of R' as it must for groups. It says that the image of the unity element must map to the unity element of the *range* of the homomorphism. In the event that ϕ is surjective, then unity gets mapped to unity. But in case you're still not seeing the difference, the following exercise should illuminate this issue.

Exercise 12.24. Let $\phi : \mathbb{Z}\times\mathbb{Z} \to \mathbb{Z}\times\mathbb{Z}$ be the function given by $\phi(a, b) = (a, 0)$. Verify that ϕ is a ring homomorphism, and that $\phi(1, 1) \neq (1, 1)$, but that $\phi(1, 1)$ is the unity element for the range of ϕ.

Exercise 12.25. Prove that there is exactly one ring automorphism of $\mathbb{Z}$, and that $n\mathbb{Z}$ and $m\mathbb{Z}$ are never isomorphic as rings when $n \neq \pm m$.

Chapter 2

Geometry

Gottfried Wilhelm (von) Leibniz (sometimes spelled Leibnitz) [11], French: Godefroi Guillaume Leibnitz;[15] 1 July 1646 [O.S. 21 June] { 14 November 1716) was a prominent German polymath and one of the most important logicians, mathematicians and natural philosophers of the Enlightenment. As a representative of the seventeenth-century tradition of rationalism, Leibniz's most prominent accomplishment was conceiving the ideas of differential and integral calculus, independently of Isaac Newton's contemporaneous developments.[16] Mathematical works have consistently favored Leibniz's notation as the conventional expression of calculus. It was only in the 20th century that Leibniz's law of continuity and transcendental law of homogeneity found mathematical implementation (by means of non-standard analysis). He became one of the most prolific inventors in the field of mechanical calculators. While working on adding automatic multiplication and division to Pascal's calculator, he was the first to describe a pinwheel calculator in 1685[17] and invented the Leibniz wheel, used in the arithmometer, the first mass-produced mechanical calculator. He also refined the binary number system, which is the foundation of all digital computers.

In philosophy, Leibniz is most noted for his optimism, i.e. his conclusion that our universe is, in a restricted sense, the best possible one that God could have created, an idea that was often lampooned by others such as Voltaire. Leibniz, along with Rene Descartes and Baruch Spinoza, was one of the three great 17th-century advocates of rationalism. The work of Leibniz anticipated modern logic and analytic philosophy, but his philosophy also assimilates elements of the scholastic tradition, notably that conclusions are produced by applying reason to first principles or prior definitions rather than to empirical evidence.

Leibniz made major contributions to physics and technology, and anticipated notions that surfaced much later in philosophy, probability theory, biology, medicine, geology, psychology, linguistics, and computer science. He wrote works on philosophy, politics, law, ethics, theology, history, and philology. Leibniz also contributed to the field of library science. While serving as overseer of the Wolfenbuttel library in Germany, he devised a cataloging system that would serve as a guide for many of Europe's largest libraries.[18] Leibniz's contributions to this vast array of subjects were scattered in various learned journals, in tens of thousands of letters, and in unpublished manuscripts. He wrote in several languages, but primarily in Latin, French, and German.[19] There is no complete gathering of the writings of Leibniz translated into English.[20]

Gottfried Leibniz was born on 1 July 1646, toward the end of the Thirty Years' War, in Leipzig, Saxony, to Friedrich Leibniz and Catharina Schmuck. Friedrich noted in his family journal:

21. Juny am Sontag 1646 Ist mein Sohn Gottfried Wilhelm, post sextam vespertinam 1/4 uff 7 uhr abents zur welt gebohren, im Wassermann.

In English:

On Sunday 21 June [NS: 1 July] 1646, my son Gottfried Wilhelm was born into the world a quarter before seven in the evening, in Aquarius.[21][22]

Leibniz was baptized on 3 July of that year at St. Nicholas Church, Leipzig; his godfather was the Lutheran theologian Martin Geier [de].[23] His father died when he was six years old, and from that point on he was raised by his mother.[24]

Leibniz's father had been a Professor of Moral Philosophy at the University of Leipzig, and the boy later inherited his father's personal library. He was given free access to it from the age of seven. While Leibniz's schoolwork was largely confined to the study of a small canon of authorities, his father's library enabled him to study a wide variety of advanced philosophical and theological works|ones that he would not have otherwise been able to read until his college years.[25] Access to his father's library, largely written in Latin, also led to his proficiency in the Latin language, which he achieved by the age of 12. He also composed 300 hexameters of Latin verse, in a single morning, for a special event at school at the age of 13.[26]

In April 1661 he enrolled in his father's former university at age 14,[27][1][28] and completed his bachelor's degree in Philosophy in December 1662. He defended his Disputatio Metaphysica de Principio Individui (Metaphysical Disputation on the Principle of Individuation),[29] which addressed the principle of individuation, on 9 June 1663. Leibniz earned his master's degree in Philosophy on 7 February 1664. He published and defended a dissertation Specimen Quaestionum Philosophicarum ex Jure collectarum (An Essay of Collected Philosophical Problems of Right),[29] arguing for both a theoretical and a pedagogical relationship between philosophy and law, in December

1664. After one year of legal studies, he was awarded his bachelor's degree in Law on 28 September 1665.[30] His dissertation was titled De conditionibus (On Conditions).[29]

In early 1666, at age 19, Leibniz wrote his first book, De Arte Combinatoria (On the Combinatorial Art), the first part of which was also his habilitation thesis in Philosophy, which he defended in March 1666.[29][31] His next goal was to earn his license and Doctorate in Law, which normally required three years of study. In 1666, the University of Leipzig turned down Leibniz's doctoral application and refused to grant him a Doctorate in Law, most likely due to his relative youth.[32][33] Leibniz subsequently left Leipzig.[34]

Leibniz then enrolled in the University of Altdorf and quickly submitted a thesis, which he had probably been working on earlier in Leipzig.[35] The title of his thesis was Disputatio Inauguralis de Casibus Perplexis in Jure (Inaugural Disputation on Ambiguous Legal Cases).[29] Leibniz earned his license to practice law and his Doctorate in Law in November 1666. He next declined the offer of an academic appointment at Altdorf, saying that "my thoughts were turned in an entirely different direction".[36]

As an adult, Leibniz often introduced himself as "Gottfried von Leibniz". Many posthumously published editions of his writings presented his name on the title page as "Freiherr G. W. von Leibniz." However, no document has ever been found from any contemporary government that stated his appointment to any form of nobility.[37]

A **metric space** is an ordered pair (M, d) where M is a set and d is a metric on M, i.e., a function

$$d\colon M \times M \to \mathbb{R}$$

such that for any $x, y, z \in M$, the following holds:[2]

1. $d(x,y) = 0 \Leftrightarrow x = y$ identity of indiscernibles
2. $d(x,y) = d(y,x)$ symmetry
3. $d(x,z) \leq d(x,y) + d(y,z)$ subadditivity or triangle inequality

Given the above three axioms, we also have that $d(x,y) \geq 0$ for any $x, y \in M$. This is deduced as follows:

$d(x,y) + d(y,x) \geq d(x,x)$	by triangle inequality
$d(x,y) + d(x,y) \geq d(x,x)$	by symmetry
$2d(x,y) \geq 0$	by identity of indiscernibles
$d(x,y) \geq 0$	we have non-negativity

Figure 2.114: Metric Space - Wiki.png

2.6 Metric Space

1) Metric space From Wikipedia, the free encyclopedia Jump to navigation Jump to search

In mathematics, a metric space is a set together with a metric on the set. The metric is a function that defines a concept of distance between any two members of the set, which are usually called points. The metric satisfies a few simple properties. Informally:

the distance from a point to itself is zero, the distance between two distinct points is positive, the distance from A to B is the same as the distance from B to A, and the distance from A to B (directly) is less than or equal to the distance from A to B via any third point C.

A metric on a space induces topological properties like open and closed sets, which lead to the study of more abstract topological spaces.

The most familiar metric space is 3-dimensional Euclidean space. In fact, a "metric" is the generalization of the Euclidean metric arising from the four long-known properties of the Euclidean distance. The Euclidean metric defines the distance between two points as the length of the straight line segment connecting them. Other metric spaces occur for example in elliptic geometry and hyperbolic geometry, where distance on a sphere measured by angle is a metric, and the hyperboloid model of hyperbolic geometry is used by special relativity as a metric space of velocities.

In 1906 Maurice Frechet introduced metric spaces in his work Sur quelques points du calcul fonctionnel.[1] However the name is due to Felix Hausdorff. Definition

The function d is also called distance function or simply distance. Often, d is omitted and one just writes M for a metric space if it is clear from the context what metric is used.

Ignoring mathematical details, for any system of roads and terrains the distance between two locations can be defined as the length of the shortest route connecting those locations. To be a metric there shouldn't be any one-way roads. The triangle inequality expresses the fact that detours aren't shortcuts. If the distance between two points is zero, the two points are indistinguishable from one-another. Many of the examples below can be seen as concrete versions of this general idea.

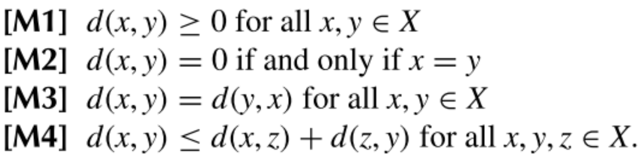
2) Metric space mathematics Written By:
Stephan C. Carlson
See Article History

Metric space, in mathematics, especially topology, an abstract set with a distance function, called a metric, that specifies a nonnegative distance between any two of its points in such a way that the following properties hold: (1) the distance from the first point to the second equals zero if and only if the points are the same, (2) the distance from the first point to the second equals the distance from the second to the first, and (3) the sum of the distance from the first point to the second and the distance from the second point to a third exceeds or equals the distance from the first to the third. The last of these properties is called the triangle inequality. The French mathematician Maurice Frechet initiated the study of metric spaces in 1905.

The usual distance function on the real number line is a metric, as is the usual distance function in Euclidean n-dimensional space. There are also more exotic examples of interest to mathematicians. Given any set of points, the discrete metric specifies that the distance from a point to itself equal 0 while the distance between any two distinct points equal 1. The so-called taxicab metric on the Euclidean plane, this \taxicab distance" gives the minimum length of a path from x, y to z, w constructed from horizontal and vertical line segments. In analysis there are several useful metrics on sets of bounded real-valued continuous or integrable functions.

Thus, a metric generalizes the notion of usual distance to more general settings. Moreover, a metric on a set X determines a collection of open sets, or topology, on X when a subset U of X is declared to be open if and only if for each point p of X there is a positive (possibly very small) distance r such that the set of all points of X of distance less than r from p is completely contained in U. In this way metric spaces provide important examples of topological spaces.

A metric space is said to be complete if every sequence of points in which



[M1] $d(x, y) \geq 0$ for all $x, y \in X$
[M2] $d(x, y) = 0$ if and only if $x = y$
[M3] $d(x, y) = d(y, x)$ for all $x, y \in X$
[M4] $d(x, y) \leq d(x, z) + d(z, y)$ for all $x, y, z \in X$.

Figure 2.115: Metric Space - Sacks.png

the terms are eventually pairwise arbitrarily close to each other (a so-called Cauchy sequence) converges to a point in the metric space. The usual metric on the rational numbers is not complete since some Cauchy sequences of rational numbers do not converge to rational numbers. For example, the rational number sequence 3, 3.1, 3.14 ... converges to n, which is not a rational number. However, the usual metric on the real numbers is complete, and, moreover, every real number is the limit of a Cauchy sequence of rational numbers. In this sense, the real numbers form the completion of the rational numbers. The proof of this fact, given in 1914 by the German mathematician Felix Hausdorff, can be generalized to demonstrate that every metric space has such a completion. IMPORTANT

Metric Spaces

Paul Sacks, in Techniques of Functional Analysis for Differential and Integral Equations, 2017 3.1 Axioms of a Metric Space

The idea of a metric space is that of a set on which some natural notion of distance may be defined. The formal definition is as follows.

Definition 3.1

A metric space is a pair (X, d) where X is a set and d is a real valued mapping on X x X, such that the following axioms hold.

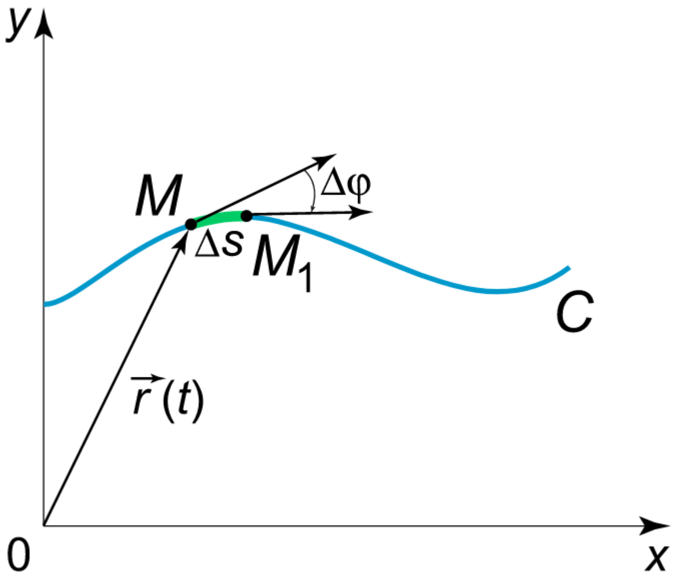
2.8 Curvature of Plane Curve

Let a plane curve C be defined parametrically by the radius vector r(t). While a point M moves along the curve C, the direction of the tangent changes (Figure 1).



[!h]

Figure 2.116: Curvature Definition 1

Teste de imagem:

==========

The curvature of the curve can be defined as the ratio of the rotation angle of the tangent the traversed arc length In the image 2.116, observation of client,

$$\frac{\frac{a}{x\ \ y}+\frac{b}{x+y}}{1+\frac{a\ \ b}{a+b}} \tag{2.1}$$

Osculating (google tradutor) (of a curve or surface) touch (another curve or surface) so as to have a common tangent at the point of contact. "the plots have been drawn using osculating orbital elements";
Should the students be asked to sketch the osculating circle to a given curve at a given point, and then notice that as the point of contact changes, the radius of the circle is inversely proportional to the measure of curvature?; If

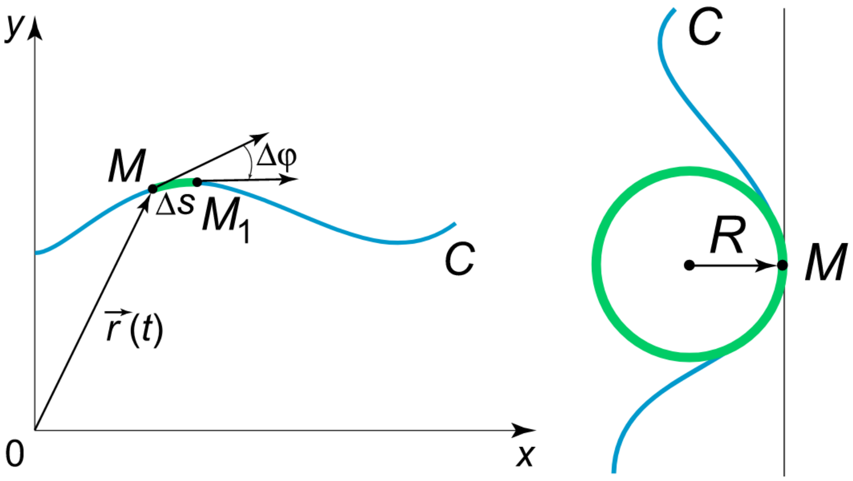


Figure 2.117: Curva 1 - Curva 2

seven points on a twisted cubic be joined, two and two, by twenty-one lines, then any seven planes that contain these 21 lines will osculate a second cubic curve.

2.8.1 Curvature and Intrinsic Geometry of a Surface in the Works of Euler

By the curvature of a curve at a point we mean the limit of the ratio of the angle Aa between the tangents at the endpoints of an arc to the length As of that arc as the latter contracts to the point; that is, the limit

k=da/ds = lim delta s para 0 delta a / delta s

k is also the reciprocal of the radius of curvature at the point in question, that is, the radius of the osculating circle at that point. (The osculating circle at a point P of a curve is defined as the limit of circles determined by three points on the curve as they tend to P.) The concepts of the curvature of a curve and of the osculating (literally "kissing," from the Latin osculans) circle were already known to Leibniz.1 Leibniz also suggested the possibility of characterizing the curvature of a surface by means of an osculating sphere.2 Euler characterized the curvature of a surface in his Investigations of the curvature of surfaces (Recherches sur la courbure des surfaces. Berlin, 1767) [176, vol. 28,pp. 1-22]. Euler called a normal section of a surface z =f(x, y) perpendicular to the xOy plane a principal section. By varying the angle q> between a normal section and the principal section Euler found that at each point of the surface there is a maximal radius of curvature/and a minimal radius of curvature g, that their planes are perpendicular to one another, and that the connection between an arbitrary radius of curvature r = r(q>) and the radii of curvature/and g is given by

1 Leibniz first considered osculation of curves|in particular, osculation of curves and circles|in his New reflections on the nature of the angles of tangency and osculation and their use in mathematical practice to replace complex figures with simpler ones (Meditatio nova de natura Anguli contactus et osculi, horumque usu in practica Mathesi ad figures faciliores succedaneas dicilioribus substituendas. Leipzig 1686) [312, v. 7, pp. 326-329J. 2 In a letter to Johann Bernoulli, dated July 29, 1698.

2.8.2 Cycloid

a curve (resembling a series of arches) traced by a point on a circle being rolled along a straight line. "Many famous mathematicians, including Descartes, have worked on a class of curves called cycloids ." Exemplos de cycloid Neile's parabola was the first algebraic curve to have its arc length calculated; only the arc lengths of transcendental curves such as the cycloid and the logarithmic spiral had been calculated before this. He defines evolutes and involutes of curves and, after giving some elementary properties, finds the evolutes of the cycloid and of the parabola. Viviani determined the tangent to the cycloid but he was not the first to succeed in this. Many famous mathematicians, including Descartes, have worked on a class of curves called cycloids . The ships are fitted with two independent Voith Schneider 18GH cycloidal propellers, which provide propulsion and steering in cruising and minehunting modes, and two twin tube bow thrusters. To estimate the relative surface area of basal lamina and apertures, we used a line intercept technique with cycloids . Our arch is a cycloidal arch, inspired by the one in Kahn's Kimbell Museum. Huygens believed that a pendulum swinging in a large are would be more useful at sea and he invented the cycloidal pendulum with this in mind. Desargues proposed cycloidal teeth for gear wheels in the 1630's. He also worked on cycloidal pendulums, the laws of resistance in a fluid and differential geometry.

2.8.3 Affine

allowing for or preserving parallel relationships. "Still to be implemented are geometric primitives and affine transformation of images-001." Exemplos de affine The simplest way to see why this assertion is true is to observe that any triangle in the plane can be mapped by an invertible affine transformation to an equilateral triangle. It can be obtained from the previous description by applying affine transformations to keep the polygon bounded as it degenerates. Using parallelograms to define affine transformations may be a mixed blessing. Still to be implemented are geometric primitives and affine transformation of images-001. Our interest is in the space of affine equivalence classes of equal-area polygons.

2.8.4 Homogeneous coordinates

From Wikipedia, the free encyclopedia

In mathematics, homogeneous coordinates or projective coordinates, introduced by August Ferdinand Mobius in his 1827 work Der barycentrische Calcul,[1][2] are a system of coordinates used in projective geometry, as Cartesian coordinates are used in Euclidean geometry. They have the advantage that the coordinates of points, including points at infinity, can be represented using finite coordinates. Formulas involving homogeneous coordinates are often simpler and more symmetric than their Cartesian counterparts. Homogeneous coordinates have a range of applications, including computer graphics and 3D computer vision, where they allow affine transformations and, in general, projective transformations to be easily represented by a matrix.

If the homogeneous coordinates of a point are multiplied by a non-zero scalar then the resulting coordinates represent the same point. Since homogeneous coordinates are also given to points at infinity, the number of coordinates required to allow this extension is one more than the dimension of the projective space being considered. For example, two homogeneous coordinates are required to specify a point on the projective line and three homogeneous coordinates are required to specify a point in the projective plane.

2.8.5 Riemann Sphere

Stereographic projection of a complex number A onto a point a of the Riemann sphere.

2.8.6 Riemann Hypothesis

In mathematics, the Riemann hypothesis is a conjecture that the Riemann zeta function has its zeros only at the negative even integers and complex numbers with real part 1/2. Many consider it to be the most important

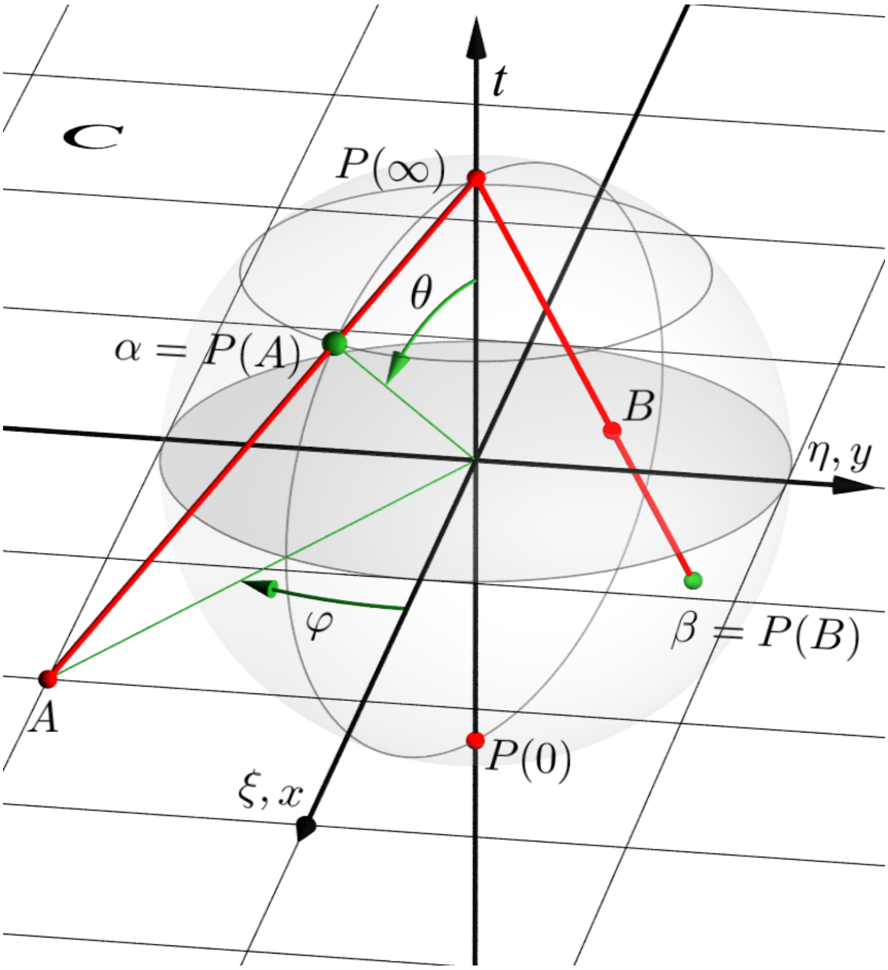

Figure 2.119: Riemann Sphere

unsolved problem in pure mathematics (Bombieri 2000). It is of great interest in number theory because it implies results about the distribution of prime numbers. It was proposed by Bernhard Riemann (1859), after whom it is named.

The Riemann hypothesis and some of its generalizations, along with Goldbach's conjecture and the twin prime conjecture, comprise Hilbert's eighth problem in David Hilbert's list of 23 unsolved problems; it is also one of the Clay Mathematics Institute's Millennium Prize Problems. The name is also used for some closely related analogues, such as the Riemann hypothesis for curves over finite fields.

2.8.7 Atiyah Riemann Hypothesis proof: final thoughts

Source: https://aperiodical.com/2018/09/atiyah-riemann-hypothesis-proof-final-thoughts/

By Katie Steckles and Christian Lawson-Perfect. Posted September 28, 2018 in News

After Sir Michael Atiyah's presentation of a claimed proof of the Riemann Hypothesis earlier this week at the Heidelberg Laureate Forum, we've shared some of the immediate discussion in the aftermath, and now here's a round-up of what we've learned.

Firstly, it's become clear that the work presented by Atiyah doesn't constitute a proof of the Riemann Hypothesis, so the Clay Institute can rest easy with their 1 million dollars, and encryption on the internet remains safe. The argument Atiyah put forward rests on his function having certain properties, and many have concluded that no function with such properties can exist, including in a comment on our own post from an academic who's written about the Riemann Hypothesis extensively. Dick Lipton and Ken Regan have written a blog post looking at the detail of how is supposed to behave. According to some sources, Atiyah has stated he'll be publishing a more detailed paper shortly, but not many are holding their breath.

This is not easy mathematics, and even top-level mathematicians sometimes find their proofs don't hold together; it's no surprise that a solution to this problem wouldn't be found in a few lines of mathematics, and it's just a shame that this was so built up and sensationalised when it's becoming obvious that Atiyah didn't consult with anyone else about his proof before presenting it in a public forum.

Atiyah's is by no means the first claimed proof of the Riemann Hypothesis of recent years; many end up in the wastepaper bins of academic mathematicians around the world, who get sent them in handfuls. Only some claimed proofs get this level of attention though, and this one has been somewhat unique in that it was taken a lot more seriously than usual.

You might remember that a few years ago, the BBC reported that Opeyemi Enoch had proved the Riemann hypothesis, and we immediately said "no, he hasn't". Now Sir Michael Atiyah claims he's proved it, and before his lecture we said "well, let's see". Why the difference?

Enoch looked like any crank: went straight to the wrong venue – BBC News, not other mathematicians – didn't publish his proof in the open, and presented it at a very scammy looking conference run by Nina Ringo, who has previous form. And we'd never heard of him: the false-positive rate for

\anyone on the planet" with a claimed big proof is much, much higher than for, say, professors of maths in big universities. So for all those reasons, we were fairly sure he hadn't done it, like I can fairly confidently say you're not holding a winning lottery ticket right now.

Atiyah, on the other hand, has a Fields medal, an Abel prize, and a very long list of publications. We still thought he probably hadn't proved it, based on his other recent pronouncements, but he said he was going to present his proof, so we gave him the benefit of the doubt.

It's also valid to ask, why was Atiyah given such a prestigious platform to present his work? Well, the HLF isn't an ordinary academic conference { on their own website, they stipulate that \the Heidelberg Laureate Forum is not a classical scientific conference but a networking event meant to motivate and inspire the next generation of scientists." The Forum doesn't vet the talks submitted by the Laureates, as up until now they've never needed to { most people give talks about their historical achievements, or occasionally the work of their students, and some even give the same talk every year. It's still fair to say that a word of advice to Atiyah, to maybe stick to a general historical account of the problem (which his talk mostly was) might have been useful, if he could have been convinced.

Atiyah's proof is a very good example of what a proof isn't: it doesn't contain enough detail to convince someone of the truth of his argument, or even enough detail for someone to point to as wrong. There simply wasn't much to it, and the real glory of maths is in the gritty technical details, all of which were missing from this. Broad strokes are useful to give an overview, but they need to be backed up with working out.

The press has been patchy in its coverage of both Atiyah's presentation and the reaction to it. It's been a good example of how ill-equipped the general press is to cover maths news { breathless coverage from The Times, The Mirror and The Independent reveal a distinct lack of skepticism { but for anyone outside of mathematics, it's not easy to know whether skepticism is warranted. At least some outlets looked like they'd tried to ask a professional mathematician, but many claimed that nobody was prepared to comment { a point that Jacob Aron of New Scientist has complained about.

Quite a few places, including this Science Alert article (which was shared by the Australian Mathematical Sciences Institute on Twitter!) make slightly inaccurate claims, including \the hypothesis has been checked for the first 1,000,000,000,000 prime numbers", and that's not really how that works. Fortunately, we didn't see anyone saying \it's definitely proved", but did see a few stories framed as \rivals disagree", which isn't quite how this went down.

One positive side effect of this whole affair has been the amount of buzz it's created around the Riemann Hypothesis, big results like this, and maths in general. It's reminded us how exciting it would truly be if someone were to prove a result of this nature, and it was cool to see hundreds if not thousands of mathematicians (and non-mathematicians) talking about the proof on social media.

\Being wrong isn't a bad thing like they teach you in school. It is an opportunity to learn something." { Richard Feynman

Some commented ahead of the proof announcement that they hoped it was a real proof, as otherwise it would be terrible for someone like Atiyah, being publicly seen to be totally wrong about something. This sentiment, or equivalents post-hoc, have been echoed with varying levels of concern for his reputation. We think that's a really unhelpful thing to say: being wrong is an inevitable part of mathematics research, and it happens to everyone. Promulgating the idea that maths is all about being 100% right all of the time not only makes it harder for people at research level but is also one of the major reasons people are put off maths at an early age. Yes, it is possible on occasion to come up with an unassailably correct solution to a maths problem, unlike other disciplines which are more subjective in their assessment, but terror of failure causes some people to freeze up and not even try { when in fact being wrong is inevitable, and an important part of the learning process. That said, there are less public forums in which to be wrong, and as we've discussed, steering Atiyah towards one of those might have been kinder.

We wish Sir Michael a pleasant retirement in the knowledge that he has made a huge contribution to maths over the course of his life, and that shouldn't feel lessened or soured by these events. It's fantastic that someone can continue working on mathematics into their old age, especially if, through collaboration, they can inspire the next generation. We are grateful to him for his work.

2.8.8 A subsection

2.8.9 Gottfried Wilhelm Leibniz

2.8.10 Transformation of Lorentz

Em [[física]], as "'transformações de Lorentz"', em homenagem ao físico neerlandês [[Hendrik Lorentz]], descrevem como, de acordo com a [[relatividade especial]], as medidas de espaço e tempo de dois observadores se alteram em cada sistema de referência. Elas refletem o fato de que observadores se movendo com [[velocidade]]s diferentes medem diferentes valores de distância, tempo e, em alguns casos, a ordenação de eventos.

Matematicamente, o "'fator de Lorentz "é determinado por:

$$= \frac{1}{\sqrt{(1 \quad \frac{v^2}{c^2})}} \qquad (2.2)$$

A transformação de Lorentz foi originalmente o resultado da tentativa de Lorentz e outros cientistas, como Woldemar Voigt,[1] para explicar as propriedades observadas da luz propagando-se no que se presumia ser o éter luminífero; Albert Einstein posteriormente reinterpreta a transformação como sendo uma consequência da natureza do espaço e tempo. A transformação de Lorentz substitui a transformação de Galileu da física newtoniana, que assumia um espaço e tempo absoluto. De acordo com a relatividade especial, a transformação de Galileu é apenas uma boa aproximação para velocidades relativas muito menores que a velocidade da luz.

Transformação de Lorentz para referenciais na configuração padrão

Assuma que há dois observadores O e Q, cada qual usando seu próprio sistema de coordenadas espacial para medir os intervalos de espaço e relógios estáticos devidamente posicionados e adequadamente sincronizados para permitir medidas de tempo (sistema de coordenadas relativístico 3). O utiliza t , x , y , z e Q utiliza t 1 , x 1 , y 1 , z 1 para designar a ocorrência de um mesmo evento. Suponha ainda que os sistemas de coordenadas são orientados de maneira que os eixos x e x' são colineares, os eixos y é paralelo ao eixo y' , assim como o eixo z ao z' . A velocidade relativa entre os dois observadores é v no sentido do eixo x. Assuma também que as origens de ambos sistemas de coordenadas coincidem em um dado instante referido como instante zero em ambos os referenciais (t=t'=0 quando x=0 coincide com x'=0). Se todas essas suposições são válidas, então os sistemas de coordenadas são ditos estarem na configuração padrão. Uma apresentação simétrica entre as transformadas direta em inversa de Lorentz podem ser obtidas se o sistema de coordenadas estão em configuração simétrica. A forma simétrica ressalta que todas as leis fsicas devem ser de tal tipo que permanecem inalteradas sob uma transformação de Lorentz.

A transformação de Lorentz para sistemas de referências na configuração padrão pode ser apresentada como

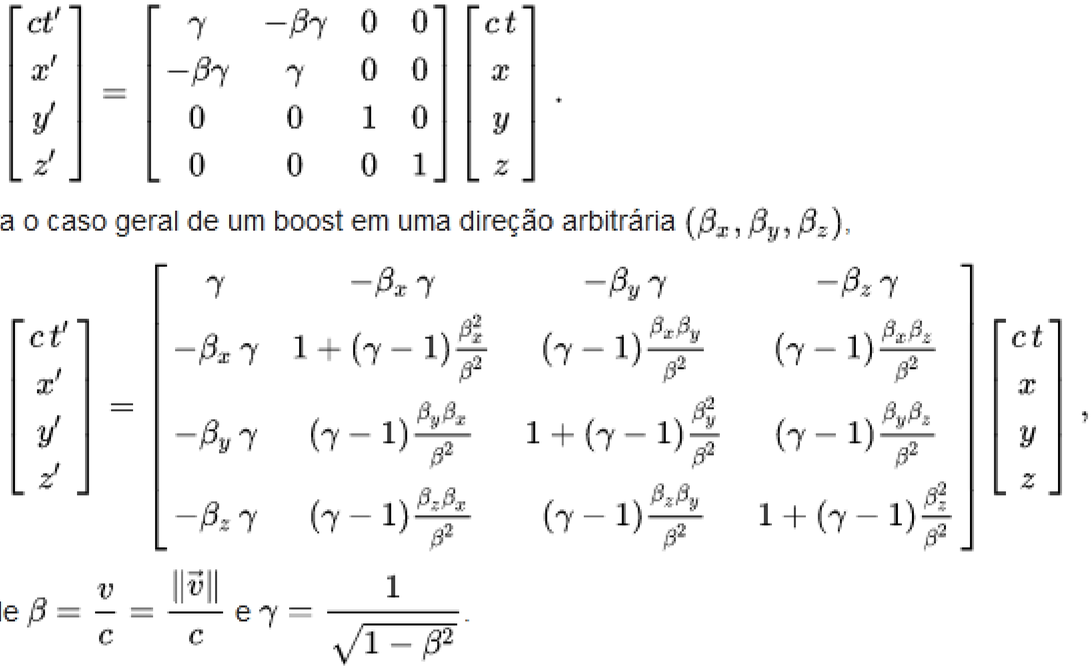
$$t1 = \quad t \quad vx=c^2 \;\; x1 = \quad (x \quad vt)\; y1 = yz1 = z \qquad (2.3)$$

onde

$$= \mathrm{q}\frac{1}{1 \quad \frac{v^2}{c^2}} \qquad (2.4)$$

e chamado [[fator de Lorentz]].

Forma matricial=== A transformação de Lorentz e dita um "boost" na direção "x" e e frequentemente expressa na forma matricial como



$$\begin{bmatrix} ct' \\ x' \\ y' \\ z' \end{bmatrix} = \begin{bmatrix} \gamma & -\beta\gamma & 0 & 0 \\ -\beta\gamma & \gamma & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} ct \\ x \\ y \\ z \end{bmatrix} .$$

Para o caso geral de um boost em uma direção arbitrária $(\beta_x, \beta_y, \beta_z)$,

$$\begin{bmatrix} ct' \\ x' \\ y' \\ z' \end{bmatrix} = \begin{bmatrix} \gamma & -\beta_x\gamma & -\beta_y\gamma & -\beta_z\gamma \\ -\beta_x\gamma & 1+(\gamma-1)\frac{\beta_x^2}{\beta^2} & (\gamma-1)\frac{\beta_x\beta_y}{\beta^2} & (\gamma-1)\frac{\beta_x\beta_z}{\beta^2} \\ -\beta_y\gamma & (\gamma-1)\frac{\beta_y\beta_x}{\beta^2} & 1+(\gamma-1)\frac{\beta_y^2}{\beta^2} & (\gamma-1)\frac{\beta_y\beta_z}{\beta^2} \\ -\beta_z\gamma & (\gamma-1)\frac{\beta_z\beta_x}{\beta^2} & (\gamma-1)\frac{\beta_z\beta_y}{\beta^2} & 1+(\gamma-1)\frac{\beta_z^2}{\beta^2} \end{bmatrix} \begin{bmatrix} ct \\ x \\ y \\ z \end{bmatrix} ,$$

onde $\beta = \frac{v}{c} = \frac{\|\vec{v}\|}{c}$ e $\gamma = \frac{1}{\sqrt{1-\beta^2}}$.

Motivação original

Desde as epocas de Galileu e Newton, era sabido que medidas laboratoriais de processos mecânicos não deveriam mostrar diferenças entre um equipamento em repouso e um outro que estivesse em movimento com velocidade constante e em linha reta: era o chamado princpio da relatividade. Mas, nem todas as leis da fsica eram consideradas universais e independentes do observador: de acordo com a teoria eletromagnética de Maxwell (refinada depois por Lorentz e outros) a luz não devia obedecer a esse princpio e deveria mostrar o efeito do movimento. Michelson e Morley fizeram uma experiência, em 1887, em que tentaram detectar a diferença entre a velocidade da luz se movendo na mesma direção do movimento da Terra (afetado pelo vento de éter resultante) e a velocidade da luz se movendo numa direção em ângulo reto com ela. Mas, o valor da velocidade da luz parecia não se alterar quando era alterada a velocidade do seu emissor — o que estava em desacordo com os modelos da Física Clássica.

Em 1889, Fitzgerald, um irlandês, sugeriu que talvez fosse uma contração do próprio equipamento experimental, que ocorria quando este atravessava o éter e que fazia com que a mudança na velocidade da luz não fosse detectável, ou seja, sugeriu que os corpos se contraíam quando se moviam com velocidades próximas à velocidade da luz. Independentemente, em 1895, Lorentz sugeriu uma hipótese do mesmo tipo, porém mais detalhada, em que, para assegurar a completa impossibilidade de detecção do éter, acrescentava a hipótese de haver uma mudança no tempo local marcado pelos relógios usados na experiência. As transformações de Lorentz, introduzidas por ele em 1904, descrevem esse efeito de diminuição do comprimento e dilatação do tempo para objetos que se movem a velocidades próximas à velocidade da luz.

O descrédito das teorias do éter acabou por levar à aceitação da proposta de Albert Einstein de que as transformações de Lorentz não fossem entendidas como transformações de objetos físicos mas, sim, como transformações do espaço e do tempo em si. Na sua Teoria da Relatividade Restrita, propôs que a razão pela qual não se conseguiam detectar diferentes velocidades da luz era, simplesmente, porque a velocidade da luz é uma constante universal. E mostrou que isso tornava o princípio da relatividade compatível com a teoria electromagnética. A necessidade de se modificar as equações da transformação de Galileu foi reconhecida ao se tentar usá-las nas equações de Maxwell. O raciocínio a seguir, atribuído a Einstein, ilustra intuitivamente a inconsistência.

Considere que seja possível a uma pessoa viajar à velocidade da luz. A luz, pelas equações de Maxwell, é uma oscilação dos campos elétricos E e magnéticos B, periódica no espaço e oscilante no tempo. No referencial dessa pessoa, a luz seria uma perturbação do campo eletromagnético periódica no espaço e constante no tempo. Tal solução, no entanto, não existe como solução das equações de Maxwell que governam a propagação da Luz.

Portanto, restam duas alternativas:

Modificar as equações Maxwell e manter a transformada de Galileu Ou modificar a transformada de Galileu

Não basta dizer que, já que as equações de Maxwell são confirmadas em laboratório, devemos modificar as transformadas de Galileu. Essas transformadas também são importantes pois são a base de toda a Mecânica Clássica, que portanto deveria ser revista.

Esse impasse foi resolvido em 1905 por Albert Einstein. A sua interpretação das Transformadas de Lorentz permitiu manter as equações de Maxwell inalteradas, mas exigiu uma revisão completa dos conceitos de tempo e espaço tão caros e fundamentais à Mecânica Clássica.

A transformação de Lorentz

Para se chegar as equações da transformação de Lorentz basta analisar como as equações de Maxwell se comportam com relação a uma transformação geral de coordenadas. Mas para simplificar a matemática, utiliza-se no lugar das equações de Maxwell uma de suas soluções, isto é, a equação da onda eletromagnética no vácuo:

$$\frac{\partial^2 \psi}{\partial x^2} - \frac{1}{c^2}\frac{\partial^2 \psi}{\partial t^2} = 0$$

propagando-se na direção x com velocidade c.

Quer-se uma transformação linear de coordenadas x, t para um novo referencial, x', t' que se move com velocidade v:

$$\begin{aligned} x' &= \alpha x + \beta t \\ t' &= \gamma x + \delta t \end{aligned}$$

O problema é encontrar a, b, g, delta de forma a que a equação de onda acima continue sendo uma equação de onda no novo referencial. Substituindo na equação de onda e resolvendo a equação para (a, b, g, delta) obtém-se:

$$\alpha^2 - \frac{\beta^2}{c^2} = 1$$
$$\frac{c^2\gamma}{\beta} = 1$$
$$\alpha = \delta$$

Substituindo na transformação linear original:

$$x' = \alpha\left(x + \frac{\beta}{\alpha}t\right)$$
$$t' = \alpha\left(\frac{\beta}{c^2\alpha}x + t\right)$$

Comparando com a transformada de Galileu:

$$x' = x - v \cdot t$$
$$t' = t$$

encontra-se:

$$\frac{\beta}{\alpha} = -v$$
$$\alpha = \frac{1}{\sqrt{(1 - \frac{v^2}{c^2})}}$$

substituindo na transformação linear inicial, encontra-se a transformada de Lorentz entre dois referenciais em movimento relativo com velocidade v:

$$x' = \frac{1}{\sqrt{(1-\frac{v^2}{c^2})}}(x - v\cdot t) = \gamma(x - v\cdot t)$$
$$t' = \frac{1}{\sqrt{(1-\frac{v^2}{c^2})}}(t - \frac{v}{c^2}x) = \gamma(t - \frac{v}{c^2}x)$$

Onde:

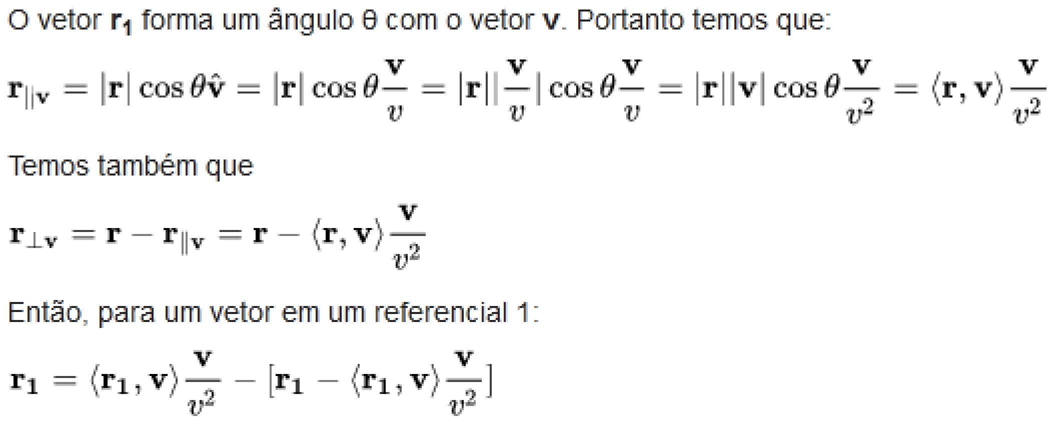
$$\gamma = \frac{1}{\sqrt{(1-\frac{v^2}{c^2})}}$$

e chamado de fator de Lorentz.

Forma Vetorial:

A transformação de Lorentz deduzida até então supõe um movimento relativo na direção do eixo-x, mas esta forma pode ser generalizada para um movimento em qualquer direção. Supondo que os referenciais se movam com uma velocidade em direção arbitrária v, então qualquer vetor r1 pode ser decomposto em suas componentes perpendicular e ortogonal ao vetor v.

O vetor r1 forma um ângulo 0 com o vetor v. Portanto temos que:



O vetor $\mathbf{r_1}$ forma um ângulo θ com o vetor $\mathbf{v}$. Portanto temos que:

$$\mathbf{r}_{||\mathbf{v}} = |\mathbf{r}|\cos\theta\hat{\mathbf{v}} = |\mathbf{r}|\cos\theta\frac{\mathbf{v}}{v} = |\mathbf{r}||\frac{\mathbf{v}}{v}|\cos\theta\frac{\mathbf{v}}{v} = |\mathbf{r}||\mathbf{v}|\cos\theta\frac{\mathbf{v}}{v^2} = \langle\mathbf{r},\mathbf{v}\rangle\frac{\mathbf{v}}{v^2}$$

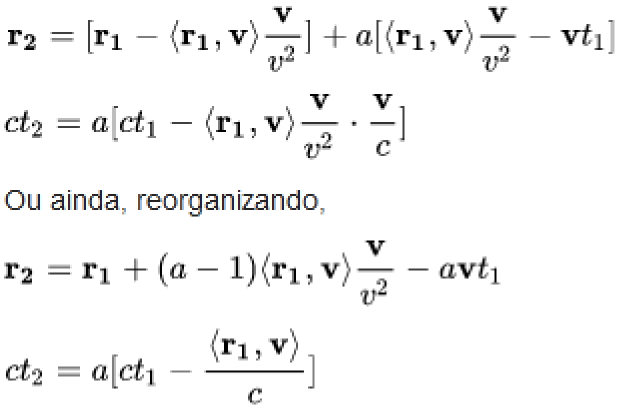
Temos também que

$$\mathbf{r}_{\perp\mathbf{v}} = \mathbf{r} - \mathbf{r}_{||\mathbf{v}} = \mathbf{r} - \langle\mathbf{r},\mathbf{v}\rangle\frac{\mathbf{v}}{v^2}$$

Então, para um vetor em um referencial 1:

$$\mathbf{r_1} = \langle\mathbf{r_1},\mathbf{v}\rangle\frac{\mathbf{v}}{v^2} - [\mathbf{r_1} - \langle\mathbf{r_1},\mathbf{v}\rangle\frac{\mathbf{v}}{v^2}]$$

No entanto a componente perpendicular não sofre alterações frente à transformação de Lorentz e a componente perpendicular à velocidade o é. Então, de modo análogo ao feito para o movimento relativo na direção do eixo-x, temos:



$$\mathbf{r_2} = [\mathbf{r_1} - \langle \mathbf{r_1}, \mathbf{v}\rangle \frac{\mathbf{v}}{v^2}] + a[\langle \mathbf{r_1}, \mathbf{v}\rangle \frac{\mathbf{v}}{v^2} - \mathbf{v}t_1]$$

$$ct_2 = a[ct_1 - \langle \mathbf{r_1}, \mathbf{v}\rangle \frac{\mathbf{v}}{v^2} \cdot \frac{\mathbf{v}}{c}]$$

Ou ainda, reorganizando,

$$\mathbf{r_2} = \mathbf{r_1} + (a-1)\langle \mathbf{r_1}, \mathbf{v}\rangle \frac{\mathbf{v}}{v^2} - a\mathbf{v}t_1$$

$$ct_2 = a[ct_1 - \frac{\langle \mathbf{r_1}, \mathbf{v}\rangle}{c}]$$

Bibliografia:

Ernst, A. och Hsu, J.-P.; First proposal of the universal speed of light by Voigt 1887 Chinese Journal of Physics (2001), pag 211-230 Vol 39-3; A tradução de Voigt (1887) em Inglês. University Physics – With Modern Physics (12th Edition), H.D. Young, R.A. Freedman (Original edition), Addison-Wesley (Pearson International), 1st Edition: 1949, 12th Edition: 2008, ISBN 0-321-50130-6, ISBN 978-0-321-50130-1 (em inglês) A inferência de tempo (t, ou t') por um observador (O, ou Q) não pode ser feita apenas a partir do relógio na respectiva origem. A variável tempo (t, ou t'), refere-se ao valor indicado por um relógio justaposto ao local do evento quando da sua ocorrência; sincronizado com outros análogos espacialmente distribuídos - todos sempre relativamente estáticos com aquele colocado na origem - segundo método fixo; e não ao valor indicado pelo relógio "no braço do observador" quando ele o vê. Se um dos relógios da malha situa-se a uma distância x da origem, deve ser ali colocado com um valor x/c acima (adiantado) em relação àquele indicado pelo relógio na origem. Um pulso de luz oriundo da origem (com velocidade c) dispara os relógicos quando os atinge. Tem-se assim um sistema de referência para medida de espaçotempo de um evento [(x,y,z,t), ou (x',y',z',t')] pelo respectivo observador [O, ou Q] na origem. Repare que, mesmo inicialmente adiantados, ao fim o observador (O, ou Q) verá, na origem, imagem de todos os relógios de sua própria malha espaçotempo,

cada qual tanto mais atrasados quanto mais distante estiver da origem (considere o tempo de ida da luz na sincronização, e o de retorno do sinal luminoso que carrega a "imagem" do relógio de volta à origem). Ao se olhar o céu à noite, em um dado momento, quanto mais longe está o que se olha, mais no passado ("t" menor) ocorreu o que agora se vê.

1.4 Subspaces

1) C:/DATA-NovoVivo-87-2020/Books-87-2020 Active Subspaces Emerging Ideas for Dimension Reduction in Parameter Studies/1611973856.pdf
3.3.1 Approximate gradients
Large-scale simulations often lack simple-to-evaluate expressions for the gradient of the quantity of interest with respect to the inputs. Finite difference approximations are useful when m is not too large and f is neither too expensive nor too noisy. More and Wild's recent work characterizes the gradient when function evaluations contain noise [91, 92]. Next we extend the bounds on errors in the estimated igenpairs to the case when the gradient is computed with some error. The error model we analyze is generic. Let g(x) denote the approximate gradient computed at x pert X.

Pag. 161 (178) - 4.1.2 Coordinate Surfaces and Coordinate Curves The surfaces with ui = const are called coordinate surfaces. Except at singular

points, they cover the space simply, i. e. every point lies on exactly one coordinate surface of each of the three families of coordinate surfaces. Each pair of coordinate surfaces intersects along a coordinate curve, so that, again except for singular points, three coordinate curves intersect at each point.

First, they stated beyond any reasonable doubt that our Universe is (at least) (3+1)-dimensional. Moreover, Einstein taught us that introducing extra dimensions (time, in this case) can provide a better description of (and even simplify) the laws of nature (electromagnetism for Special Rela- tivity and gravity for General Relativity). This latter teaching by Einstein was followed by Kaluza [111] and Klein [112], who added a fifth dimension to the four space{time ones in order to unify electromagnetism and gravitation (let us recall however that Nordstrom [113] was the first to realize that in a 5D space-time the field equations do split naturally into Einstein's and Maxwell's equations). Although unsuccessful, the Kaluza{Klein (KK) theory constituted the first attempt to unification of fundamental interactions within a multidimensional space{time. The KK scheme, in which the coefficient of the fifth coordinate is constant, was later generalized by Jordan [114] and Thiry [115], who considered it to be a general function of the space{ time coordinates. The 5D KK formalism has been later extended to higher dimensions, also in the hope of achieving unification of all interactions, including weak and strong forces [116{118]. Six dimensions were e.g., con- sidered by Ingraham [117] and Podolanski [118]. However, a true revival of multidimensional theories starting from 1970 was due to the advent of string theory [119]

and supersymmetry [120]. As is well known, their combination, superstring theory [121], provides a framework for gravity quantization. Modern generalizations [122,123] of the Kaluza{Klein scheme require a minimum number of 11 dimensions in order to accommodate the Standard Model of electroweak and strong interactions; let us recall that 11 is also the maximum number of dimensions required by supergravity theories [124]. For an exhaustive review of Kaluza{Klein theories we refer the reader to [125].

Pag.227 (259) Pseudo-Riemannian Submersions A submersion Pi : M -> B is a differentiable map between differentiable manifolds whose differential is everywhere surjective. The notion of sub- mersions is a fundamental concept in differential topology. The bundle map Pi : E -> B of a fiber bundle is an example of a submersion. Submersions appear often in classical differential geometry, e.g. a surface of revolution or a family of parallel surfaces in E 3 each leads in an obvious way to a submersion. IMPORTANT Riemannian submersions are submersions equipped with compatible Riemannian metrics. The theory of Riemannian submersions arose from [Hermann (1960); Nagano (1960); O'Neill (1966); Gray (1967)]. Rieman- nian submersions are natural generalizations of warped products, which occur widely in geometry. For instance, when a Lie group acts isomet- rically, freely and properly on a Riemannian manifold M, IMPORTANT the projection Pi : M -> B to the quotient space B = M/G equipped with quotient metric is a Riemannian submersion.

1.12 Pi - Calculation

Date: 20200718

1) The Pi Machine Source: https://wordplay.blogs.nytimes.com/2014/03/10/pi/

This coming Friday, 3.14 is Pi Day. Let's celebrate math's favorite number with a remarkable puzzle suggested several years ago by Alon Amit of Origami Logic. Dr. Amit and I were sitting on a couch in the old Palo Alto Facebook headquarters (Dr. Amit was working there at the time) surrounded by frenzy (the film \The Social Network" had just been released) when he told me something amazing: someone had recently figured out a completely original way to calculate pi. It was also a remarkably simple method, requiring just two balls and a wall. With these you have a pi machine.

I could barely believe it, so Dr. Amit continued. To calculate pi, take two identical balls. Put one near a wall and roll the other ball toward it. The first ball will hit the second, which will bounce off the wall and come back to hit the first ball. Click click click. Three collisions. The first digit of pi is a three. The machine works!

This isn't very convincing, of course. We need something a bit more precise. Can this machine tell us pi is 3.1? Or 3.14?

With a little modification, it can. A first ball that's 100 times as massive will create 31 clicks. 10,000 times as massive will create 314 clicks.

The machine can be used to generate (in theory, at least) as many digits of pi as you'd like. Simply amazing.

Our challenge for this week is | how does it work?

To solve this puzzle, it may help to experiment a bit with the following Pi Machine Gizmo created by Adam Bowman. (Thank you, Mr. Bowman!)

It may also help to try a simple physics simulation tool, like Algodoo. \Make and test your own contraptions with Algodoo."

Before closing, we have two exciting math events to announce.

If you're in the San Francisco Bay Area on Sunday, check out the Nueva School's 2014 Science, Technology, Engineering and Mathematics Fair. Among the speakers and activities: Josh Herbach of Google will give a presentation about the Google self-driving car project; I'll be there as well, giving a talk on creative genius, sharing what I've learned from conversations with artists, inventors and Olympians, as well as from so many here at Numberplay.

And if you're in New York | Tetsuya Miyamoto, famed inventor of the KenKen arithmetic and logic puzzle, will be at the Chappaqua Library on Thursday to speak about his innovative teaching philosophy, \The Art of Teaching Without Teaching."

That's it for this week's challenge. As always, use Gary Hewitt's Enhancer for an optimal Numberplay experience. And send your favorite puzzles and excess machinery to gary.antonick@NYTimes.com. Solution

How can two bouncing balls compute pi? Dave hit upon (and Hans and Mark | who simultaneously found another approach | also explored) a beautifully simple explanation that happened to be the same one I originally used: the collisions mark segments around a circle in a way that exactly determine pi. Although this explanation seems fairly obvious, it appears to be original | it's distinct from the method used by Gregory Galperin, who discovered this property nearly twenty years ago, and wasn't an approach Dr. Galperin was familiar with when I spoke to him a couple weeks ago by phone.

Dr. Galperin's own technique is ingenious | we'll get to that in a moment | but we'll start with the simpler approach.

I think it's easiest to forget about the bouncing balls for a moment and focus on pi. What does it mean to jot out pi to a particular number of digits? One way to think about it: pi to one digit, for starters, is simply the number of times you can fully wrap the diameter of a circle around that circle.

To figure this out we would pick up the diameter, wrap it around the first part of the circle, then mark where it ends. We'd then repeat the process until we ran out of circle, giving us a one-digit value of pi of 3.

Key is that first mark. If we can figure out another way to find it we'll have an alternative way way to determine pi. (We just need to ensure that this estimate is accurate enough, which means, in this case, it falls between the points created by three-sided and four-sided polygons.)

One alternative way: take the diameter and tilt it up against the right

Figure 1.3: pi machine solution 1.png

side of the circle, and then draw the red line as shown, creating a triangle. This red line gives us a mark that falls within the range we need. And if we rotate this triangle we find it marks the same spot.

A bit unwieldy, but it seems to work. For two digits of pi, we're looking for the number of times a tenth of the diameter can be wrapped around the circle. Following the same process gives us a very accurate estimate for that first mark. Repeating this we produce 31 of these tenth-diameter segments.

Figure 1.4: pi machine solution 2.png

Divide the diameter into 100 segments and the process will produce an initial segment that will fit 314 times around the circle. The method will give us pi to as many digits as we'd like.

But how does this relate to colliding balls? There's actually an exact connection: the balls will actually create, with a little rescaling, this same circle-and-line diagram, with the circle showing a graph of their kinetic energy and the line indicating momentum. A plot of ball velocities (the first ball's velocity on the x axis and the second ball's on the y) will plot out pi around the circle to whatever accuracy we'd like.

Take the first example, where the ball masses are equal. The balls start out as velocities (1,0) after the first ball is given a push. After the first collision the first ball stops and the second starts (0,1); the second then

Figure 1.5: pi machine solution 3.png

hits the wall and reverses (0,-1) and finally hits the first ball again (-1,0). Three collisions (though the pattern doesn't jump around the circle counter-clockwise { instead it zig-zags up and down around the circle) and three intersections after that first point.

In the second example, where the first ball is now 100 times more massive than before, we get a circle with a more vertical line that will create 31 intersections. (See Dave's comments for detail.)

Dr. Galperin's approach was also geometric but very different (using an unfolding geodesic), building on prior related insights. Dr. Galperin, who studied under well-known Russian mathematician Andrei Kolmogorov, had recently written (with Yakov Sinai) extensively on ball collisions, realized just before a talk in 1995 that a plot of the ball positions of a pair of colliding balls could be used to determine pi. (When he mentioned this insight in the talk, no one in the audience believed him.) This finding was ultimately published as \Playing Pool With Pi" in a 2003 issue of Regular and Chaotic Dynamics.

I recently reached Dr. Galperin by phone and asked about the key insight behind this idea and how he in particular happened to see it. \The Greeks could not have discovered this," he said, \because they didn't know about kinetic energy and momentum. Leibniz, who proposed the idea of kinetic energy, did not work in this area. As for others | mathematics is a broad field. This came to me as the collision of several ideas in areas I have worked deeply in."

Thank you, Dr. Galperin, and thank you as well to everyone who participated in this week's challenge: Mark, Gary, Ibabel, Hans, Ravi, Dave, Mark, Giovanni Ciriani, Kurt and Sheldon Ross.

5) Finding a consistente constant
Source:
https://physicsworld.com/a/finding-a-consistent-constant/

08 Jul 2020 Taken from the July 2020 issue of Physics World. Members of the Institute of Physics can enjoy the full issue via the Physics World app.

The Planck mission gave us the most precise value of the Hubble constant to date by measuring the cosmic microwave background. But studies made since using different methods provide different values. Keith Cooper investigates the discrepancies and asks what it might mean for cosmology

When astronomer Edwin Hubble realized that the universe is expanding, it was the greatest cosmological discovery of all time. The breakthrough acted as a springboard to learning about the age of the cosmos, the cosmic microwave background (CMB) radiation, and the Big Bang.

Hubble was the right man in the right place at the right time. In April 1920 his fellow astronomers Harlow Shapley and Heber D Curtis famously debated the size of the universe, and the nature of spiral nebulae, at the Smithsonian Museum of Natural History in the US. Within four years, Hubble had the answer for them.

Using the 100-inch (2,5 m) Hooker Telescope at Mount Wilson Observatory in California, Hubble was able to identify Cepheid variables – a type of star whose period-luminosity relationship allows accurate distance determination – in the spiral nebulae, which allowed him to measure them as extragalactic. The finding meant the Milky Way was not the entire universe, but just one galaxy among many.

Soon, Hubble had discovered that almost all of these galaxies are moving away from us – their light is redshifted via the Doppler effect. These observations were seized upon by the Belgian cosmologist Georges Lemaître, who realized that they implied that the universe is expanding. Independently, both Hubble and Lemaître derived a mathematical relationship to describe this expansion, subsequently known as the Hubble–Lemaître law. It says that the recession velocity (v) of a galaxy is equal to its distance (D) multiplied by the Hubble constant (H0), which describes the rate of expansion at the current time.

In the nearly 100 years since Hubble's discovery, we've built up a detailed picture of how the universe has developed over time. Granted, there are still some niggles, such as the identities of dark matter and dark energy, but our understanding reached its peak in 2013 with the results from the Planck mission of the European Space Agency (ESA).

Launched in 2009, Planck used microwave detectors to measure the anisotropies in the CMB { the slight temperature variations corresponding to small differences in the density of matter just 379,000 years after the Big Bang. The mission revealed that only 4.9% of the universe is formed of ordinary baryonic matter. Of the rest, 26.8% is dark matter and 68.3% is dark energy. From Planck's observations, scientists also deduced that the universe is 13.8-billion years old, confirmed that the universe is flat, and showed how baryonic acoustic oscillations (BAOs) { sound waves rippling through the plasma of the very early universe, resulting in the anisotropies { neatly matched the large-scale structure of matter in the modern universe, which we know has expanded according to the Hubble{Lemaître law.

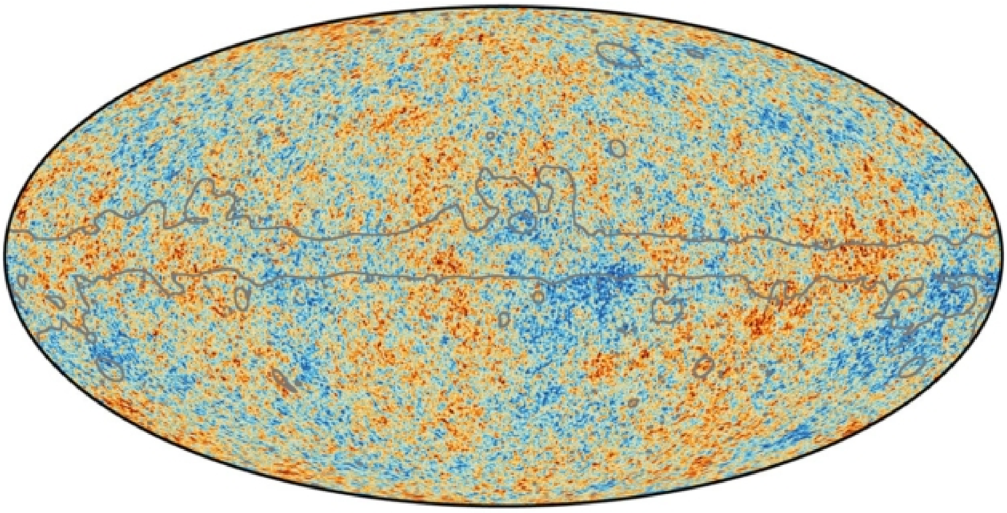

Figure 1.6: Planck-2018-T-CMB.jpg

Mapping the universe By measuring the temperature anisotropies of the cosmic microwave background { as demonstrated in this 2018 map { the Planck mission provided the most precise measurement of the Hubble constant to date: 67.4 /km/s/mpc with just 1% uncertainty. (Courtesy: ESA and the Planck Collaboration)

Planck's view of the CMB is the most detailed to date. Plus, by mapping our best cosmological models to fit Planck's observations, a whole host of cosmological parameters have come tumbling out, including H0. In fact, scientists were able to extrapolate the value of H0 to the greatest precision ever, finding it to be 67.4 /km/s/mpc, measured to an uncertainty of less than 1%. In other words, every stretch of space a million parsecs (3.26 million light-years) wide is expanding by a further 67.4 km every second.

With Planck's results, we thought that this picture was complete, and that we knew exactly how the universe had expanded over those 13 billion e 800 millions years. Yet it turns out that we may be wrong (see box \Not a constant constant over time").

Not a constant constant over time

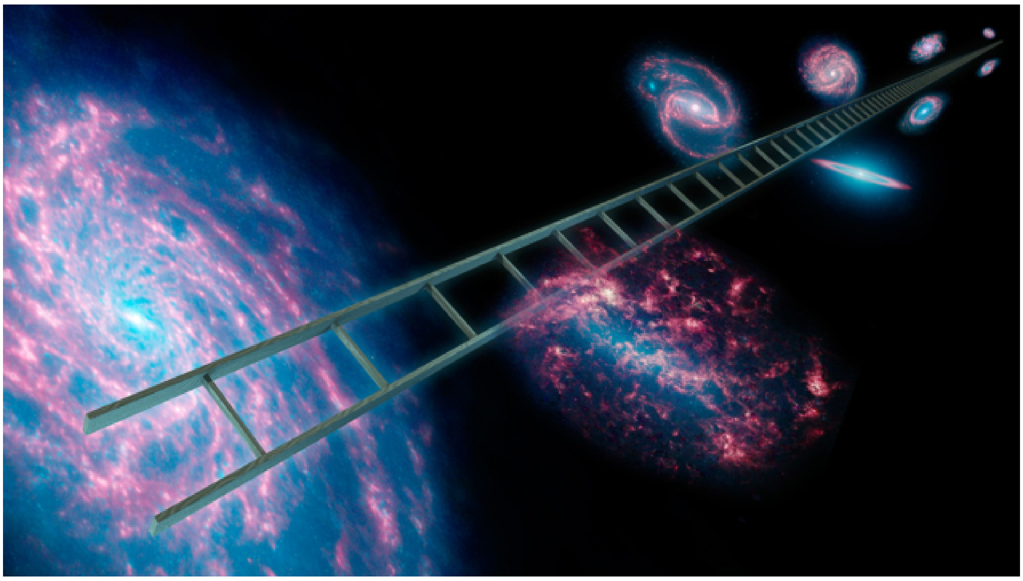

Figure 1.7: Distance Ladder

Describing H0 as \the Hubble constant" is a little bit of a misnomer. It is true that it is a constant at any given point in time since it describes the current expansion. However, the expansion rate itself has changed throughout cosmic history { H0 is just the current value of a broader quantity that we call the Hubble parameter, H, which describes the expansion rate at other times. Therefore, while the local measurement, H0, should only have one value, H can take on different values at different points in time. Prior to the discovery of dark energy, it was assumed that the expansion of the universe was slowing down, and hence H would be larger in the past than in the future. On the face of it, since dark energy is accelerating the expansion, you might therefore expect H to increase with time, but that's not necessarily the case. Rearranging the Hubble{Lemaître law such that h - v over d , where v is an object's recession velocity, we see that H depends strongly on distance D, since in a universe with accelerating expansion, the distance is increasing at an exponential rate. The bottom line is that H is likely to be decreasing with time, which is what we think is happening, even though the recession velocity and hence the expansion are still increasing with distance.

Moving parts

Traditionally, H0 is determined by measuring the distance and recession velocity of galaxies using \local" standard candles within those galaxies. These include type 1a supernovae { the explosion of white-dwarf stars with a certain critical mass { and Cepheid variable stars. The latter have a robust period{luminosity relationship (discovered by Henrietta Swan Leavitt in 1908) whereby the longer the period of the star's variability as it pulses, the intrinsically brighter the star is at peak luminosity. But as astrophysicist Stephen Feeney of University College London explains, these standard candles have many \moving parts", including properties such as stellar metallicity, differing populations at different redshifts, and the mechanics of Cepheid variables and type Ia supernovae. All the moving parts lead to uncertainties that limit the accuracy of these observations and we have seen over the years how the resulting calculations of H0 can vary quite a bit.

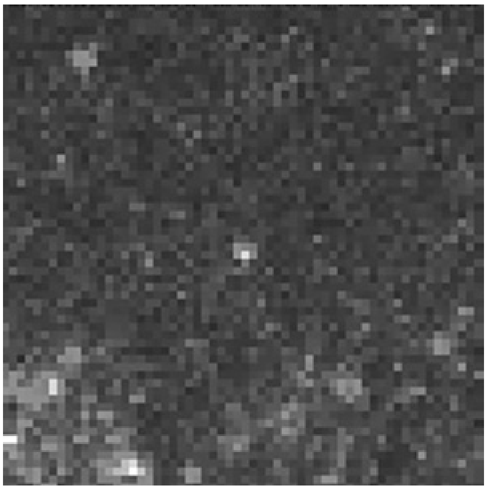

Figure 1.8: cepheid-variable.jpg

A star's pulse Cepheid variable stars { such as this one in galaxy M100 { have a strong period-luminosity relationship that allows astronomers to work out how far away they are. (Courtesy: Wendy L Freedman, Observatories of the Carnegie Institution of Washington/NASA)

On the other hand, Planck's value of H0 is a relatively straightforward measurement { even if it does depend on the assumption that lambda cold dark matter (ACDM) cosmology { which incorporates the repulsive force of dark energy (A) and the attractive gravitational force of cold dark matter

(CDM) { is correct. Still, when all the known uncertainties and sources of error are taken into account, Planck's value of H0 is to a precision greater than ever before, to just 1%.

Although the Planck value of H0 is calculated from measurements of the CMB, it is important to note that it is not the expansion rate at the time of the CMB's creation. Rather, \think of the CMB measurement as a prediction instead", says Feeney. It extrapolates from what the CMB tells us the universe was like 379,000 years after the Big Bang, factoring in what we know of how the universe would have expanded in the time since based on the Hubble{Lemaître law and ACDM, to arrive at an estimate of how fast the universe should be expanding today. In other words, however we measure H0, whether it be with the CMB or more local measurements of Cepheid variables and supernovae, we should get the same answer. A spanner in the works

In 2013, when the Planck measurement was revealed, this wasn't a problem. Although local measurements differed from the Planck value, their uncertainties were still large enough to accommodate the differences. The expectation was that as the uncertainties become smaller over time with more sophisticated measurements, the local measured value would converge on the Planck value.

However, in 2016 a major milestone was reached in local measurements of H0 that brought our understanding of the universe into question. It involved Adam Riess of Johns Hopkins University, US, who in 1998 had co-discovered dark energy using type Ia supernovae as standard candles to measure the distance to receding galaxies based on how bright the supernovae appeared. He was now leading the cumbersomely named SH0ES (Supernova, H0, for the Equation of State for dark energy) project, which was set up to calibrate type Ia supernovae measurements to determine H0 and the behaviour of dark energy. In order to provide this calibration, the SH0ES team used a lower rung on the \cosmic distance ladder", namely Cepheid variables. The project aimed to identify these pulsating stars in nearby galaxies that also had type Ia supernovae, which would mean that the Cepheid distance measurement could then be used to calibrate the supernova distance measurement, and this new calibration could in turn be used on supernovae in more distant galaxies. The method produced a value of H0 with an uncertainty of just 2.4%.

A star's death A type 1a supernova { as illustrated here in an artist's impression { results from the destruction of a white dwarf star above a critical mass. Their standardizable luminosity makes them a useful rung on the cosmic distance ladder. (Courtesy: ESA/ATG medialab/C Carreau)

Riess and his group were stunned by their result, however. Using the local

Figure 1.9: Gaia-SNIa-Artist-Impression.jpg

cosmic distance ladder, they inferred a value of H0 as 73.2km/s/mpc. With the vastly reduced uncertainties, there was no way this could be reconciled with Planck's measurement of 67.4km/s/Mpc. If these results are correct, then there is something deeply wrong with our knowledge of how the universe works. As Sherry Suyu of the Max Planck Institute for Astrophysics in Garching, Germany, says, \We may need new physics."

Rather than assume Planck's high-precision H0 is wrong and therefore rush to take apart the fundamentals of our best cosmological models, a scientist's first instinct should be to test whether there has been an experimental mistake that means something about our measurement of the cosmic distance ladder is awry.

\That's where my instinct still lies," admits Daniel Mortlock of Imperial College London, UK, and Stockholm University, Sweden. Mortlock works in the field of astro-statistics { that is, drawing conclusions from incomplete astrophysical data, and accounting for various kinds of uncertainty and error in the data. It's worth remembering there are two types of error in any measurement. The first is statistical error { errors in individual measurements, for example read-out noise from the detector, or uncertainties in the sky background brightness. Statistical errors can be reduced by simply increasing your sample size. But the other kind of errors { systematic errors { aren't like that. \It doesn't matter if you have a sample five times, or 10 times, or

50 times as large, you just get this irreducible uncertainty," says Mortlock. An example of a systematic error might be the reddening of a star's light by intervening interstellar dust { no matter how often you measure the star's brightness, the star's light would always be obscured by the dust, and its effect would increase the more you measure it.

Mortlock has considered that this could be what is happening with the local measurements of H0 { there may be some systematic error that astronomers have not yet identified, and if found, the tension between the Planck measurement and the local measurement of H0 could go away. However, Mortlock acknowledges that the evidence for the discrepancy in the H0 values being real \has been steadily growing more convincing". Einstein to the rescue

Presented with such an exceptional result, astronomers are double-checking by measuring H0 with other, independent means that would not be subject to the same systematic errors as the Cepheid variable and type Ia supernovae measurements.

One of these can be traced back to 1964, when a young astrophysicist by the name of Sjur Refsdal at the University of Oslo, Norway, came up with a unique way to measure the Hubble constant. It involved using a phenomenon predicted by Einstein but which at the time had not been discovered: gravitational lenses.

The general theory of relativity describes how mass warps space, and the greater the mass, the more space is warped. In the case of so-called \strong gravitational lensing", massive objects such as galaxies, or clusters of galaxies, are able to warp space enough that the path of light from galaxies beyond is bent, just like in a glass lens. Given the uneven distribution of mass in galaxies and galaxy clusters, this lensing can result in several light paths, each of slightly different length.

Refsdal realized that if a supernova's light passes through a gravitational lens, then its change in brightness would be delayed by different amounts in each of the lensed images depending on the length of their light path. So, image A might be seen to brighten first, followed a few days later by image B, and so on. The time delay would tell astronomers the difference in the length of the light paths, and the expansion of space during those time delays would therefore allow H0 to be measured.

Einstein's lenses Gravitational lensing, as seen in galaxy cluster Cl 0024+17, presents another means of determining cosmic distances, and therefore calculating Hubble's constant. (Courtesy: NASA, ESA, M J Jee and H Ford (Johns Hopkins University))

Unfortunately, even after the first gravitational lens was discovered in 1979, it turned out that gravitationally lensed supernovae are exceptionally

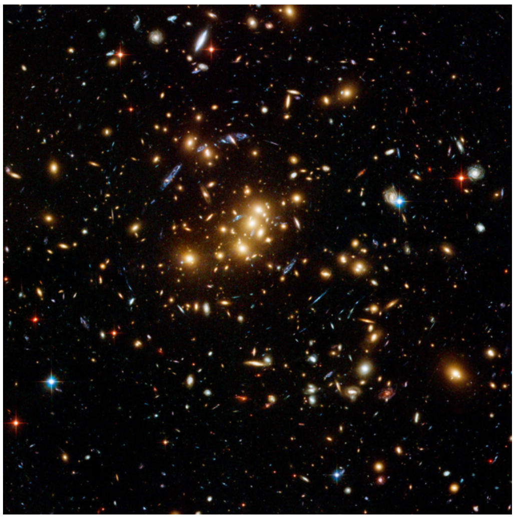

Figure 1.10: lensing.jpg

rare. Instead, quasars { luminous active galactic nuclei that also exhibit brightness variations { have been found to be the more common lensed object. That was what led Suyu to launch a project in 2016 to study lensed images of quasars in order to provide an independent measure of H0. It goes under the even more cumbersome name of H0LiCOW, which stands for H0 Lenses in COSMOGRAIL's Wellspring, where COSMOGRAIL refers to a programme called the COSmological MOnitoring of GRAvitational Lenses, led by Frederic Courbin and Georges Meylan at the Ecole Polytechnique Federale de Lausanne.

Throughout this analysis, Suyu and team kept the final result hidden from themselves { a technique known as blind data analysis { to avoid confirmation bias. It was only at the very end of the process, once they had completed all their data analysis and with their paper describing their observations almost completely written, that they revealed to themselves the value of H0 that they had measured. Would it come out in favour of Planck, or would it boost the controversial SH0ES result?

The value that they got was 73.3 km/s/Mpc, with an uncertainty of 2.4%. \Our unblinded result agrees very well with the SH0ES measurement, adding further evidence that there seems to be something going on," Suyu tells Physics World.

It's still too early to claim the matter settled, however. The initial H0LiCOW analysis involved only six lensed quasars, and efforts are being made to increase the sample size. Suyu is also returning to Refsdal's original idea of using lensed supernovae, the first example of which was discovered by the Hubble Space Telescope in 2014, followed by a second in 2016. Hundreds are expected to be discovered by the Vera C Rubin Observatory in Chile, formerly known as the Large Synoptic Survey Telescope, which will begin scientific observations in October 2022.

\It would be really interesting if the H0LiCOW measurements can be shown to be correct and in agreement with the Cepheid measurements," says Feeney, who for his part is pursuing another independent measurement of H0, using another phenomenon predicted by Einstein: gravitational waves.

On 17 August 2017 a burst of gravitational waves resulting from the collision of two neutron stars in a galaxy 140 million light-years away triggered the detectors at the Laser Interferometry Gravitational-wave Observatory (LIGO) in the US and the Virgo detector in Italy. That detection has allowed Feeney and a team of other astronomers including Mortlock and Hiranya Peiris, also of University College London, to revive an idea, originally proposed by Bernard Schutz in 1986, to use such events to measure the expansion rate of the universe.

The strength of the gravitational waves indicates how distant a neutron-star merger is, but the merger also produces a handy burst of light known as a kilonova. This can be used to pinpoint the host galaxy, the redshift of which in turn provides the galaxy's recession velocity. Feeney and Peiris have estimated that a sample of 50 kilonovae would be required to derive an accurate determination of H0, but Kenta Hotokezaka of Princeton University, US, and colleagues have found a way to speed this up. They point out that we would see the gravitational waves from a neutron-star merger at their strongest if we looked perpendicular to the plane of the collision. The merger produces a relativistic jet that's also moving perpendicular to the plane, so measuring the angle at which we see the jet will tell us how large our viewing angle is from the plane, and therefore allow a determination of the true strength of the gravitational waves and hence the distance. Hotokezaka estimates that a sample size of just 15 kilonovae studied in this fashion will be enough to provide an accurate assessment of H0. Unfortunately, so far astronomers have observed just one kilonova, and based on that sample of one, Hotokezaka calculates H0 to be 703km/s/Mpc, with a big uncertainty of 10%.

Other approaches abound

Beta ceti A red rung The red giant star B Ceti has begun fusing helium, and can therefore be used as a standard candle. (Courtesy: NASA/CXC)

Cepheid variables and type 1a supernovae are common rungs on the cosmic distance ladder that are used to find a local value for Hubble's constant. But researchers led by Wendy Freedman of the University of Chicago have used another. They looked at the brightness of red giant stars that have be-

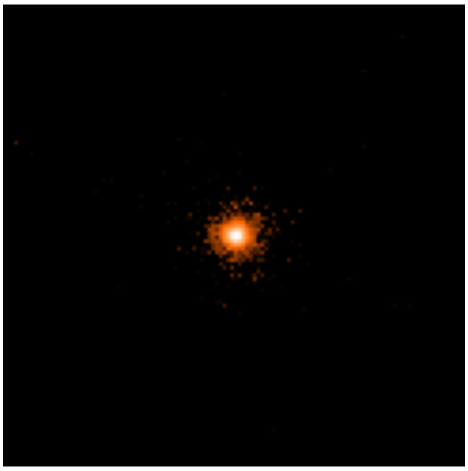

Figure 1.11: Bceti-xray.jpg

gun fusing helium in their cores, to measure the distance to galaxies in which these stars can be seen. Initially they calculated H0 as 69.8km/s/Mpc { but then things got complicated. Their data was reanalysed by Wenlong Yuan and Adam Riess to account for dust reddening, resulting in a revised measurement of 72.4km/s/Mpc with an uncertainty of 1.45%. However, Freedman's team have performed the same reanalysis and got a value of 69.6km/s/Mpc, with an uncertainty of 1.4%, so the jury is still out on that one.

Meanwhile, the Megamaser Cosmology Project makes use of radio observations tracking water masers in gas orbiting supermassive black holes at the centres of distant galaxies. The angular distance that the masers traverse on the sky allows for a straightforward geometrical distance measurement to their host galaxy, producing a value of 73.9km/s/Mpc for H0 with an uncertainty of 3%.

Changing the game

Taken together, all the available evidence seems to be pointing towards the dichotomy between the local measurements and the Planck measurement being real { and not some unidentified systematic error. However, a greater sample size is required before these results can be considered truly robust. With new observatories coming online, we could have the required observations within 10 years.

\If either the gravitational waves or the lensing methods give very strong results that match the SH0ES result, then I think that will change the game," says Mortlock.

However, don't expect a speedy resolution. After all, we're still grappling with the nature of dark matter and dark energy, and current research is focused on trying to identify the dark-matter particle and trying to characterize the behaviour of dark energy. \Whatever is going on with the Hubble constant is still several steps behind those," says Mortlock. \People are still debating whether the effect is real."

The value of H0 will have many consequences. It will dictate the age of the universe, and the history of how the universe expanded and allowed large-scale structure to form

One way or another, figuring out whether the discrepancy in our measurements of H0 is real or not will have significant repercussions for cosmology. Feeney describes the local and Planck values of H0 as \a really potent combination of measurements, because you are constraining the universe now and how it looked 13.8 billion years ago, so you pin down the universe at both ends of its evolution".

The value of H0 will have many consequences. It will dictate the age of the universe (a higher H0 would mean the universe might be substantially younger than 13.8 billion years, which would contradict the age of some of the oldest stars that we know). It would also influence the history of how the universe expanded and allowed large-scale structure to form. And if new physics is needed, as Suyu suggests, then it's impossible as yet to say how dramatic an effect that would have on cosmology, since we don't yet know what shape that new physics might take.

\It would be something in addition to our current ACDM model," says Suyu. \Maybe we are missing some new, very light and relativistic particle, which would change Planck's measurement of H0. Or it could be some form of early dark energy that's not in our current model."

Or it could be neither of these, but instead something we've not thought of yet. The prospect is tantalizing researchers, but Suyu warns about jumping the gun.

\First we need to get the uncertainties down to the 1% level on multiple methods to see if this tension is real," she says. So we need to be a little bit patient, but if we come back in 10 years' time, we may find that the universe is suddenly a very different place indeed.

Geometric Approximation via Coresets PANKAJ K. AGARWAL, SARIEL HAR-PELED, AND KASTURI R. VARADARAJAN Abstract. The paradigm of coresets has recently emerged as a powerful tool for efficiently approximating various extent measures of a point set P . Using this paradigm, one quickly computes a small subset Q of P , called a coreset, that approximates the original set P and and then solves the problem on Q using a relatively inefficient algorithm. The solution for Q is then translated to an approximate solution to the original point set P . This paper describes the ways in which this paradigm has been successfully applied to various optimization and extent measure problems.

Pag. 87 - Figure 39 e elevado a in theta for module z > igual 0. The conclusion is that for really big circles, g wraps the big circle on the complex plane around the unit circle n times (Fig.39), because as theta varies from 0 to 2pi, g varies from 1 to exp(2piin).

Pag. 93 - Gravitational Lenses Einstein offered a geometric explanation of gravity. Rather than viewing gravity as an attractive force between massive objects, which is how Newton described it, Einstein’s theory is based on the notion of curvature. The presence of mass, he teaches us, literally causes the fabric of space and time to curve or warp. The warping of space and time affects the motions of objects nearby, and that, in essence, is the phenomenon we call gravity. To explore this idea, consider two points on the sphere. There is a unique shortest path (or geodesic) on the sphere between these two points (Fig.45). Although this path is not \straight" in the conventional sense, it is still the shortest path that lies in the sphere. Actually, there are exceptions: there are infinitely many shortest-length paths between antipodal points. Instead we can start from a given point on the sphere and go in a given direction in as straight a manner as we can. This is what is called a geodesic. The path we thus get will be a great circle on the sphere.

FIGURE 45. There is normally only one shortest path between any two points on the sphere.

Other kinds of situations can arise. On the torus, a donut shaped object as in Fig.46, there are topologically inequivalent geodesics paths between points lying on opposite sides of a cross-sectional circle.

FIGURE 46. On a torus, there are two shortest paths between points sitting on opposite sides of a cross-sectional circle.

Einstein's theory predicts that light always travels in the shortest path between two points.However, the curvature of space-time means that the path may not look straight in Euclidean space. The theory tells us, for example, that the sun, being a massive body, should bend passing light. This prediction was the first experimentally confirmed prediction of Einstein's general theory of relativity, when the bending of light around the sun was indeed observed during an eclipse.

Pag. 72 (83) - 3.2 Intersections The difference between analytic and synthetic geometry can be illustrated with Euclid's very first proposition, the construction of the equilateral triangle on a line segment AB. Recall from Section 2.2 that Euclid did this by finding the intersection of two circles, one with center A and radius AB and the other with center Band radius BA. It follows that each point of intersection is distant from both A and B by the length of AB and hence forms an equilateral triangle. Analytic geometry takes its cue from this construction, but it also finds the intersections by finding the common solutions of the equations to the two circles.

Pag. 103(116) - Chapter 6 - Factors Affecting Size Constancy Much of the spatial perception literature is not quantitative in a way that is de- tailed enough to really say much about the geometry of visual space. Many researchers and theorists seek to describe the cues used for depth perception or the internal mechanisms that underlie spatial representations using standard experi- mental techniques that vary conditions across groups (Gibson, 1950; Herschen- son, 1999; Rock, 1983). These types of studies do not generate data that is sufficiently rich to support detailed mathematical modeling. Obviously, the last chap- ter, which looked at the direct estimation of spatial metrics, reported on one body of research that is an exception to this rule. Another area in space perception that has also yielded a numerically rich database is the size-constancy literature. This chapter will discuss the size-constancy paradigm and lay out some of the factors that influence size constancy. Following this, I offer a review of the lit- erature that presents major theoretical positions on size constancy in chronologi- cal order along with empirical work that bears on each theory (some of which may be of more recent origin). The chapter will then summarize the literature and present my own theory that can explain much of this literature in a way that is consistent with the direct estimation literature discussed in the previous chapter.

Pag. 113(126) -IMPORTANT Figure 6.2. Average ratio of comparison to standard as a function of distance to the standard in Gilinsky's (1955) data. Objective data show overconstancy and are represented with open symbols. Projective data shows strong underconstancy and are represented by closed symbols. Circles collected with 42 in standard, squares with 55 in standard, upward pointing triangles with 66 in standard, and downward pointing triangles with 78 in standard. Solid lines represent best fitting full model curves. The dashed line represents perfect constancy.

Pag. 17(38) - 2.2 MULTIPLE INTEGRALS AND DIVERGENCE THEOREM In this section, we state two important results, namely, the Green's theorem and the divergence theorem. These are extensively used in the analysis of PDE. In a sense these theorems are the higher dimensional versions of the familiar fundamental theorem of calculus and integration by parts formula in one dimension. Hence they are also important by themselves and are particular cases of a general result called Stokes theorem on smooth manifolds. However, even for the statements of these theorems, we need a lot of machinery from differential geometry; some of these are the concept of a smooth domain, smooth surface (curve in two dimensions), integration over these objects, tangent space and smoothly varying unit normal to a surface. In this brief introduction to the subject, it will not be possible to present all these concepts in a rigorous manner. The reader should refer to the cited references for much deeper treatment of these topics. Our discussion here is just explaining these important theorems in some simple geometric situations. 2.2.1 Multiple Integrals In this sub-section, we briefly discuss the notion of multiple integrals, iterated integrals and integration by parts in multiple integrals leading to Green's theorem in two dimensions and divergence theorem (called Gauss-Ostrogadskii formula)in more than two variables. The general references for multiple integrals and their applications are Rund (1973), Spivak (1965), Apostol (2002), Taylor and Mann (1983), and Widder (1961). The Riemann integral of a bounded function in a rectangular domain in R n is very similar to the one-dimensional integral. However, for a general domain on which we wish to define the concept of integral, certain restrictions apply, especially in relation to the boundary of the domain. A very general description of these restrictions is indeed a difficult task, requiring the tools from differential geometry. Our presentation here will be simple, requiring the domains we consider have some specific geometric properties.

1.15 Projection Orthogonale de C sur Pi

Date: 20200725

1) C:/DATA-NovoVivo-122-2020/Books-122-2020/Math-Important/Bernard

Gostiaux - Cours de mathematiques speciales - tome 4 - Geometrie affine et metrique - 1995.pdf IMPORTANT

Pag. 163 (185) - 6. Soit P le plan du cercle C, le plan 7r coupe P suivant une droite A qui coupe le cercle en Cet D. Soient A et B intersections du cercle C et du diametre perpendiculaire a [DG].

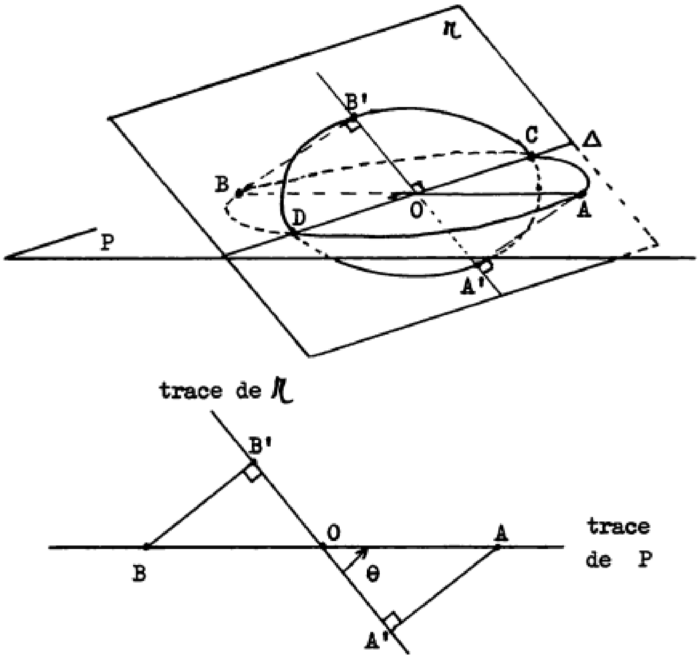

Figure 1.15: po.png

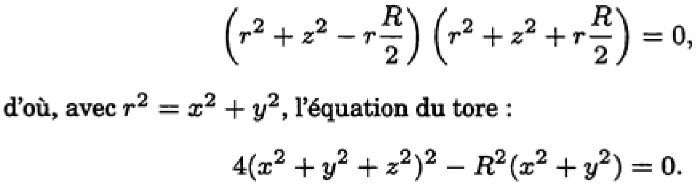
L'ellipse e, projection orthogonale de C sur Pi a pour grand axe CD et petit axe A' B', projection orthogonale de AB sur Pi. Dans le plan Q, orthogonala A en 0, les points A' et B' decrivant les deux cercles de diametres OA et OB, tangents en 0, ceci lorsque pour A fixe, l'angle Theta du diedre (P, Pi) varie. Lorsque A pivote autour de 0, ces cercles engendrent donc un tore de collier nul.

Si on veut y mettre de l'analytique, les deux cercles de diametres R, tangents en 0 a Oz, dans un plan rOz, ont pour equation:

2) C:/DATA-NovoVivo-122-2020/Books-122-2020/Math-Important/Bernard Gostiaux - Cours de mathematiques speciales - tome 4 - Geometrie affine et metrique - 1995.pdf IMPORTANT

Pag. 179(191) - CHAPITRE 5 Geometrie plane euclidienne Pourquoi ce chapitre, ce favoritisme pour la dimension deux? Peut-être parce que l'aspect



$$\left(r^2+z^2-r\frac{R}{2}\right)\left(r^2+z^2+r\frac{R}{2}\right)=0,$$

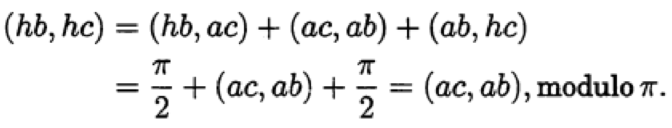
d'où, avec $r^2=x^2+y^2$, l'équation du tore :

$$4(x^2+y^2+z^2)^2-R^2(x^2+y^2)=0.$$

Figure 1.16: po2.png

livresque de notre culture a accentué l'importance du support plan. Pensez a la mise en place de la perspective en peinture, qui permet au cerveau de concevoir l'espace a partir d'une figuration plane. C'est aussi pour justifier des résultats utilisés de ci, de là, les centres d'homothétie de deux ou trois cercles par exemple, et enfin pour parler de la géométrie du triangle, si riche qu'elle peut faire l'objet de livres entiers. La difficulté de ce chapitre sera de savoir jusqu'où ne pas aller trop loin! Son cadre est celui des plans affines euclidiens.

Pag. 188 (200) - THEOREME 5.19. -Les symétriques de l'orthocentre h d'un triangle abc, par rapport aux côtés sont sur le cercle circonscrit au triangle. Vous souvenez-vous de ce qu'est l'orthocentre d'un triangle? C'est le point d'intersection des trois hauteurs, et nous justifierons en 5.20 qu'elles se coupent. Pour l'instant on l'admet. Soit ici h l'orthocentre du triangle abc inscrit dans le cercle C, (voir figure 5.19), et h' symétrique de h par rapport au côté be : on a (hb, hc) = -(h'b, h'c) vu l'action d'une symétrie sur les angles. Mais (hb, hc) = (ac, ab), angles a côtés perpendiculaires: on justifie en décomposant en



$$\begin{aligned}(hb,hc)&=(hb,ac)+(ac,ab)+(ab,hc)\\&=\frac{\pi}{2}+(ac,ab)+\frac{\pi}{2}=(ac,ab),\textbf{modulo}\,\pi.\end{aligned}$$

Figure 1.17: po3.png

Donc (h'b, h'c) = -(ac, ab) = (ab, ac) : les points h', a, b, et c sont cocycliques d'après 5.18.

Pag. 189 (201) - THEOREME 5.20. - Soit un triangle abc du plan affine euclidien. Les trois hauteurs issues de a, b et c sont concourantes en un point appelé orthocentre du triangle. Soit g le centre de gravité du

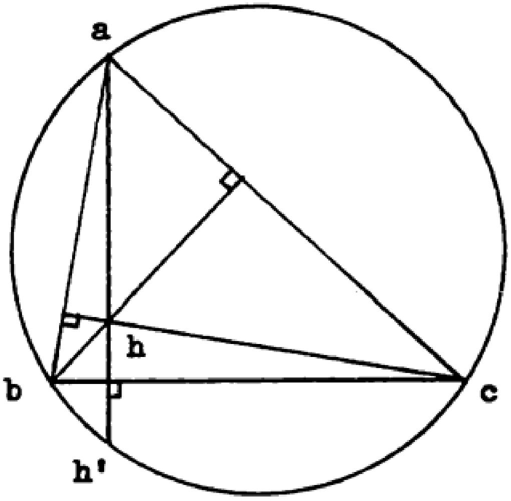


Figure 1.18: po4.png

triangle, isobarycentre des sommets. Si m est le milieu de [a, b], g est aussi le barycentre de (m, 2) et (a, 1) donc on a

$$2\overrightarrow{gm} + \overrightarrow{ga} = 0, \text{ ou } \overrightarrow{ga} = -2\overrightarrow{gm}$$

Figure 1.19: po5.png

Considérons l'homothétie de centre g, de rapport -2, notée phi. On a phi(m) = a, donc l'image par phi de la droite a (b, c) est la parallèle a a (b, c) passant par a. On obtient de même les images des droites a (a, b) et a (a, c), d'où leurs intersections, images de a, b et c, notées a', b', c', (voir figure 5.20).

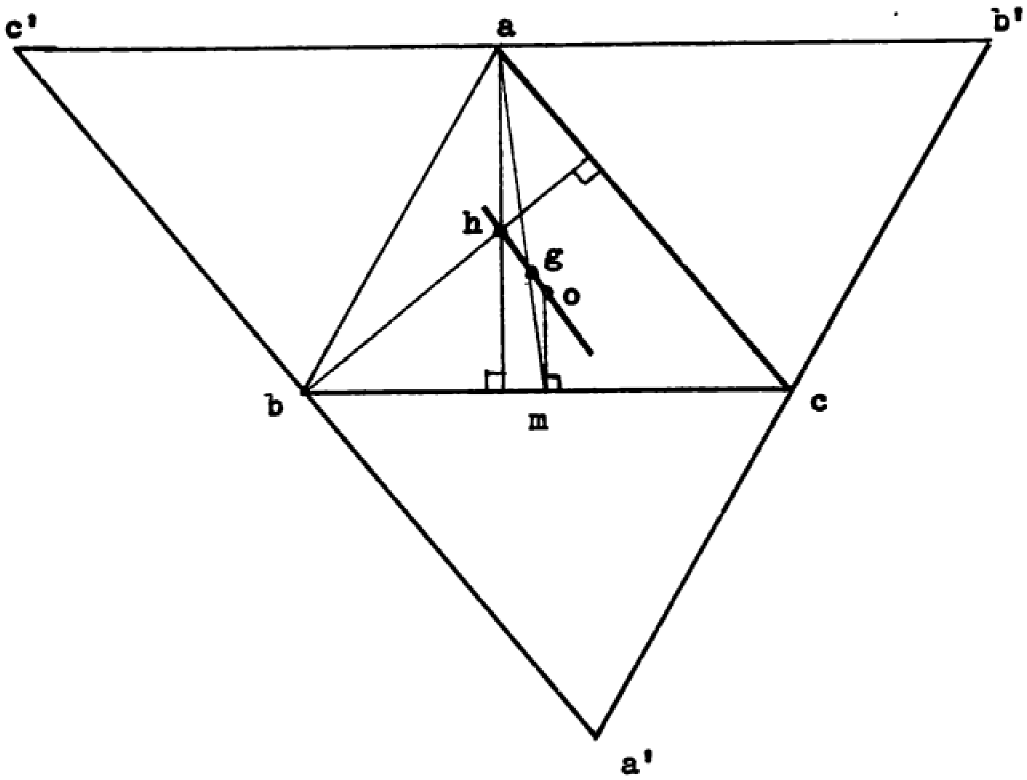

Figure 1.20: po6.png

Dans l'homothétie phi, la perpendiculaire en a à b'c', (donc la hauteur issue de a pour le triangle abc), est l'image par phi de la perpendiculaire en m à be, c'est-à-dire de la médiatrice de [b, c]. Les images par cp des trois médiatrices du triangle abc sont donc ses trois hauteurs. Or les médiatrices se coupent en 0, centre du cercle circonscrit au triangle, (si 0 est l'intersection des médiatrices de [a, b] et [b, c] on a Oa =Ob et Ob= Oc d'où Oa =Oc; donc 0 est sur la troisième médiatrice). Il en résulte que phi(0) est sur les trois hauteurs, d'où l'existence de h, mais aussi la relation

$$\overrightarrow{gh} = -2\overrightarrow{go}$$

Figure 1.21: po7.png

On a donc: COROLLAIRE 5.21. - Dans ce triangle abc , l'orthocentre h, le centre de gravité g et le centre du cercle circonscrit 0 sont alignés et on

a

$$\overrightarrow{gh} = -2\overrightarrow{go}$$

Figure 1.22: po7.png

(autrement dit g est entre h et 0, aux deux tiers à partir de h.

THEOREME 5.22. - Une condition nécessaire et suffisante pour qu'un point m soit sur le cercle C circonscrit à un triangle abc est que les projetés a', b' etc' de m sur be, ca et ab soient alignés. Si c'est le cas, la droite D = a (a', b', c') est appelée droite de Simson de triangle abc pour le point m.

Si on projette un point m du plan en a' sur be, b' sur ca et c' sur ab, comme (c' a, c' m) = Pi/2 = (b' a, b' m), les points a, m, c', b' sont cocycliques, donc on a également (b'a, b'c') =(ma, mc'), (voir figure 5.22).

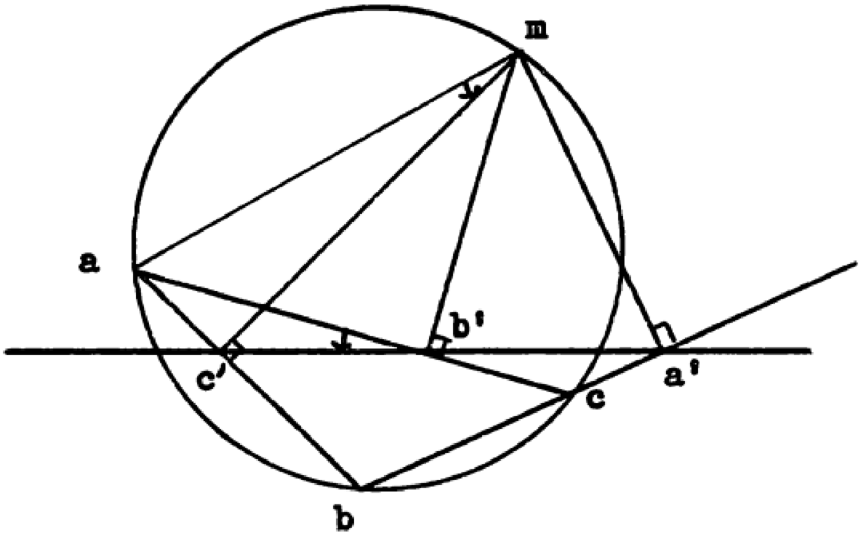

Figure 1.23: po8.png

On a de même: (b'c,b'a') =(me, ma').

or (ma, mc')= (ma, ma')+ (ma',mc') et (mc, ma')= (mc, ma)+ (ma, ma').

Comme enfin les points m, b, c', a' sont cocycliques, (toujours (c'b, dm) = Pi/2 = (a'm, a'b)), on a l'égalité des angles de droites (ma', mc') = (ba', bc') = (bc, ba) car il s'agit des mêmes droites. On en déduit donc que :

5.23

(b'a,b'c') =(ma, ma')+ (ma',md) =(ma, ma')+ (bc,ba) et (b'c,b'a') =(mc, ma)+ (ma, ma').

Si on suppose m sur le cercle C, (me, ma)= (be, ba), d'où: (b' a, b' c') = (b' c, b' a'). Mais alors, par Chasles, on a : (b'c',b'a') = (b'c',b'a) + (b'a,b'c) + (b'c,b'a') = (b'c',b'a) +0+ (b'a,b'c') = (b'c',b'c') = 0 car a, c et b' sont alignés. On a donc a', b' et c' alignés. Si réciproquement a', b' et c' sont alignés, b' c' et b' a' définissent la même droite, ainsi que b' a et b' c, (b' projeté orthogonal de b sur ac), donc (b' a, b' d) = (b' c, b' a') et vu les égalités 5.23, on en déduit que (mc, ma)= (bc, ba), donc que m est sur le cercle circonscrit au triangle a, b, c.

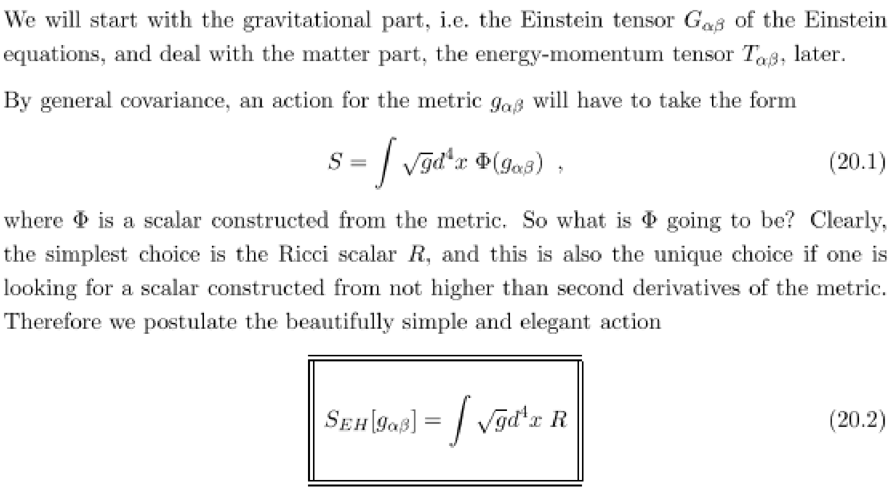
Pag. 380(381) - 20 Einstein Equations from an Action Principle 20.1 Einstein-Hilbert Action



We will start with the gravitational part, i.e. the Einstein tensor $G_{\alpha\beta}$ of the Einstein equations, and deal with the matter part, the energy-momentum tensor $T_{\alpha\beta}$, later.

By general covariance, an action for the metric $g_{\alpha\beta}$ will have to take the form

$$S = \int \sqrt{g} d^4x \; \Phi(g_{\alpha\beta}) \ , \qquad (20.1)$$

where Φ is a scalar constructed from the metric. So what is Φ going to be? Clearly, the simplest choice is the Ricci scalar R, and this is also the unique choice if one is looking for a scalar constructed from not higher than second derivatives of the metric. Therefore we postulate the beautifully simple and elegant action

$$\boxed{S_{EH}[g_{\alpha\beta}] = \int \sqrt{g} d^4x \; R} \qquad (20.2)$$

Assunto: Introduction to Modified Gravity

Pag.: 16 (24) - As an example, we consider the Gödel-type metric (2.26). One can show, that, unlike general relativity, such solutions are possible not only for dust but also for the vacuum (with non-zero cosmological constant), in particular, completely causal vacuum solutions are present [26]. Clearly, the solutions of this form are possible also for the presence of the matter given by the relativistic fluid and a scalar field. Again, as in [22], all Einstein equations will take the form of purely algebraic relations between density, pressure, field amplitude and constants from the gravity Lagrangian. As for the cosmological metric, the possibility of accelerating solutions can be shown just in the same manner as in the previous sections. Among other possible solutions in $f(R, Q)$ gravity, it is worth to mention Reissner{Nordström black holes [27] and wormholes [28].

Chapter 2

Pappus Theorem

Date: 20200728

1) Pappus' Theorem Today we will learn about Pappus' theorem. This theorem states that if we take three points 1, 3, 5 on a line, and another three points 2, 4, 6 on another line, then the three intersection points of the following line pairs 12,45, 23,56, 34,61

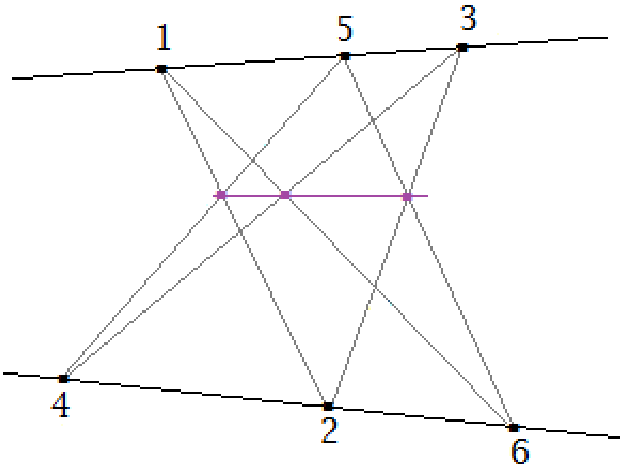

Figure 2.1: pt1.png

Pappus' theorem looks very similar to Pascal's hexagon theorem. In Pascal's theorem, we have a hexagon 123456 inscribed in a circle and the intersection points of the three pairs of opposite sides 12,45, 23,56, 34,61 of the hexagon lie on a straight line.

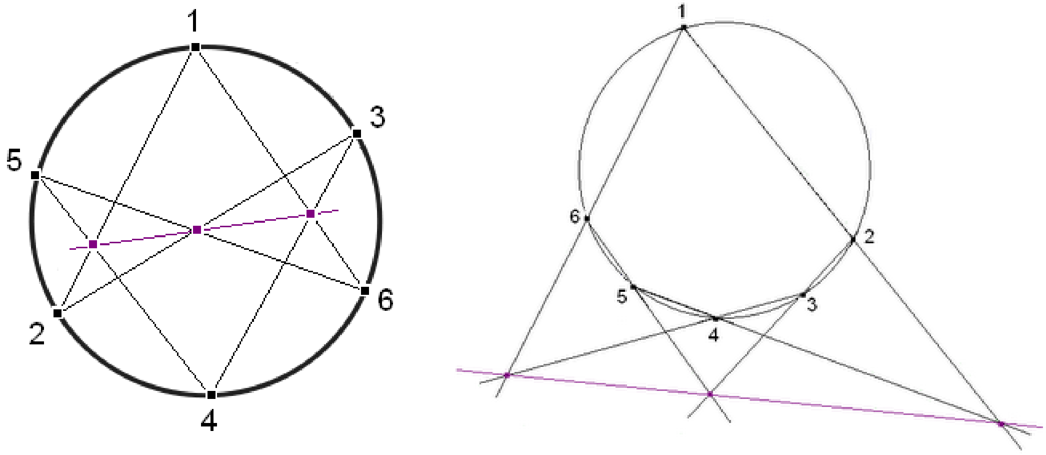

Figure 2.2: pt2.png

So instead of being inscribed in a circle as in Pascal's theorem, in Pappus' theorem, we may say that the hexagon 123456 "inscribed" in two lines and again, the intersection points of the three pairs of opposite sides 12,45, 23,56, 34,61 of the hexagon also lie on a straight line.

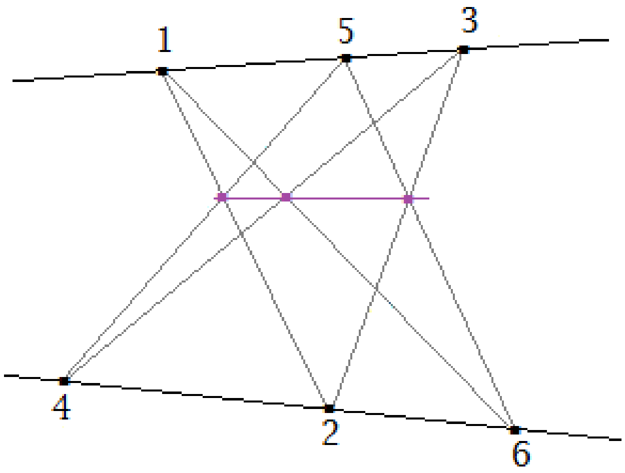

Figure 2.3: pt3.png

Different configurations of Pappus' theorem

Similar to Pascal's theorem, Pappus' theorem also has many configurations. The six vertices of the hexagon can be arranged on the two lines in any particular order. With each arrangement of the vertices, we have an instance of Pappus' theorem. Below is an example:

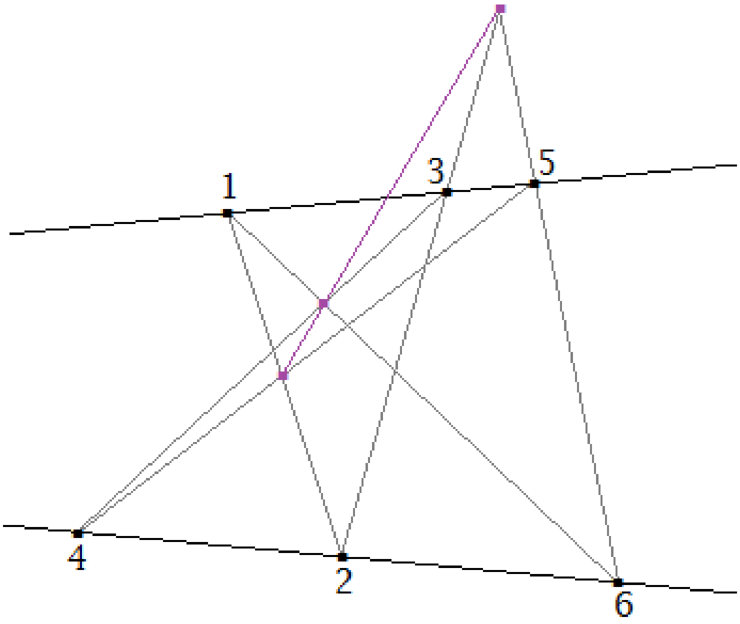

Figure 2.4: pt4.png

Now, why don't you try to draw for yourself your own picture of Pappus' theorem?! This theorem is so cool, isn't it?!

The picture below illustrates another interesting aspect of Pappus' theorem, that is the roles of the hexagon's vertices and the intersection points can be interchanged. As we can see, in the middle figure, the intersection points are interchanged with the vertices 1, 3, 5; and in the right-hand-side figure, the intersection points are swapped with 2, 4, 6.

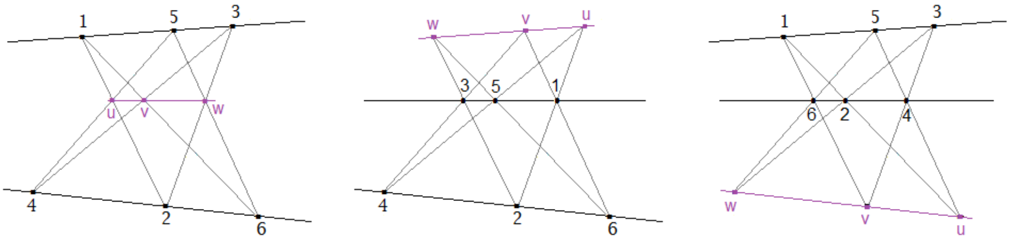

Figure 2.5: pt5.png

Note that, in all three figures above, u is always the intersection point of the pair 12,45, v is always the intersection point of the pair 34,61 and w is always the intersection point of 23,56.

Proving Pappus' theorem

We will use Menelaus' theorem to prove Pappus' theorem. Menelaus' theorem is a useful tool to prove the collinearity of points. The theorem is stated as follows:

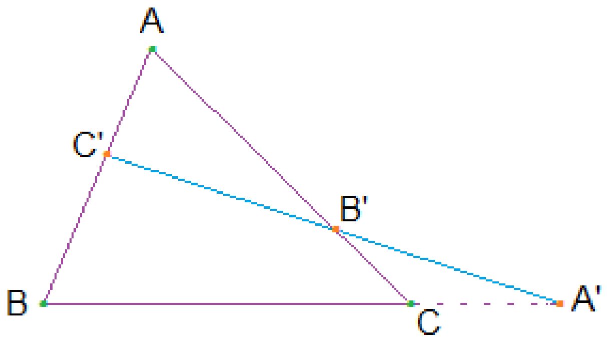

Figure 2.6: pt6.png

Menelaus' theorem: Given a triangle ABC and three points A', B', C' lying on the three lines BC, CA, AB, respectively. Then the three points A', B', C' are collinear if and only if

$$\frac{A'B}{A'C}\frac{B'C}{B'A}\frac{C'A}{C'B} = 1 : \qquad (2.1)$$

The proof that we are about to present is very similar to the proof of Pascal' theorem that we show in the previous post. Before going into detail, let us review that proof of Pascal' theorem. Let us consider the following figure.

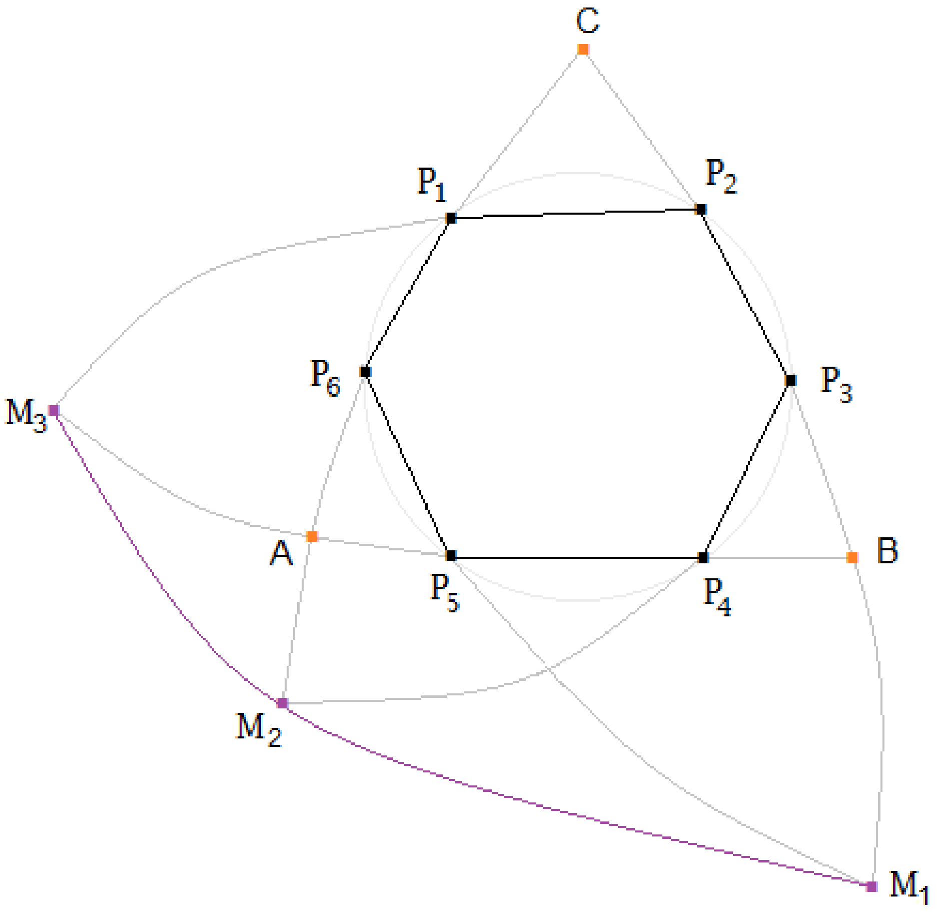

Figure 2.7: pt7.png

On this figure, we see a Pascal's hexagon P1P2P3P4P5P6 and the three intersection points M1, M2, M3. To prove that M1, M2, M3 lies on a straight line, we apply Menelaus' theorem for the triangle ABC. Since M1 belongs to the line BC, M2 belongs to the line CA and M3 belongs to the line AB, to prove that they are collinear, we show that

$$\frac{\widetilde{M_1B}}{\widetilde{M_1C}} \frac{\widetilde{M_2C}}{\widetilde{M_2A}} \frac{\widetilde{M_3A}}{\widetilde{M_3B}} = 1: \qquad (2.2)$$

Now we do the same to prove Pappus' theorem. We will use Menelaus' theorem for the triangle ABC. The triangle ABC is determined exactly in the same way as in the proof of Pascal's theorem: A is the intersection of P4P5 and P6P1, B is the intersection of P2P3 and P4P5, and C is the intersection of P2P3 and P6P1.

P_5
P_4
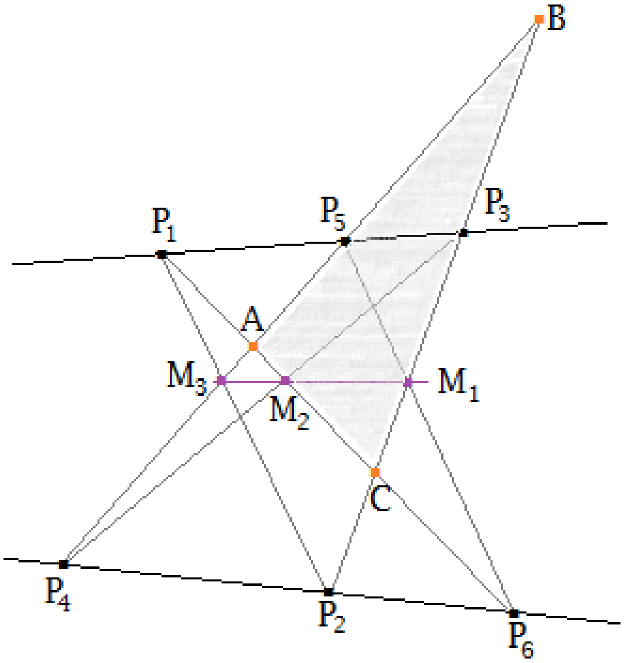
B

Figure 2.8: pt8.png

Let us write down the proof.

Applying Menelaus' theorem for the triangle ABC with the following triples of collinear points M1,P6,P5, M2,P4,P3, M3,P2,P1, P1,P3,P5, P2,P4,P6,



B
P_1
P_5
P_3
A
M_3
M_2
M_1
C
P_4
P_2
P_6

Figure 2.9: pt9.png

we have

$$\frac{\widetilde{M_1B}}{\widetilde{M_1C}}\ \frac{\widetilde{P_6C}}{\widetilde{P_6A}}\ \frac{\widetilde{P_5A}}{\widetilde{P_5B}} = \frac{\widetilde{M_2C}}{\widetilde{M_2A}}\ \frac{\widetilde{P_4A}}{\widetilde{P_4B}}\ \frac{\widetilde{P_3B}}{\widetilde{P_3C}} = \frac{\widetilde{M_3A}}{\widetilde{M_3B}}\ \frac{\widetilde{P_2B}}{\widetilde{P_2C}}\ \frac{\widetilde{P_1C}}{\widetilde{P_1A}} \tag{2.3}$$

$$= \frac{\widetilde{P_1A}}{\widetilde{P_1C}}\ \frac{\widetilde{P_3C}}{\widetilde{P_3B}}\ \frac{\widetilde{P_5B}}{\widetilde{P_5A}} = \frac{\widetilde{P_2C}}{\widetilde{P_2B}}\ \frac{\widetilde{P_4B}}{\widetilde{P_4A}}\ \frac{\widetilde{P_6A}}{\widetilde{P_6C}} = 1: \tag{2.4}$$

Multiply all the above identities, we derive

$$\frac{\widetilde{M_1B}}{\widetilde{M_1C}}\ \frac{\widetilde{M_2C}}{\widetilde{M_2A}}\ \frac{\widetilde{M_3A}}{\widetilde{M_3B}} = 1: \tag{2.5}$$

Thus, M1, M2, M3 are collinear, and the theorem is proved.

So, once again today, by applying Menelaus' theorem in an effective way, we have proved Pappus' theorem.

Homework.

1. Let us call the purple points as Pappus' points, and the purple line connecting them as Pappus' line.

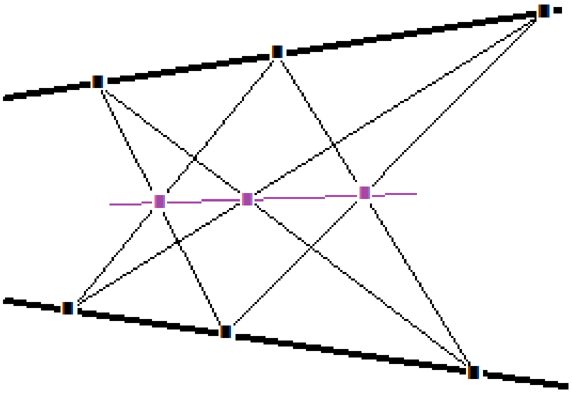


Figure 2.10: pt10.png

Now, let the six points stay fixed on the two lines. By different labeling 1,2,3,4,5,6 to the six points, the questions are

how many Pappus' lines can be generated? how many Pappus' points can be generated? each Pappus' point lies on how many Pappus' lines? each Pappus' line contains how many Pappus' points?

2. Instead of applying Menelaus' theorem for the triangle ABC as in the above proof, choose X as the intersection of P1P2 and P3P4, Y the intersection of P1P2 and P5P6, and Z the intersection of P3P4 and P5P6, prove Pappus' theorem by using Menelaus' theorem for the triangle XYZ.

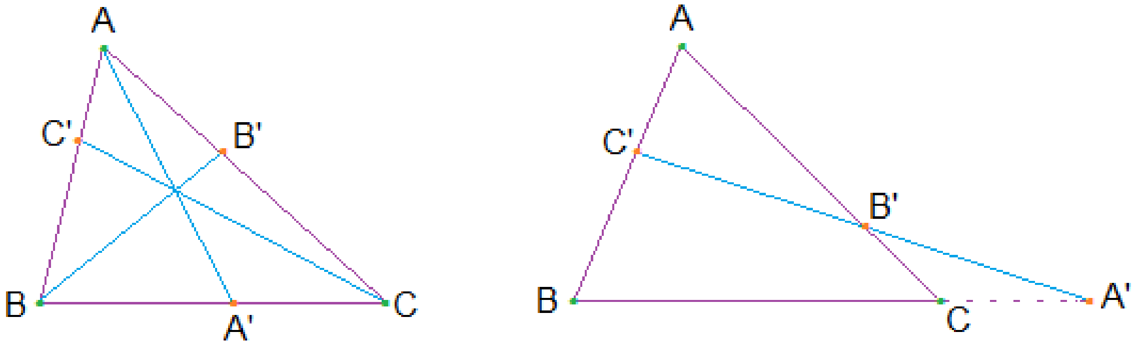
2.1 Ceva's Theorem and Menelaus' Theorem

Today we will learn about two well-known theorems in geometry, Ceva's Theorem and Menelaus' Theorem. These two theorems are very useful in plane geometry because we often use them to prove that a certain number of points lie on a straight line and a certain number of lines intersect at a single point. Both of the theorems will be proved based on a common simple principle. We also generalize the theorems for arbitrary polygons.



Ceva

Menelaus

Figure 2.13: ct1.png

Let us state the theorems.

Ceva's Theorem: Given a triangle ABC and three points A', B', C' lying on the three lines BC, CA, AB, respectively. Then the three lines AA', BB', CC' are concurrent if and only if

$$\frac{A'B}{A'C}\quad\frac{B'C}{B'A}\quad\frac{C'A}{C'B} = 1: \tag{2.6}$$

Menelaus' Theorem: Given a triangle ABC and three points A', B', C' lying on the three lines BC, CA, AB, respectively. Then the three points A', B', C' are collinear if and only if

$$\frac{\overrightarrow{A'B}}{\overrightarrow{A'C}} \quad \frac{\overrightarrow{B'C}}{\overrightarrow{B'A}} \quad \frac{\overrightarrow{C'A}}{\overrightarrow{C'B}} = 1 : \qquad (2.7)$$

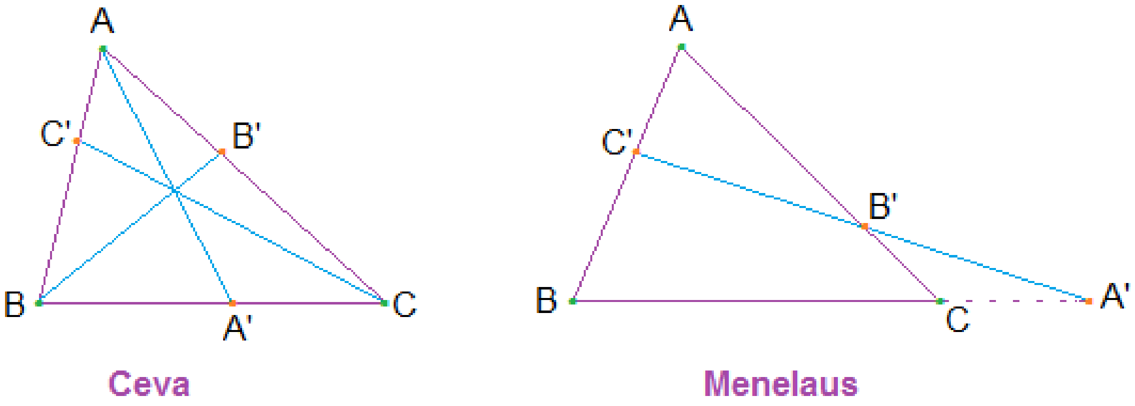


Figure 2.14: ct2.png

Signed ratio of line segments

First, let us explain a little bit about the notation that we use in the theorems. The notation $\frac{\overrightarrow{A'B}}{\overrightarrow{A'C}}$ is called a signed ratio. In the figure below, we can see that the normal (unsigned) ratio $\frac{UX}{UY} = 2$, but the signed ratio is $\frac{\overrightarrow{UX}}{\overrightarrow{UY}} = \ \ 2$. This is because $\overrightarrow{UX}$ and $\overrightarrow{UY}$ point to the same direction, and it is negative when $\overrightarrow{UX}$ and $\overrightarrow{UY}$ points to opposite directions.

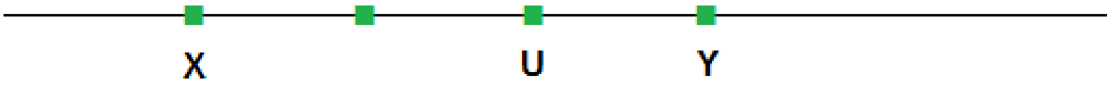

Figure 2.15: ct3.png

The normal ratio is always a positive number but the signed ratio can be negative or positive. The signed ratio $\frac{\overrightarrow{UX}}{\overrightarrow{UY}}$ is positive when $\overrightarrow{UX}$ and $\overrightarrow{UY}$ point to the same direction, and it is negative when $\overrightarrow{UX}$ and $\overrightarrow{UY}$ points to opposite directions.

So why do we need the signed ratio?

The trouble with our normal ratio is that it cannot uniquely identify a point on a line in relation to two other reference points, but the signed ratio can.

Let us consider an example. Suppose on the line XY, we want to specify a point Z so that $\frac{ZX}{ZY} = 2$.

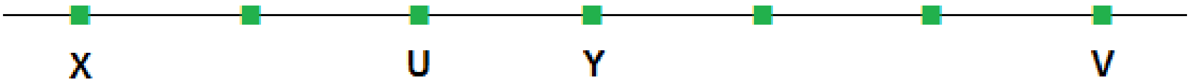

Figure 2.16: ct4.png

In the above figure, we can see that using our usual unsigned ratio, there are two points, U and V, satisfying this condition since

$$\frac{UX}{UY} = \frac{VX}{VY} = 2. \tag{2.8}$$

But if we consider signed ratio, then there is a unique point, which is V satisfying $\frac{\overline{VX}}{\overline{VY}} = 2$.

The point U no longer satisfies because $\frac{\overline{UX}}{\overline{UY}} = -2 \neq 2$.

Signed area

Similar to signed ratio, we have the concept of signed area. The normal (unsigned) area of a polygon is always a positive number but a signed area can be positive or negative depending on the orientation of the vertices of the polygon.

If we draw a coordinate system 0xy on the plane then any point A on the plane will have an associated coordinate (Ax,Ay). We define

$$[A; B] = A_x B_y - A_y B_x \tag{2.9}$$

and define the signed area of a triangle ABC to be

$$\overline{s}(ABC) = \frac{1}{2}([A; B] + [B; C] + [C; A]). \tag{2.10}$$

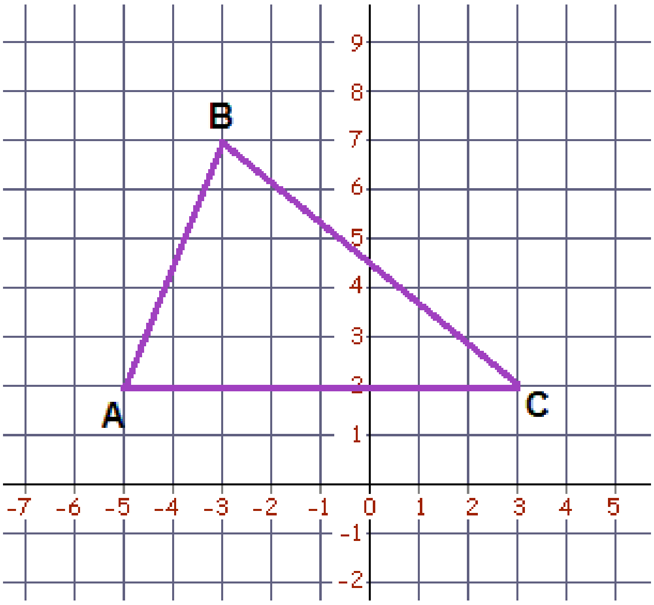

Figure 2.17: ct5.png

In the above figure, we have the coordinates A(-5,2), B(-3,7), C(3,2). So we can calculate

$$[A;B] = A_x B_y - A_y B_x = (-5)(7) - (2)(-3) = -29; \quad (2.11)$$

$$[B;C] = B_x C_y - B_y C_x = (-3)(2) - (7)(3) = -27; \quad (2.12)$$

$$[C;A] = C_x A_y - C_y A_x = (3)(2) - (2)(-5) = 16: \quad (2.13)$$

Thus,

$$\bar{s}(ABC) = \frac{1}{2}([A;B] + [B;C] + [C;A]) = \frac{1}{2}(-29 - 27 + 16) = -20: \quad (2.14)$$

On the other hand, [A,C]=-16, [C,B]=27, [B,A]=29 and $\bar{s}(ACB) = 20$.

A theorem on ratio of signed areas

Let us now state a simple theorem concerning about the ratio of the signed areas of two triangles that share a common edge. We will use this theorem later to prove the Ceva's theorem and the Menelaus' theorem.

A Theorem on Ratio of Signed Areas. Given two triangles ABU and ABV that share a common edge AB. The line connecting the two vertices UV intersects with the line AB at a point T. Then it must hold that

$$\frac{\overline{s}(ABU)}{\overline{s}(ABV)} = \frac{\overline{TU}}{\overline{TV}}: \qquad (2.15)$$

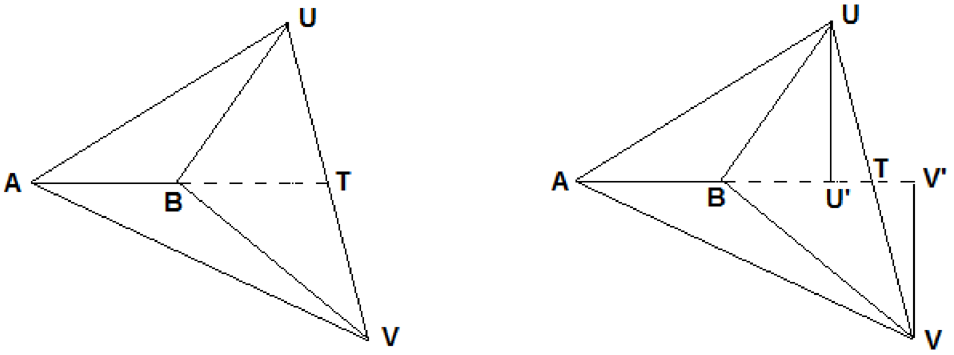

Figure 2.18: ct6.png

This theorem is quite obvious if we forget about the sign and consider the usual unsigned ratio. This is because if we draw the two altitudes UU' and VV' perpendicular to the side AB then

$$\frac{s(ABU)}{s(ABV)} = \frac{AB \quad UU^0=2}{AB \quad VV^0=2} = \frac{UU^0}{VV^0} = \frac{TU}{TV}: \qquad (2.16)$$

We will give a proof of this theorem for the signed ratio in the next post.

Proving Ceva's Theorem and Menelaus' Theorem

Let us now use the above theorem to prove Ceva's Theorem and Menelaus' Theorem.

Proof of Ceva's Theorem. Suppose the three lines AA', BB', CC' are concurrent at a point I. Then by the theorem on the ratio of signed areas, we have

$$\frac{\overline{A^0B}}{\overline{A^0C}} = \frac{\overline{s}(IAB)}{\overline{s}(IAC)}; \quad \frac{\overline{B^0C}}{\overline{B^0A}} = \frac{\overline{s}(IBC)}{\overline{s}(IBA)}; \quad \frac{\overline{C^0A}}{\overline{C^0B}} = \frac{\overline{s}(ICA)}{\overline{s}(ICB)}: \qquad (2.17)$$

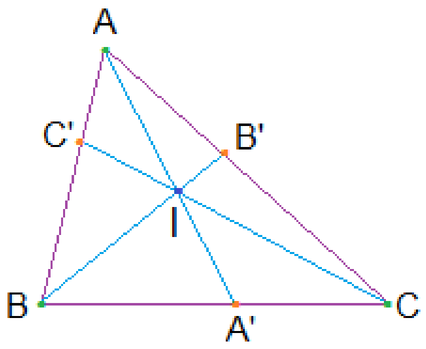

Figure 2.19: ct7.png

Thus,

$$\frac{A'B}{A'C}\frac{B'C}{B'A}\frac{C'A}{C'B} = \frac{s(IAB)}{s(IAC)}\frac{s(IBC)}{s(IBA)}\frac{s(ICA)}{s(ICB)} \tag{2.18}$$

$$= \left(\frac{s(IAB)}{s(ICA)}\right)\left(\frac{s(IBC)}{s(IAB)}\right)\left(\frac{s(ICA)}{s(IBC)}\right) = 1. \tag{2.19}$$

In the reverse direction, if

$$\frac{A'B}{A'C}\frac{B'C}{B'A}\frac{C'A}{C'B} = 1, \tag{2.20}$$

we need to prove that the three lines AA', BB', CC' are concurrent. In this case, let AA' and BB' intersect at a point I, let CI and AB intersect at C", we need to show that C"=C'. Indeed, since AA', BB', CC" are concurrent, by what we have just proved, we have

$$\frac{A'B}{A'C}\frac{B'C}{B'A}\frac{C''A}{C''B} = 1, \tag{2.21}$$

Thus,

$$\frac{C''A}{C''B} = \frac{C'A}{C'B}. \tag{2.22}$$

Since the signed ratio determines a point uniquely on the line AB, we obtain C'=C".

So we have proved the Ceva's Theorem.

Proof of Menelaus' Theorem. Suppose that the three points A', B', C' are collinear. Take two arbitrary points I and J on the line A'B'C', then by the theorem on the ratio of signed areas, we have

$$\frac{A'B}{A'C} = \frac{\overline{s}(IJB)}{\overline{s}(IJC)}; \quad \frac{B'C}{B'A} = \frac{\overline{s}(IJC)}{\overline{s}(IJA)}; \quad \frac{C'A}{C'B} = \frac{\overline{s}(IJA)}{\overline{s}(IJB)}: \qquad (2.23)$$

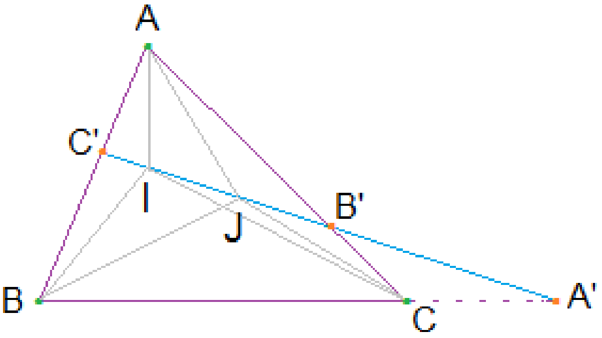

Figure 2.20: ct8.png

Thus,

$$\frac{A'B}{A'C} \frac{B'C}{B'A} \frac{C'A}{C'B} = \frac{\overline{s}(IJB)}{\overline{s}(IJC)} \frac{\overline{s}(IJC)}{\overline{s}(IJA)} \frac{\overline{s}(IJA)}{\overline{s}(IJB)} = 1: \qquad (2.24)$$

The reverse direction of Menelaus' Theorem is proved similar to that of Ceva's Theorem.

So we have finally proved Ceva's Theorem and Menelaus' Theorem. This proof also works if we only consider the usual unsigned ratio. We remark that for Menelaus' theorem, instead of using the ratio of the areas of the triangles, the same result can be obtained if we use the ratio of the altitudes drawing from A, B, C perpendicular to the line A'B'C'.

Generalization of Ceva's Theorem and Menelaus' Theorem

The above proof of Ceva's theorem and Menelaus' theorem motivates us to generalize the theorems for arbitrary polygons.

Here are Ceva's theorem and Menelaus' theorem for pentagon.

Ceva's theorem for pentagon. Given a pentagon A1A2A3A4A5 and five points B1, B2, B3, B4, B5 lying on the lines A5A2, A1A3, A2A4, A3A5, A4A1, respectively. If the lines A1B1, A2B2, A3B3, A4B4, A5B5 are concurrent then

$$\frac{\widetilde{B_1A_5}}{\widetilde{B_1A_2}}\quad\frac{\widetilde{B_2A_1}}{\widetilde{B_2A_3}}\quad\frac{\widetilde{B_3A_2}}{\widetilde{B_3A_4}}\quad\frac{\widetilde{B_4A_3}}{\widetilde{B_4A_5}}\quad\frac{\widetilde{B_5A_4}}{\widetilde{B_5A_1}} = 1. \tag{2.25}$$

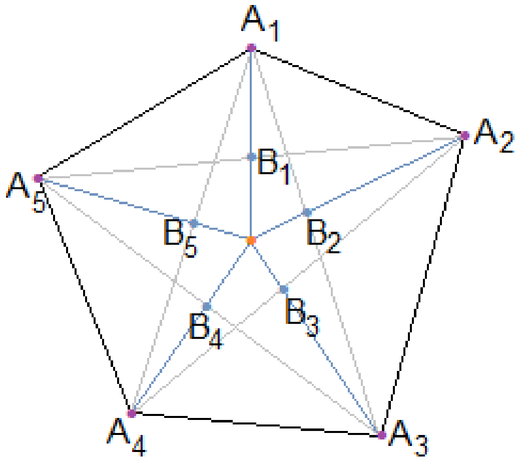

Figure 2.21: ct9.png

Proof. If the five lines A1B1, A2B2, A3B3, A4B4, A5B5 are concurrent at a point I then

$$\frac{\widetilde{B_1A_5}}{\widetilde{B_1A_2}}\quad\frac{\widetilde{B_2A_1}}{\widetilde{B_2A_3}}\quad\frac{\widetilde{B_3A_2}}{\widetilde{B_3A_4}}\quad\frac{\widetilde{B_4A_3}}{\widetilde{B_4A_5}}\quad\frac{\widetilde{B_5A_4}}{\widetilde{B_5A_1}} \tag{2.26}$$

$$= \frac{\overline{s}(IA_1A_5)}{\overline{s}(IA_1A_2)}\quad\frac{\overline{s}(IA_2A_1)}{\overline{s}(IA_2A_3)}\quad\frac{\overline{s}(IA_3A_2)}{\overline{s}(IA_3A_4)}\quad\frac{\overline{s}(IA_4A_3)}{\overline{s}(IA_4A_5)}\quad\frac{\overline{s}(IA_5A_4)}{\overline{s}(IA_5A_1)} \tag{2.27}$$

$$= \left(\frac{\overline{s}(IA_5A_1)}{\overline{s}(IA_1A_2)}\right)\left(\frac{\overline{s}(IA_1A_2)}{\overline{s}(IA_2A_3)}\right)\left(\frac{\overline{s}(IA_2A_3)}{\overline{s}(IA_3A_4)}\right)\left(\frac{\overline{s}(IA_3A_4)}{\overline{s}(IA_4A_5)}\right)\left(\frac{\overline{s}(IA_4A_5)}{\overline{s}(IA_5A_1)}\right) = 1. \tag{2.28}$$

Menelaus' theorem for pentagon. Given a pentagon A1A2A3A4A5 and five points B1, B2, B3, B4, B5 lying on the lines A1A2, A2A3, A3A4, A4A5, A5A1, respectively. If the points B1, B2, B3, B4, B5 are collinear then

$$\frac{\widetilde{B_1A_1}}{\widetilde{B_1A_2}}\quad\frac{\widetilde{B_2A_2}}{\widetilde{B_2A_3}}\quad\frac{\widetilde{B_3A_3}}{\widetilde{B_3A_4}}\quad\frac{\widetilde{B_4A_4}}{\widetilde{B_4A_5}}\quad\frac{\widetilde{B_5A_5}}{\widetilde{B_5A_1}} = 1. \tag{2.29}$$

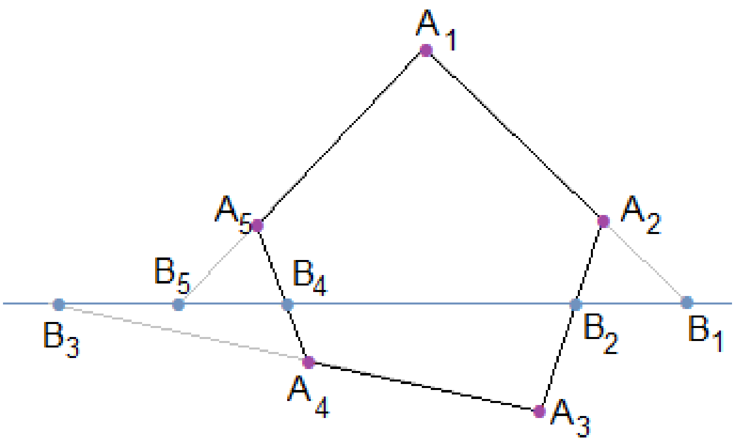

Figure 2.22: ct10.png

Proof. If the five points B1, B2, B3, B4, B5 lie on the same straight line then take two arbitrary points I, J on this line, we have

$$\frac{\overline{B_1A_1}}{\overline{B_1A_2}} \frac{\overline{B_2A_2}}{\overline{B_2A_3}} \frac{\overline{B_3A_3}}{\overline{B_3A_4}} \frac{\overline{B_4A_4}}{\overline{B_4A_5}} \frac{\overline{B_5A_5}}{\overline{B_5A_1}} \tag{2.30}$$

$$= \frac{\overline{s}(IJA_1)}{\overline{s}(IJA_2)} \frac{\overline{s}(IJA_2)}{\overline{s}(IJA_3)} \frac{\overline{s}(IJA_3)}{\overline{s}(IJA_4)} \frac{\overline{s}(IJA_4)}{\overline{s}(IJA_5)} \frac{\overline{s}(IJA_5)}{\overline{s}(IJA_1)} = 1: \tag{2.31}$$

Here are Ceva's Theorem and Menelaus' Theorem for general polygons.

Ceva's Theorem for polygon. Given a polygon A1A2...An and n points B1, ..., Bn, where each point Bi lies on the line Ai-1 Ai+1. If n lines A1B1, A2B2, ..., AnBn are concurrent then

$$\prod_{i=1}^{n} \frac{\overline{B_iA_{i-1}}}{\overline{B_iA_{i+1}}} = (-1)^n: \tag{2.32}$$

Menelaus' Theorem for polygon. Given a polygon A1A2...An and n points B1, ..., Bn, where each point Bi lies on the line Ai Ai+1. If the points B1, B2, ..., Bn are collinear then

$$\prod_{i=1}^{n} \frac{\overline{B_iA_i}}{\overline{B_iA_{i+1}}} = 1: \tag{2.33}$$

Today we have learned about Ceva's Theorem and Menelaus' Theorem. Both of these theorems are proved by using a simple theorem on the ratio of triangle's areas. This proof is so simple, yet it helps us to generalize the theorems for arbitrary polygons.

Let us stop here for now, hope to see you again in the next post.

Homework.

1. In the following figure, prove that

$$\frac{UB}{UC} = \frac{VB}{VC}: \tag{2.34}$$

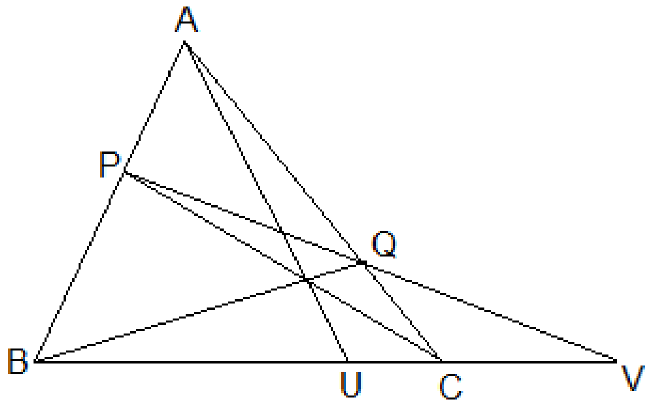

Figure 2.23: ct11.png

2. Given a triangle ABC with the lengths of the sides AB=c, BC=a, CA=b. Suppose that the incircle touches the sides of the triangle at A', B', C'. Determine the lengths of AB', AC', BA', BC', CA', CB' in terms of a, b, c. Prove that the three lines AA', BB', CC' are concurrent.

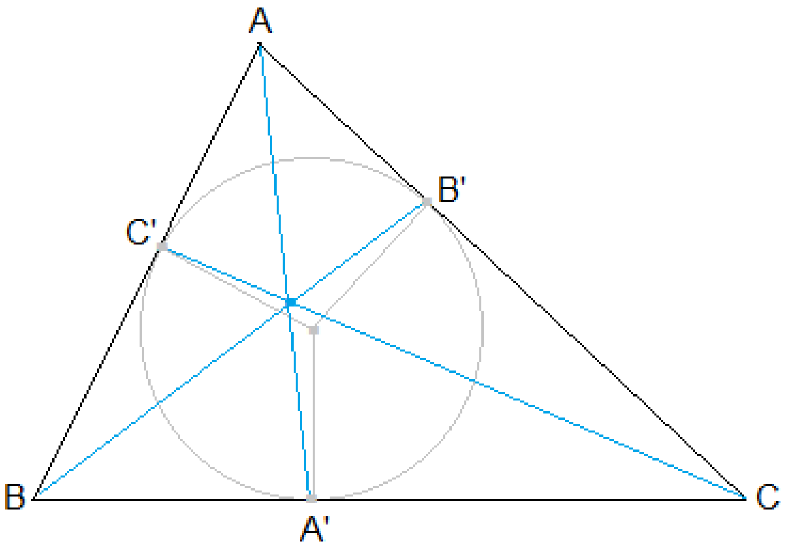

Figure 2.24: ct12.png

3. Generalize Menelaus' Theorem for points in 3D space. Below is a version of Menelaus' Theorem for tetrahedron.

Given a tetrahedron ABCD. A plane intersects the four lines AB, BC, CD, DA at the points X, Y, Z, T, respectively. Prove that

$$\frac{\widetilde{XA}}{\widetilde{XB}} \quad \frac{\widetilde{YB}}{\widetilde{YC}} \quad \frac{\widetilde{ZC}}{\widetilde{ZD}} \quad \frac{\widetilde{TD}}{\widetilde{TA}} = 1: \tag{2.35}$$

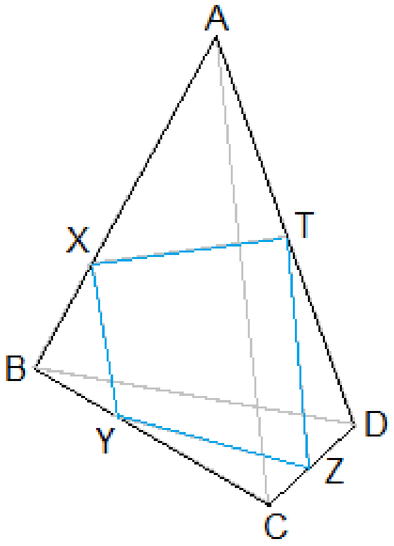

Figure 2.25: ct13.png

4. Take some examples of three points A, B, C on a coordinate system 0xy and calculate the signed area $\overline{s}(ABC)$. When do you see $\overline{s}(ABC)$ is a positive number and when $\overline{s}(ABC)$ is negative?

5. Take some examples of three points A, B, C lying on a same straight line on a coordinate system 0xy and calculate the signed area $\overline{s}(ABC)$.

6. Prove that [A,B]=-[B,A], [A,A]=0 and $\overline{s}(ABC) = \quad \overline{s}(ACB)$

7. Suppose O is the center of a coordinate system 0xy. Prove that

$$\overline{s}(OAB) = \frac{1}{2}[A; B]; \qquad \overline{s}(OBC) = \frac{1}{2}[B; C]; \qquad \overline{s}(OCA) = \frac{1}{2}[C; A]; \qquad (2.36)$$

it follows that

$$\overline{s}(ABC) = \overline{s}(OAB) + \overline{s}(OBC) + \overline{s}(OCA): \qquad (2.37)$$

Using the above identity to prove that for any point M,

$$\overline{s}(ABC) = \overline{s}(MAB) + \overline{s}(MBC) + \overline{s}(MCA) \qquad (2.38)$$

8. Take some examples of four points A, B, C, D on a coordinate system 0xy and then calculate the signed area

$$\overline{s}(ABCD) = \frac{1}{2}([A; B] + [B; C] + [C; D] + [D; A]): \qquad (2.39)$$

Check if the normal unsigned area s(ABCD) is agreeable to the signed area $\bar{s}(ABCD)$. Generalize the concept of signed area for polygons.

2.2 Pascal's Theorem

In a previous post, we were introduced to Pascal's Hexagrammum Mysticum Theorem - a magical theorem - which states that if we draw a hexagon inscribed in a conic section then the three pairs of opposite sides of the hexagon intersect at three points which lie on a straight line.

For example, as in the following figure we have a hexagon inscribed in a circle and the intersection points of the three pairs of the opposite sides of the hexagon 12,45, 23,56, 34,61 are collinear.

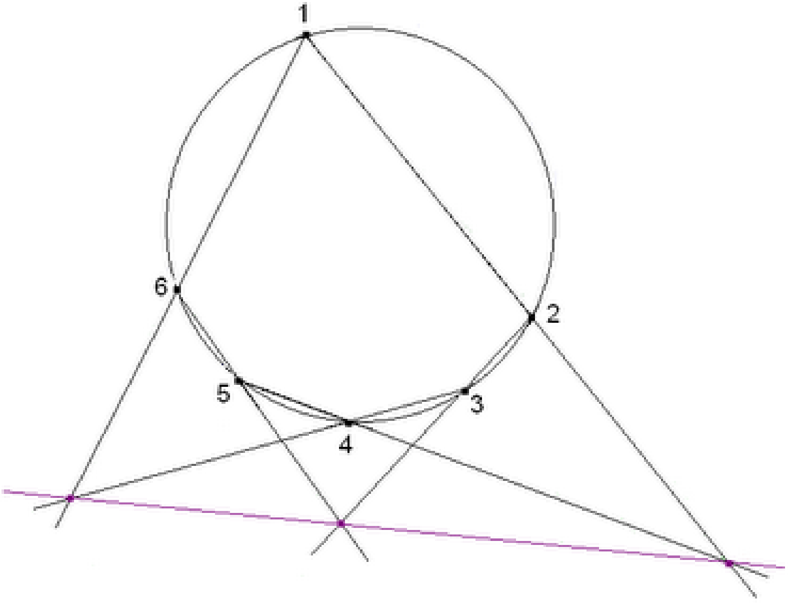

Figure 2.26: pascal1.png

There is a useful tool to prove the collinearity of points - the Menelaus' Theorem - which states as follows:

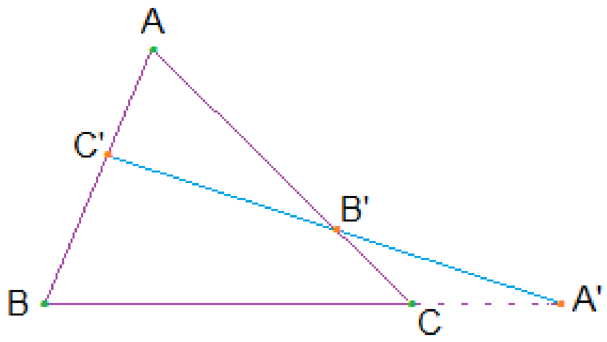

Figure 2.27: pascal2.png

Menelaus' Theorem: Given a triangle ABC and three points A', B', C' lying on the three lines BC, CA, AB, respectively. Then the three points A', B', C' are collinear if and only if

$$\frac{A'B}{A'C}\,\frac{B'C}{B'A}\,\frac{C'A}{C'B} = 1: \tag{2.40}$$

Today, we will use Menelaus' theorem to prove Pascal's theorem for the circle case.

When we want to use Menelaus' theorem to prove three certain points lying on a same straight line, we need to specify a triangle such that these three points belong to the three sides of the triangle.

In the following figure, for the Pascal's hexagon P1P2P3P4P5P6, to show that the three intersection points M1, M2, M3 are collinear, we need to find a triangle whose three sides contain M1, M2, M3. Since M1, M2, M3 lie on the sides of the hexagon, there are two natural choices for the triangle: either ABC, or XYZ.

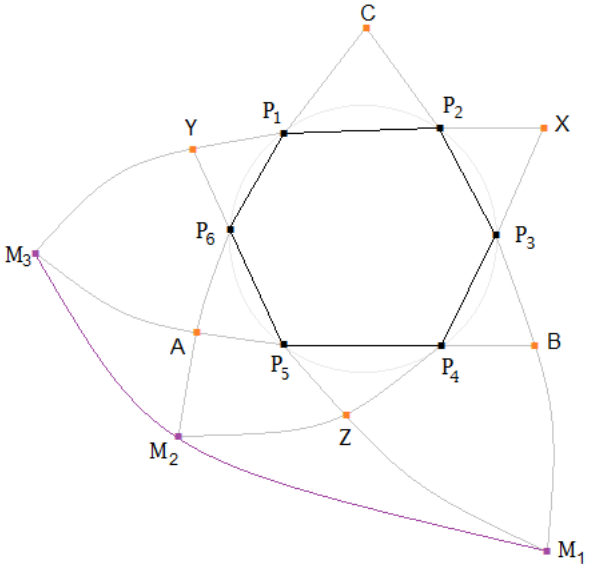

Figure 2.28: pascal3.png

Suppose we choose the triangle ABC, then we can see that the point M1 lying on the line BC, the point M2 lying on the line CA and the point M3 lying on the line AB. To use Menelaus' theorem, we need to show

$$\frac{M_1B}{M_1C}\frac{M_2C}{M_2A}\frac{M_3A}{M_3B} = 1: \qquad (2.41)$$

To calculate these quotients, we will apply Menelaus' theorem for the following triples of collinear points:

$$\{M_1; P_5; P_6\}; \quad \{M_2; P_3; P_4\}; \quad \{M_3; P_1; P_2\}: \qquad (2.42)$$

Let us now write down the proof in details.

A proof of Pascal's theorem

We will apply Menelaus' theorem for the triangle ABC.

Since M1, M2, M3 lie on the three sides of the triangle ABC, to prove that they are collinear, we need to show

$$\frac{M_1B}{M_1C}\frac{M_2C}{M_2A}\frac{M_3A}{M_3B} = 1: \qquad (2.43)$$

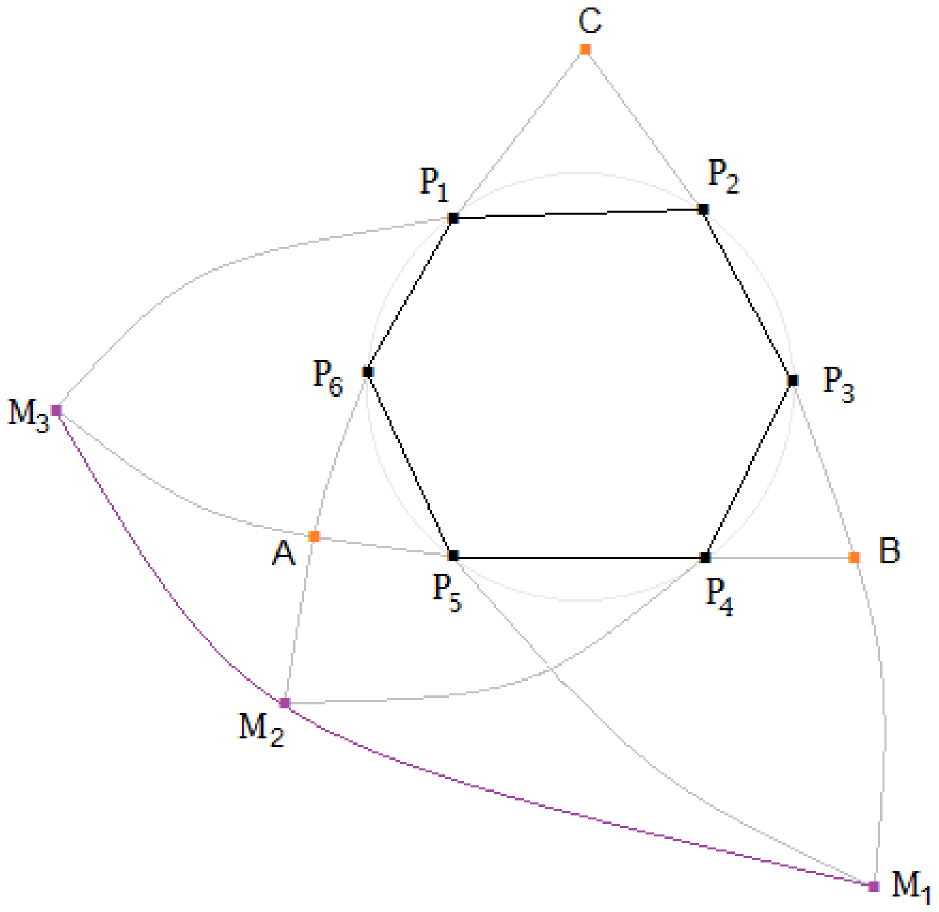

Figure 2.29: pascal4.png

Indeed, apply Menelaus’ theorem for the triangle ABC with the following triples of collinear points

$$\{M_1, P_6, P_5\}; \quad \{M_2, P_4, P_3\}; \quad \{M_3, P_2, P_1\}; \tag{2.44}$$

we have

$$\frac{\overline{M_1B}}{\overline{M_1C}} \cdot \frac{\overline{P_6C}}{\overline{P_6A}} \cdot \frac{\overline{P_5A}}{\overline{P_5B}} = \frac{\overline{M_2C}}{\overline{M_2A}} \cdot \frac{\overline{P_4A}}{\overline{P_4B}} \cdot \frac{\overline{P_3B}}{\overline{P_3C}} = \frac{\overline{M_3A}}{\overline{M_3B}} \cdot \frac{\overline{P_2B}}{\overline{P_2C}} \cdot \frac{\overline{P_1C}}{\overline{P_1A}} = 1. \tag{2.45}$$

Thus,

$$\frac{\overline{M_1B}}{\overline{M_1C}} = \frac{\overline{P_6A}}{\overline{P_6C}}\,\frac{\overline{P_5B}}{\overline{P_5A}};\quad \frac{\overline{M_2C}}{\overline{M_2A}} = \frac{\overline{P_4B}}{\overline{P_4A}}\,\frac{\overline{P_3C}}{\overline{P_3B}};\quad \frac{\overline{M_3A}}{\overline{M_3B}} = \frac{\overline{P_2C}}{\overline{P_2B}}\,\frac{\overline{P_1A}}{\overline{P_1C}}: \qquad (2.46)$$

It follows that

$$\frac{\overline{M_1B}}{\overline{M_1C}}\,\frac{\overline{M_2C}}{\overline{M_2A}}\,\frac{\overline{M_3A}}{\overline{M_3B}} = \frac{\overline{P_6A}}{\overline{P_6C}}\,\frac{\overline{P_5B}}{\overline{P_5A}}\,\frac{\overline{P_4B}}{\overline{P_4A}}\,\frac{\overline{P_3C}}{\overline{P_3B}}\,\frac{\overline{P_2C}}{\overline{P_2B}}\,\frac{\overline{P_1A}}{\overline{P_1C}} \qquad (2.47)$$

$$= \frac{\overline{AP_1}\ \overline{AP_6}}{\overline{AP_4}\ \overline{AP_5}}\,\frac{\overline{BP_4}\ \overline{BP_5}}{\overline{BP_2}\ \overline{BP_3}}\,\frac{\overline{CP_2}\ \overline{CP_3}}{\overline{CP_1}\ \overline{CP_6}} = 1: \qquad (2.48)$$

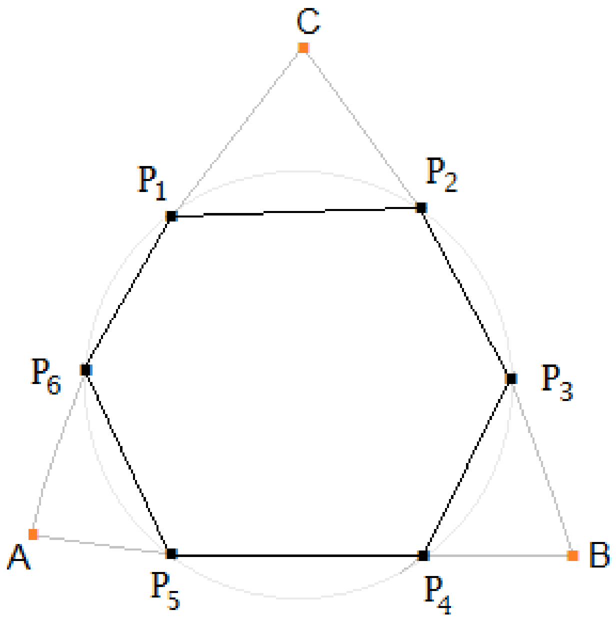

Figure 2.30: pascal5.png

Power of a point: $\overline{AP_1}\ \overline{AP_6} = \overline{AP_4}\ \overline{AP_5} = \overline{CP_2}\ \overline{CP_3} = \overline{CP_1}\ \overline{CP_6}$

The last equality is from the power of a point property when we apply the power of the points A, B, C to the circumcircle of the hexagon. Thus, we have completed the proof of Pascal's theorem.

Today, we have shown how to use Menelaus' theorem effectively to prove the Pascal's "magical" theorem. Indeed, Menelaus' theorem is a very useful tool often employed to prove the collinearity of points. Have a try now to see if we can use Menelaus' theorem to prove the Pappus' theorem!

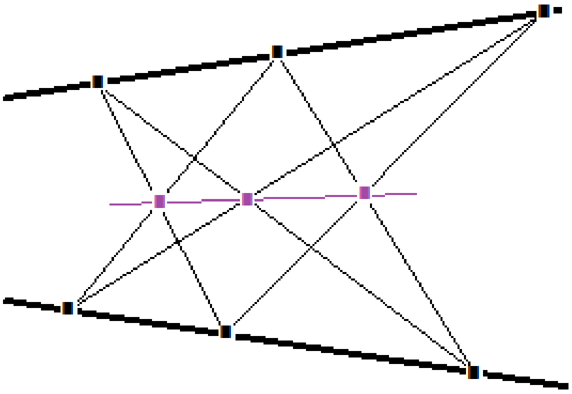

Figure 2.31: pascal6.png

Homework.

1. Prove Pascal's theorem by applying Menelaus' theorem for the triangle XYZ.

2.3 The Fermat's point of a triangle

Date: 20200728

In previous posts about modulo, we learn about the mathematician Fermat and his famous problem

$$x^n + y^n = z^n: \tag{2.49}$$

Today, we will look at a geometry problem that bears his name. As we already know, Fermat was not a professional mathematician, but was a lawyer. He was doing math probably just for fun and most of his achievements that we know of today originated from his letters to his friends and also from his occasional writings on the margin of books that he read. The most famous is, of course, the problem $x^n + y^n = z^n$ and his note "I have found a beautiful proof but there is not enough space" that he wrote on the margin of the book by Diophantus.

The problem that we investigate today was raised in a letter that Fermat sent to an Italian mathematician, Torricelli. In his letter, Fermat challenged Torricelli to find a point such that the total distance from this point to the three vertices of a triangle is the minimum possible. Well, this problem was not hard for Torricelli. Since Torricelli knew how to find such a point, today some people refer to this point as the Fermat's point, and others refer it as the Torricelli's point of the triangle.

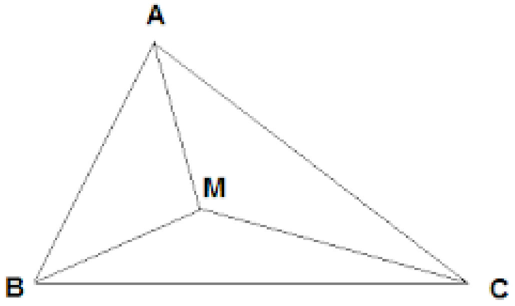

Figure 2.33: fermat1.png

the Fermat's problem: find a point M so that MA+MB+MC is minimum

To find the solution to the Fermat's problem, we are going to use a property of the ellipse. That is, if we have an ellipse with two focus points F1 and F2, then from any point P on the ellipse if we draw a tangent line to the ellipse then this tangent line will form two equal angles with the two generator lines PF1 and PF2.

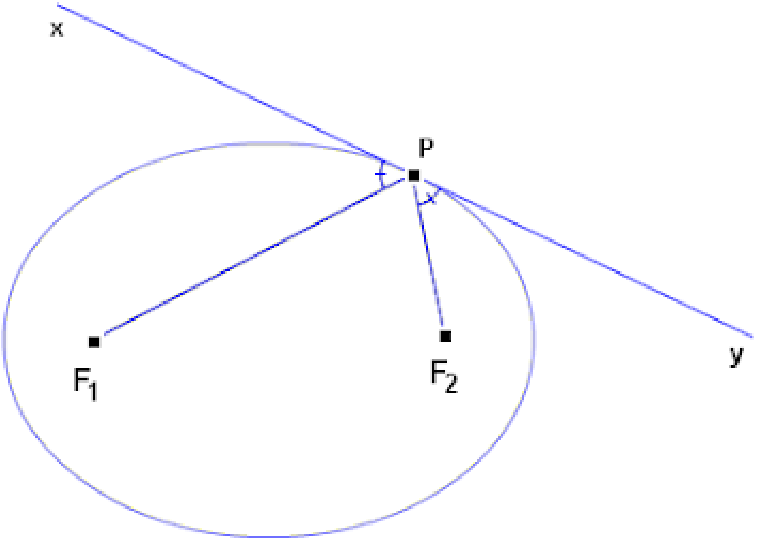

Figure 2.34: fermat2.png

a property of the tangent line: <xPF1=<yPF2

You can read more about this property of the tangent line to the ellipse at this post "A problem about finding shortest path and a property of the ellipse".

Going back to the Fermat problem, suppose that we have found a point M so that MA+MB+MC is minimum. Let us do some analysis to find out where this point should be.

Let MA+MB=l. Draw an ellipse that passes through M and that has two focus points A and B. For any point P on the ellipse we have PA+PB=MA+MB=l. But because MA+MB+MC is the minimum, we must have MC=<PC. It means that the distance from C to a point P on the ellipse is minimum when P=M.

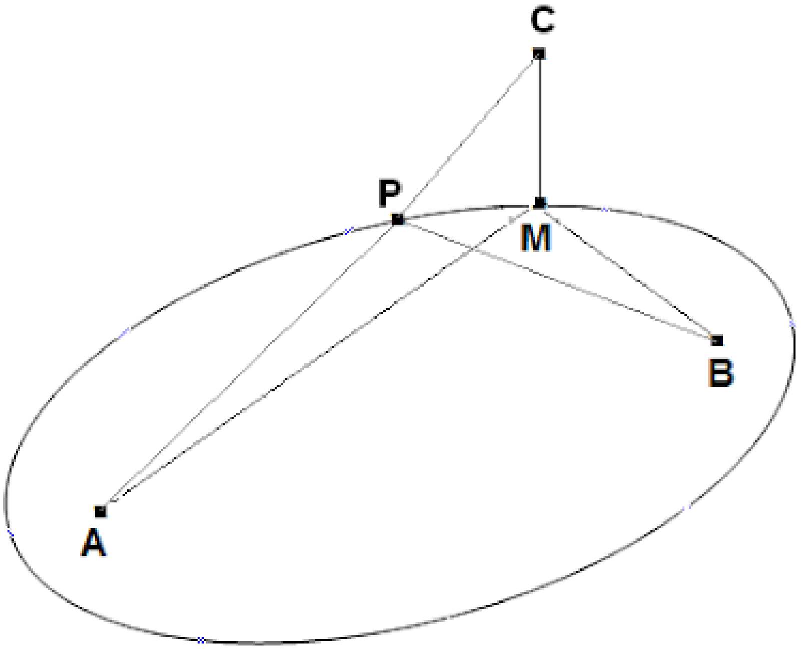

Figure 2.35: fermat3.png

from all distances from C to the ellipse, CM is the shortest

Because from all distances from C to the ellipse, CM is the shortest, if we draw a circle with the center C and radius CM then this circle must touch the ellipse at one point M.

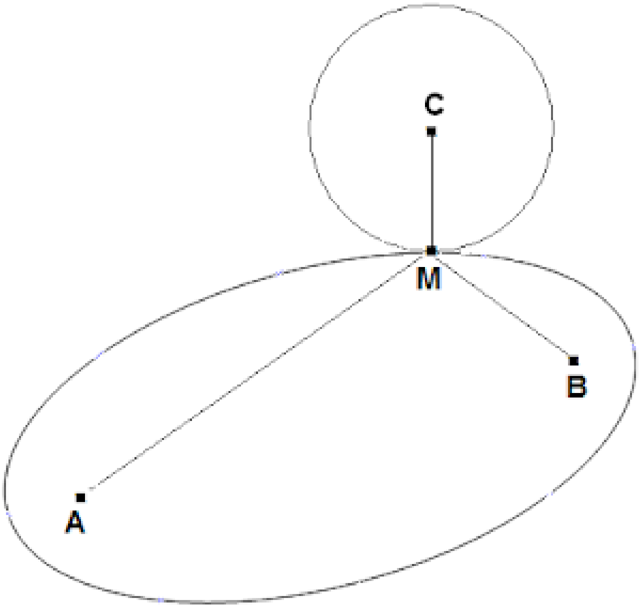

Figure 2.36: fermat4.png

the circle must touch the ellipse at one point M

It follows that the ellipse and the circle must have a common tangent line that passes through M as shown in the following figure.

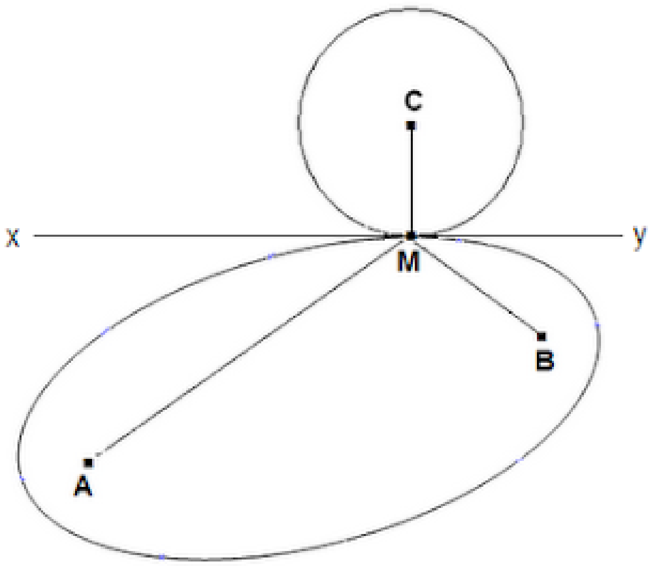

Figure 2.37: fermat5.png

Here we need to be a bit careful. There is an exceptional case that the ellipse and the circle may not have a common tangent line through M. That is when M=A or M=B. For instance, when M=B then l=MA+MB=AB, in this case there is no longer an ellipse, the ellipse has degenerated and becomes a "flat ellipse", i.e. the line segment AB. In the figure below, we can see that the tangent line to the circle is cM, on the other hand, the tangent line to the ellipse is eM { two different tangent lines.

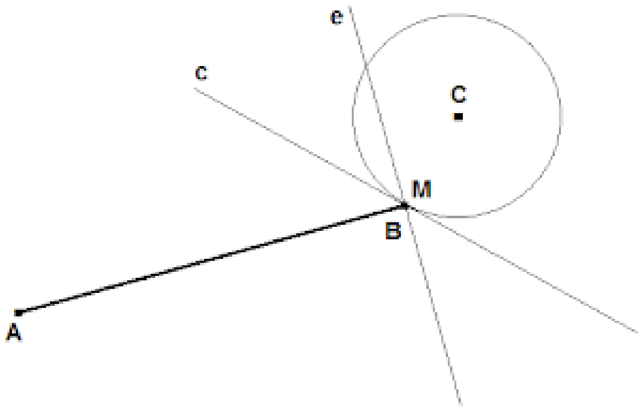

Figure 2.38: fermat6.png

in an exceptional case M=B, the tangent line to the circle is cM and the tangent line to the ellipse is eM

In summary, except for the case M=A or M=B, the circle and the ellipse will have a common tangent line through M as illustrated in the figure below. By the property of the tangent line to the ellipse, we have <xMA=<yMB. We also have <xMC=<yMC=90o. Therefore, <CMA=<CMB.

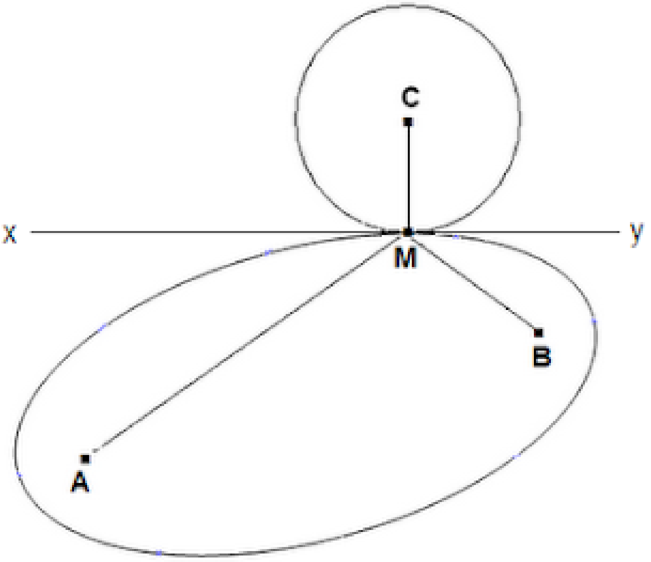

Figure 2.39: fermat7.png

except when M=A or M=B, the ellipse and the circle have a common tangent line xMy and <CMA=<CMB

By similar argument, we conclude that the point M can only be in four positions. It is either at A, B, C, or a point that is specified by <AMB=<BMC=<CMA.

In the case <AMB=<BMC=<CMA then <AMB=<BMC=<CMA=120o.

How interesting! The Fermat problem and the ellipse seem so unrelated, but we have used a property of the ellipse to work out possible solutions for the Fermat problem. The point M so that MA+MB+MC is minimum can only be in four positions. The point M can be A, B, C, or a point such that <AMB=<BMC=<CMA=120o.

Let us stop here for now. In the next post, we will solve the Fermat problem with more details. We will see that the solution goes into two cases. The first case is when one of the angles of the triangle ABC is greater than or equal to 120o. The second case is when all the angles of the triangle ABC are less than 120o.

In the first case, if <A>=120o then the point M is A.

In the second case, if all the angles of the triangle ABC are less than 120o then the point M is the point specified by <AMB=<BMC=<CMA=120o. We can construct this point M as follows. Draw outside the triangle ABC three equilateral triangles ABC', BCA', CAB'. Draw three circumcircles of these equilateral triangles then these circles will meet at one common point M. Draw the three line segments AA', BB', CC', then these three lines also meet at M (see the figure below).

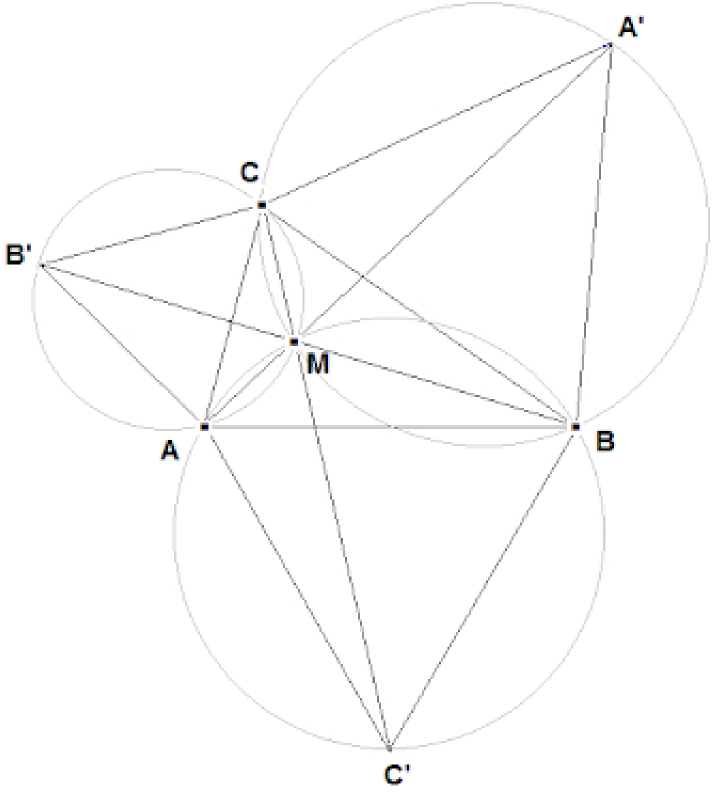

Figure 2.40: fermat*.png

Fermat's point M when <A,<B,<B<120o

Homework. Prove that if an ellipse and a circle tangent at one point then through this point we can draw a common tangent line for both the circle and the ellipse.

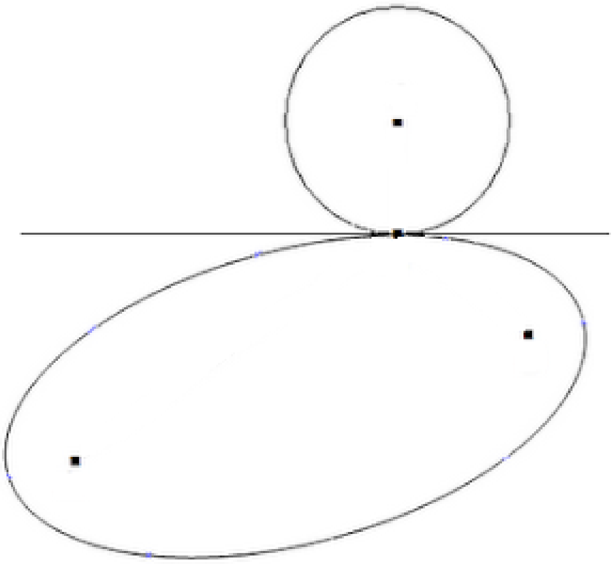

Figure 2.41: fermat9.png

Source:
http://mathgardenblog.blogspot.com/2012/07/fermat-point-of-triangle1.html

The Fermat's point of a triangle II

In the previous post, we have analyzed the Fermat's problem, the problem of finding a point M for a given triangle ABC such that MA+MB+MC is the minimum.

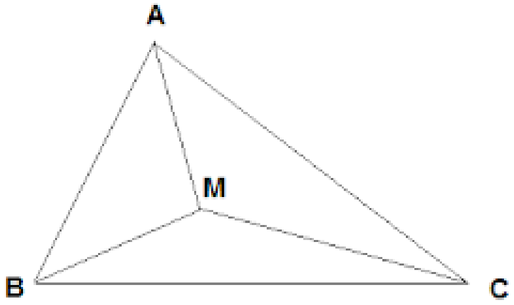

Figure 2.42: fermat10.png

the Fermat's problem: find M so that MA+MB+MC is minimum

The interesting part is that we have used a property of the ellipse to work out the solution. Our analysis shows that the point M, if it exists, can only be at four possible locations. It is either the point A, B, C, or the point specified by <AMB=<BMC=<CMA=120o.

Let us emphasize that, in the above statement, we say that if this point M exists then it has to be at four possible positions. However, we have not shown that such a point M, for which MA+MB+MC is minimal, exists. So with mathematical arguments, we have to be extra careful.

Today, we will solve the Fermat problem in a "more conventional" way! We will look at two separate cases.

The first case is when all the angles of the triangle ABC are smaller than 120o. We will show that the point M that we are looking for is specified by <AMB=<BMC=<CMA=120o.

The second case is when one of the angles of the triangle ABC is greater than or equal to 120o. For example, when <A>=120o, we will show that the point M is A.

Case 1: <A,<B,<C<120o.

Draw outside the triangle ABC three equilateral triangles ABC', BCA' and CAB'.

Take an arbitrary point P. Use A as the center, make a 60o rotation so that the triangle APB will be rotated to the triangle AQC'. By this rotation, we have obtained two things. Firstly, two triangles APB and AQC' are equal triangles, and secondly, the triangle APQ is an equilateral triangle. So we have PB=QC' and PA=PQ.

Using rotation, we transform PA+PB+PC=CP+PQ+QC'. So PA+PB+PC will be minimal when it is equal to CC', it happens when the four points C, P, Q and C', in this order, lying on the same straight line.

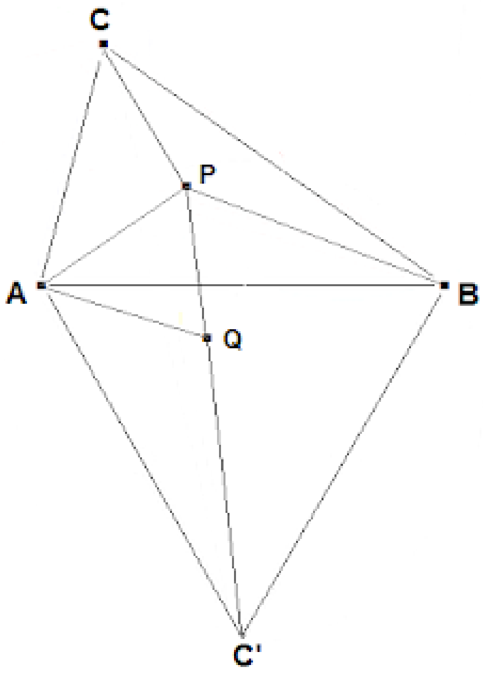

Figure 2.43: fermat11.png

PA=PQ, PB=QC’, so PA+PB+PC=CP+PQ+QC’>=CC’

To make C, P, Q lie on a straight line we must have <CPA=180o - <APQ=120o.

Similarly, to have P, Q, C’ lying on a straight line we must have <AQC’=180o. -<PQA=120o, and so <APB=<AQC’=120o.

Since <APQ=60o, if C, P, Q, C’ lie on a straight line then P must be the intersection point of CC’ with the circumcircle of the equilateral triangle ABC’.

In summary, we have shown that PA+PB+PC>=CC’ and the necessary condition for PA+PB+PC=CC’ is that <CPA=<APB=120o and the point P is the intersection point of CC’ with the circumcircle of the equilateral triangle ABC’.

To complete the proof, we construct the point M such that <CMA=<AMB=<BMC=120o and we show that MA+MB+MC=CC’, thus showing M is the point that we are looking for.

Indeed, if we take M as the intersection point of CC’ with the circumcircle of the equilateral triangle ABC’ then <AMB=120o and <AMC’=60o, and thus, <AMC=120o. Let N be the point on CC’ so that AMN is an equilateral triangle. By the rotation of 60o at center A, the triangle AMB will

be rotated to the triangle ANC'. Thus, the point M satisfies the equality MA+MB+MC=MN+NC'+MC=CC'.

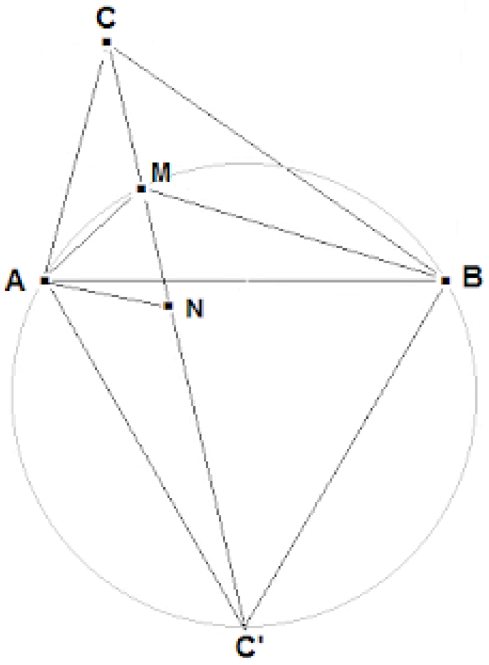

Figure 2.44: fermat12.png

At the Fermat's point M we have MA+MB+MC=CC'

We have constructed the point M such that <AMC=<AMB=<BMC=120o and showed that MA+MB+MC=CC'. Thus, M is our solution point.

By similarity, M must also lie on AA' and BB' and we have AA'=BB'=CC', and also the three circumcircles of the equilateral triangles ABC', BCA', CAB' must meet at M.

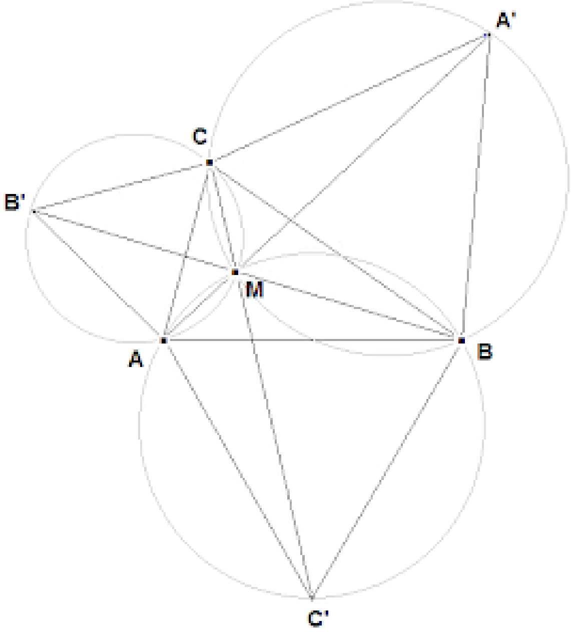

Figure 2.45: fermat13.png

We remark that the condition that <A,<B,<C<120o is a necessary condition to ensure that the four points C, M, N and C' lie on a straight line in this order. If one of the angles of the triangle ABC is greater than 120o then the points C, M, N and C' lie on a straight line, but not in this order (see the figure below).

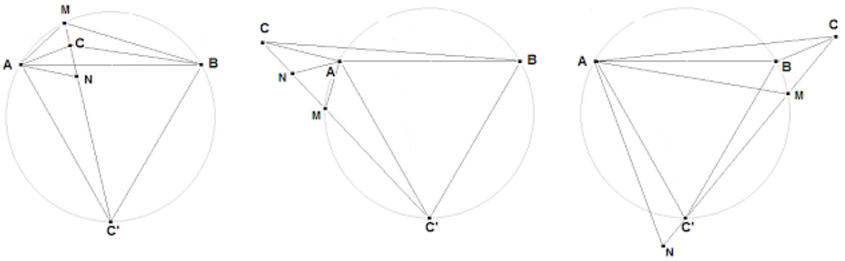

Figure 2.46: fermat14.png

if one of the angles of the triangle ABC is greater than 120o then C, M, N and C' lie on a straight line, but not in this order

Case 2: <A>=120o.

Here we will sketch the proof, the details is left for the readers.

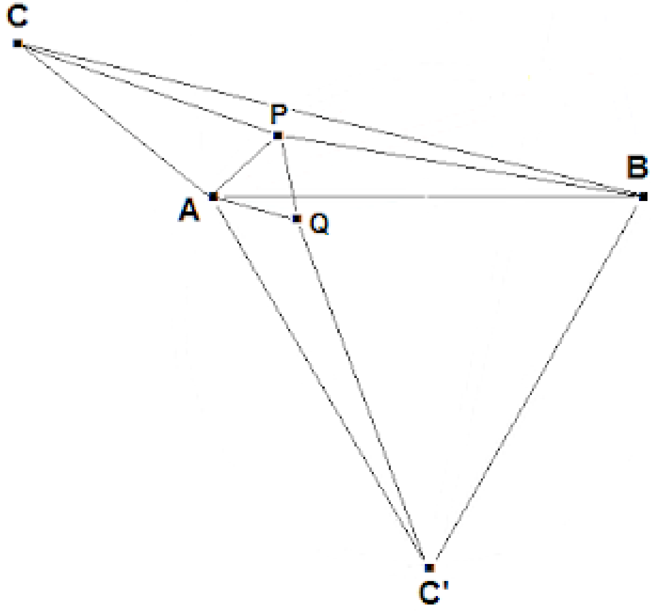

Figure 2.47: fermat15.png

PA=PQ, PB=QC', so PA+PB+PC=CP+PQ+QC'>=CA+AC'=CA+AB

The triangle AQC' is obtained from the triangle APB by a rotation so PB=QC'. The triangle APQ is an equilateral triangle, so PA=PQ. Therefore, PA+PB+PC=CP+PQ+QC'.

Next, we need to prove that CP+PQ+QC'>=CA+AC'=CA+AB and CP+PQ+QC' is minimum when P=A.

If you need some hints to prove the inequality CP+PQ+QC'>=CA+AC', please read this post "Solve for special cases first!".

Let us stop here for now. If you know other ways to solve the Fermat's problem please post it here so we all can share. See you again in the next post!

Homework. Given a square ABCD. Find on the four sides of the square four points X, Y, Z, T so that XY+YZ+ZT+TX is minimum.

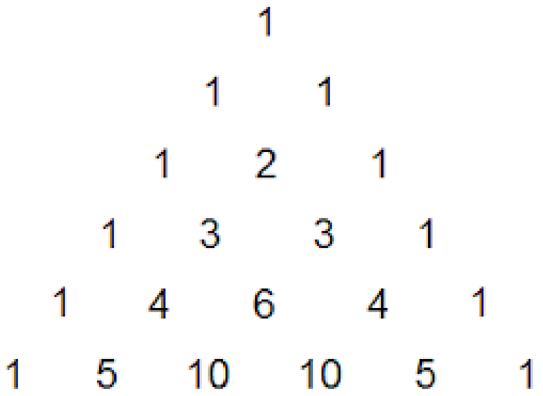
Chapter 3

Pascal’s triangle

Today, we will look at a famous number pattern, the Pascal’s number triangle.



1
1 1
1 2 1
1 3 3 1
1 4 6 4 1
1 5 10 10 5 1

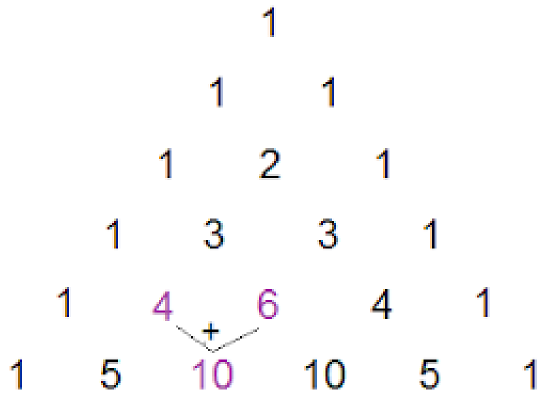
Figure 3.1: pnt1.png

Pascal’s triangle

This number triangle is constructed as follows.

In the first row, we write the number 1. In the next row, we put down two 1s. In subsequent rows, the first number and the last number are always equal to 1; for other number, it will be equal to the sum of two numbers sitting just above it in the previous row.

For example, 1+1=2, 1+2=3, 2+1=3, 1+3=4, 3+3=6, 3+1=4, etc...

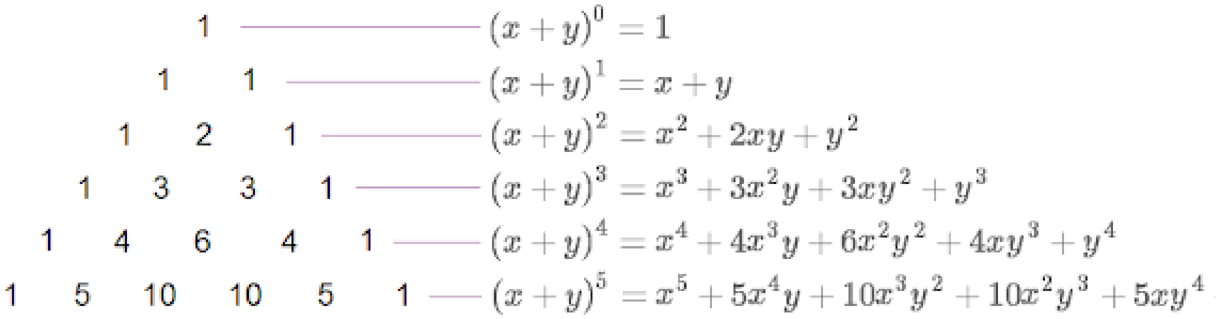


1
1 1
1 2 1
1 3 3 1
1 4 6 4 1
+
1 5 10 10 5 1

Figure 3.2: pnt2.png

constructing Pascal's triangle: 4+6=10

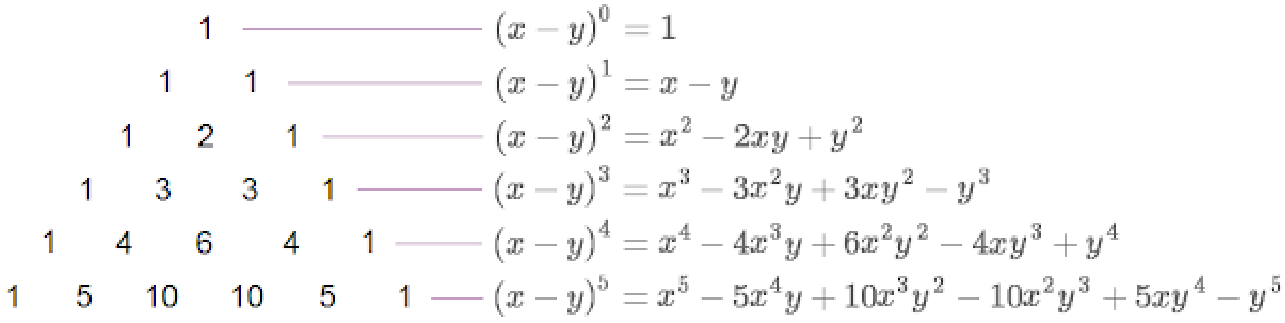
We use Pascal's triangle to determine the coefficients in the expansions of $(x + y)^n$ and $(x - y)^n$.



1 $(x+y)^0 = 1$
1 1 $(x+y)^1 = x + y$
1 2 1 $(x+y)^2 = x^2 + 2xy + y^2$
1 3 3 1 $(x+y)^3 = x^3 + 3x^2y + 3xy^2 + y^3$
1 4 6 4 1 $(x+y)^4 = x^4 + 4x^3y + 6x^2y^2 + 4xy^3 + y^4$
1 5 10 10 5 1 $(x+y)^5 = x^5 + 5x^4y + 10x^3y^2 + 10x^2y^3 + 5xy^4$

Figure 3.3: pnt3.png

expand (x+y)n using Pascal's coefficients



1 — $(x-y)^0=1$
1 1 — $(x-y)^1=x-y$
1 2 1 — $(x-y)^2=x^2-2xy+y^2$
1 3 3 1 — $(x-y)^3=x^3-3x^2y+3xy^2-y^3$
1 4 6 4 1 — $(x-y)^4=x^4-4x^3y+6x^2y^2-4xy^3+y^4$
1 5 10 10 5 1 — $(x-y)^5=x^5-5x^4y+10x^3y^2-10x^2y^3+5xy^4-y^5$

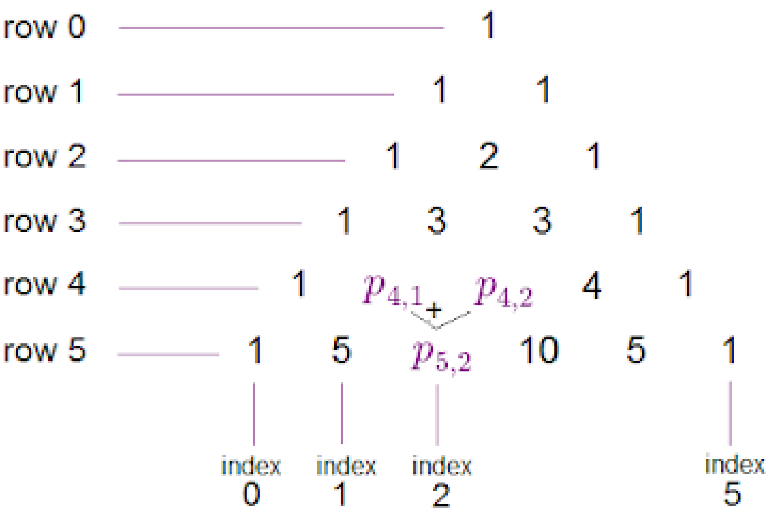
Figure 3.4: pnt4.png

expand (x-y)n using Pascal's coefficients

We will give each row of the Pascal's triangle an index. The first row of the Pascal's triangle is row 0, the next row is row 1, then row 2, ect..., The numbers on each row will also be given a similar index. The first number is number 0, then number 1, number 2, ect...

If we use $p_{n;k}$ to denote the number of index k on the row n then the Pascal's triangle is constructed based on the following rule

$$p_{n-1;k-1} + p_{n-1;k} = p_{n;k}: \tag{3.1}$$



row 0
row 1
row 2
row 3
row 4
row 5
1
1 1
1 2 1
1 3 3 1
1 $p_{4,1}$ + $p_{4,2}$ 4 1
1 5 $p_{5,2}$ 10 5 1
index 0
index 1
index 2
index 5

Figure 3.5: pnt5.png

the rule to construct Pascal's triangle $p_{n-1;k-1} + p_{n-1;k} = p_{n;k}$

The general formula for $p_{n;k}$ is

$$p_{n;k} = \binom{n}{k} = \frac{n!}{k!(n-k)!} \tag{3.2}$$

For example,

$$p_{5;2} = \binom{5}{2} = \frac{5!}{2!3!} = \frac{1 \cdot 2 \cdot 3 \cdot 4 \cdot 5}{1 \cdot 2 \cdot 1 \cdot 2 \cdot 3} = 10: \tag{3.3}$$

Finally, let us remark that we would normally start the indexing with index 1, then 2, 3, ..., but with Pascal's triangle, we use a special indexing that starts with 0. To help us remember this special indexing, let us read the following story about Sierpinski.

Waclaw Sierpinski was a great Polish mathematician. But one story told us that he was quite an absent-minded man. On one occasion, he and his wife had to move into a new residence. His wife didn't trust him very much, so when they stood down on the street with all their things, she said "Now, you stand here and watch our ten trunks, while I go and get a taxi." She left and left him there, gazing off into space and humming absently. Some minutes later she returned, presumably having called for a taxi. Said Sierpinski (possibly with a glint in his eye): "I thought you said there were ten trunks, but I've only counted to nine." Panicked that some of their possessions might have been stolen from under their noses, his wife demanded "No, they were TEN!", "No, no, no! Just count them. 0, 1, 2, 3, 4, 5, 6, 7, 8, 9 !"

Sierpinski had written a very good book on number theory, which was translated to English with the title "250 problems in elementary number theory". If you are interested in number theory, it is a good book to read.

See you again in the next post.

Homework.

1. Explain why the sum of all numbers on the row n of Pascal's triangle is equal to 2n.

2. Prove that the number of index k on the row n is equal to

$$p_{n;k} = \binom{n}{k} = \frac{n!}{k!(n-k)!}: \tag{3.4}$$

3. Prove the identity

$$(x+y)^n = x^n + \binom{n}{1} x^{n-1}y + \binom{n}{2} x^{n-2}y^2 + \cdots + \binom{n}{n-2} x^2y^{n-2} + \binom{n}{1} xy^{n-1} + y^n \tag{3.5}$$

Source: http://mathgardenblog.blogspot.com/2012/09/pascal-triangle.html

3.1 Gauss' trigonometric identities for heptadecagon

Today, we write down Gauss' magical trigonometric identities for regular heptadecagon.

$$\cos\frac{\pi}{17} = \frac{1}{16}\left(1 - \sqrt{17} + \sqrt{34 - 2\sqrt{17}} + 2\sqrt{17 + 3\sqrt{17} + \sqrt{34 - 2\sqrt{17}} + 2\sqrt{34 + 2\sqrt{17}}}\right) \tag{3.6}$$

$$\cos\frac{2\pi}{17} = \frac{1}{16}\left(-1 + \sqrt{17} + \sqrt{34 - 2\sqrt{17}} + 2\sqrt{17 + 3\sqrt{17} - \sqrt{34 - 2\sqrt{17}} - 2\sqrt{34 + 2\sqrt{17}}}\right) \tag{3.7}$$

$$\cos\frac{3\pi}{17} = \frac{1}{16}\left(1 + \sqrt{17} + \sqrt{34 + 2\sqrt{17}} + 2\sqrt{17 - 3\sqrt{17} + \sqrt{34 + 2\sqrt{17}} - 2\sqrt{34 - 2\sqrt{17}}}\right) \tag{3.8}$$

$$\cos\frac{4\pi}{17} = \frac{1}{16}\left(-1 + \sqrt{17} - \sqrt{34 - 2\sqrt{17}} + 2\sqrt{17 + 3\sqrt{17} + \sqrt{34 - 2\sqrt{17}} + 2\sqrt{34 + 2\sqrt{17}}}\right) \tag{3.9}$$

$$\cos\frac{5\pi}{17} = \frac{1}{16}\left(1 + \sqrt{17} + \sqrt{34 + 2\sqrt{17}} - 2\sqrt{17 - 3\sqrt{17} + \sqrt{34 + 2\sqrt{17}} - 2\sqrt{34 - 2\sqrt{17}}}\right) \tag{3.10}$$

$$\cos\frac{6}{17} = \frac{1}{16}\left(-1 - \sqrt{17} + \sqrt{34 + 2\sqrt{17}} + 2\sqrt{17 - 3\sqrt{17} - \sqrt{34 + 2\sqrt{17}} + 2\sqrt{34 - 2\sqrt{17}}}\right) \tag{3.11}$$

$$\cos\frac{7}{17} = \frac{1}{16}\left(1 + \sqrt{17} - \sqrt{34 + 2\sqrt{17}} + 2\sqrt{17 - 3\sqrt{17} - \sqrt{34 + 2\sqrt{17}} + 2\sqrt{34 - 2\sqrt{17}}}\right) \tag{3.12}$$

$$\cos\frac{8}{17} = \frac{1}{16}\left(-1 + \sqrt{17} + \sqrt{34 - 2\sqrt{17}} - 2\sqrt{17 + 3\sqrt{17} - \sqrt{34 - 2\sqrt{17}} - 2\sqrt{34 + 2\sqrt{17}}}\right) \tag{3.13}$$

$$\cos\frac{9}{17} = \frac{1}{16}\left(1 - \sqrt{17} - \sqrt{34 - 2\sqrt{17}} + 2\sqrt{17 + 3\sqrt{17} - \sqrt{34 - 2\sqrt{17}} - 2\sqrt{34 + 2\sqrt{17}}}\right) \tag{3.14}$$

$$\cos\frac{11}{17} = \frac{1}{16}\left(1 + \sqrt{17} - \sqrt{34 + 2\sqrt{17}} - 2\sqrt{17 - 3\sqrt{17} - \sqrt{34 + 2\sqrt{17}} + 2\sqrt{34 - 2\sqrt{17}}}\right) \tag{3.15}$$

$$\cos\frac{11}{17} = \frac{1}{16}\left(1 + \sqrt{17} - \sqrt{34 + 2\sqrt{17}} - 2\sqrt{17 - 3\sqrt{17} - \sqrt{34 + 2\sqrt{17}} + 2\sqrt{34 - 2\sqrt{17}}}\right) \tag{3.16}$$

$$\cos\frac{12}{17} = \frac{1}{16}\left(-1 - \sqrt{17} - \sqrt{34 + 2\sqrt{17}} + 2\sqrt{17 - 3\sqrt{17} + \sqrt{34 + 2\sqrt{17}} - 2\sqrt{34 - 2\sqrt{17}}}\right) \tag{3.17}$$

$$\cos\frac{13}{17} = \frac{1}{16}\left(1 - \sqrt{17} + \sqrt{34 - 2\sqrt{17}} - 2\sqrt{17 + 3\sqrt{17} + \sqrt{34 - 2\sqrt{17}} + 2\sqrt{34 + 2\sqrt{17}}}\right) \tag{3.18}$$

$$\cos\frac{14\pi}{17} = \frac{1}{16}\left(-1-\sqrt{17}-\sqrt{34+2\sqrt{17}}-2\sqrt{17-3\sqrt{17}+\sqrt{34+2\sqrt{17}}-2\sqrt{34-2\sqrt{17}}}\right) \tag{3.19}$$

$$\cos\frac{15\pi}{17} = \frac{1}{16}\left(1-\sqrt{17}-\sqrt{34-2\sqrt{17}}-2\sqrt{17+3\sqrt{17}-\sqrt{34-2\sqrt{17}}-2\sqrt{34+2\sqrt{17}}}\right) \tag{3.20}$$

$$\cos\frac{16\pi}{17} = \frac{1}{16}\left(-1+\sqrt{17}-\sqrt{34-2\sqrt{17}}-2\sqrt{17+3\sqrt{17}+\sqrt{34-2\sqrt{17}}+2\sqrt{34+2\sqrt{17}}}\right) \tag{3.21}$$

3.2 Trigonometric multiple-angle formulas

In our previous post, we show a compass-and-straightedge construction of a regular pentagon based on the following trigonometric formula

$$\cos\frac{\pi}{5} = \frac{1+\sqrt{5}}{4}. \tag{3.22}$$

We derive this formula of $\cos\frac{\pi}{5}$ by observing that $\cos\frac{2\pi}{5} = -\cos\frac{3\pi}{5}$ and then applying the trigonometric formulas for double angle and triple angle:

$$\cos 2x = 2\cos^2 x - 1; \tag{3.23}$$

$$\cos 3x = 4\cos^3 x - 3\cos x \tag{3.24}$$

to set up a cubic equation for $\cos\frac{\pi}{5}$.

It seems a good occasion now for us to learn about trigonometric multiple-angle formulas. In this post, we will show how to derive formulas for $\sin nx$, $\cos nx$, $\tan nx$ and $\cot nx$ using de Moivre’s identity of the complex numbers.

de Moivre’s identity for complex numbers

Complex numbers have the form

$$a + ib \tag{3.25}$$

where a and b are two real numbers; a is called the real part and ib is called the imaginary part. Here are a few examples of complex numbers

3+2 i, 5-3 i, 2 i+7, 8 i, 4 i-2, 5, i+1,. . .

We do addition, subtraction, multiplication and division for complex numbers exactly the same as we do normal arithmetic for real numbers, except that we need to remember

$$i^2 = -1; \quad i^3 = -i; \quad i^4 = -i^2 = 1; \quad i^5 = i; \quad i^6 = i^2 = -1; \ldots \tag{3.26}$$

Addition and Subtraction

$$(a + ib) + (c + id) = (a + c) + i(b + d); \tag{3.27}$$

$$(a + ib) - (c + id) = (a - c) + i(b - d). \tag{3.28}$$

Multiplication

$$(a + ib)(c + id) = ac + iad + ibc + i^2bd = (ac - bd) + i(bc + ad). \tag{3.29}$$

Division we need to use the identity

$$(a + ib)(a - ib) = a^2 - i^2b^2 = a^2 + b^2 \tag{3.30}$$

and so

$$\frac{c + id}{a + ib} = \frac{(c + id)(a - ib)}{(a + ib)(a - ib)} = \frac{(ac + bd) + i(ad - bc)}{a^2 + b^2} = \frac{ac + bd}{a^2 + b^2} + i\frac{ad - bc}{a^2 + b^2}. \tag{3.31}$$

Complex conjugate

$$\overline{a + ib} = a - ib; \quad \overline{a - ib} = a + ib. \tag{3.32}$$

Absolute value

$$|a + ib| = \sqrt{a^2 + b^2}. \tag{3.33}$$

There is a very important fact about complex numbers, that is, any complex number z can be written in a trigonometric form as follows

$$z = |z|(\cos\theta + i\sin\theta). \tag{3.34}$$

This trigonometric form is very convenient when we do multiplication and division. This is because

$$(\cos\theta_1 + i\sin\theta_1)(\cos\theta_2 + i\sin\theta_2) \tag{3.35}$$

$$= (\cos\theta_1\cos\theta_2 - \sin\theta_1\sin\theta_2) + i(\sin\theta_1\cos\theta_2 + \cos\theta_1\sin\theta_2) \tag{3.36}$$

$$= \cos(\theta_1 + \theta_2) + i\sin(\theta_1 + \theta_2). \tag{3.37}$$

So if we have two complex numbers

$$z_1 = |z_1|(\cos\theta_1 + i\sin\theta_1), \tag{3.38}$$

$$z_2 = |z_2|(\cos\theta_2 + i\sin\theta_2), \tag{3.39}$$

then we have the following simple formulas for multiplication and division

$$z_1z_2 = |z_1||z_2|(\cos(\theta_1 + \theta_2) + i\sin(\theta_1 + \theta_2)), \tag{3.40}$$

$$\frac{z_1}{z_2} = \frac{|z_1|}{|z_2|}(\cos(\theta_1 - \theta_2) + i\sin(\theta_1 - \theta_2)). \tag{3.41}$$

In a special case when $\theta_1 = \theta_2$, then we have

$$z^2 = |z|^2(\cos 2\theta + i\sin 2\theta). \tag{3.42}$$

By applying the multiplication formula repeatedly, we derive the following formula

$$z^n = |z|^n(\cos n\theta + i\sin n\theta). \tag{3.43}$$

When $|z| = 1$, we obtain
de Moivre's identity:

$$(\cos\theta + i\sin\theta)^n = \cos n\theta + i\sin n\theta. \tag{3.44}$$

From de Moivre's identity, if we use binomial theorem to expand the left hand side, and compare with the right hand side, we can derive formulas for $\cos n\theta$ and $\sin n\theta$!

Trigonometric multiple-angle formulas

Trigonometric formulas for double angle
Using de Moivre's identity for n=2, we have

$$\cos 2x + i \sin 2x = (\cos x + i \sin x)^2 \tag{3.45}$$

$$= \cos^2 x + 2 \cos x (i \sin x) + (i \sin x)^2 \tag{3.46}$$

$$= \cos^2 x - \sin^2 x + i 2 \sin x \cos x \tag{3.47}$$

We derive the following
formula for $\cos 2x$

$$\cos 2x = \cos^2 x - \sin^2 x = \cos^2 x - (1 - \cos^2 x) = 2 \cos^2 x - 1 \tag{3.48}$$

formula for $\sin 2x$

$$\sin 2x = 2 \sin x \cos x \tag{3.49}$$

formula for $\tan 2x$

$$\tan 2x = \frac{\sin 2x}{\cos 2x} = \frac{2 \sin x \cos x}{\cos^2 x - \sin^2 x} = \frac{2 \sin x \cos x = \cos^2 x}{(\cos^2 x - \sin^2 x) = \cos^2 x} = \frac{2 \tan x}{1 - \tan^2 x} \tag{3.50}$$

formula for $\cot 2x$

$$\cot 2x = \frac{\cos 2x}{\sin 2x} = \frac{\cos^2 x - \sin^2 x}{2 \sin x \cos x} = \frac{(\cos^2 x - \sin^2 x) = \sin^2 x}{2 \sin x \cos x = \sin^2 x} = \frac{\cot^2 x - 1}{2 \cot x} \tag{3.51}$$

Trigonometric formulas for triple angle
Using de Moivre's identity for n=3, we have

$$\cos 3x + i \sin 3x = (\cos x + i \sin x)^3 \tag{3.52}$$

$$= \cos^3 x + 3 \cos^2 x (i \sin x) + 3 \cos x (i \sin x)^2 + (i \sin x)^3 \tag{3.53}$$

$$= \cos^3 x - 3 \cos x \sin^2 x + i (3 \cos^2 x \sin x - \sin^3 x) \tag{3.54}$$

Therefore,
formula for $\cos 3x$

$$\cos 3x = \cos^3 x - 3\cos x \sin^2 x = \cos^3 x - 3\cos x(1 - \cos^2 x) = 4\cos^3 x - 3\cos x \tag{3.55}$$

formula for $\sin 3x$

$$\sin 3x = 3\cos^2 x \sin x - \sin^3 x = 3(1 - \sin^2 x)\sin x - \sin^3 x = 3\sin x - 4\sin^3 x \tag{3.56}$$

formula for $\tan 3x$

$$\tan 3x = \frac{\sin 3x}{\cos 3x} = \frac{3\cos^2 x \sin x - \sin^3 x}{\cos^3 x - 3\cos x \sin^2 x} = \frac{3\tan x - \tan^3 x}{1 - 3\tan^2 x} \tag{3.57}$$

formula for $\cot 3x$

$$\cot 3x = \frac{\cos 3x}{\sin 3x} = \frac{\cos^3 x - 3\cos x \sin^2 x}{3\cos^2 x \sin x - \sin^3 x} = \frac{\cot^3 x - 3\cot x}{3\cot^2 x - 1} \tag{3.58}$$

Trigonometric formulas for quadruple angle
Using de Moivre's identity for n=4, we have

$$\cos 4x + i\sin 4x = (\cos x + i\sin x)^4 \tag{3.59}$$

$$= \cos^4 x + 4\cos^3 x(i\sin x) + 6\cos^2 x(i\sin x)^2 + 4\cos x(i\sin x)^3 + (i\sin x)^4 \tag{3.60}$$

$$= \cos^4 x - 6\cos^2 x \sin^2 x + \sin^4 x + i(4\cos^3 x \sin x - 4\cos x \sin^3 x) \tag{3.61}$$

Therefore,
formula for $\cos 4x$

$$\cos 4x = \cos^4 x - 6\cos^2 x \sin^2 x + \sin^4 x = \cos^4 x - 6\cos^2 x(1 - \cos^2 x) + (1 - \cos^2 x)^2 \tag{3.62}$$

$$= 8\cos^4 x - 8\cos^2 x + 1 \tag{3.63}$$

formula for $\sin 4x$

$$\sin 4x = 4\cos^3 x \sin x - 4\cos x \sin^3 x = 4\cos x(1 - \sin^2 x)\sin x - 4\cos x \sin^3 x \tag{3.64}$$

$$= 4\cos x(\sin x - 2\sin^3 x) \tag{3.65}$$

formula for $\tan 4x$

$$\tan 4x = \frac{\sin 4x}{\cos 4x} = \frac{4\cos^3 x \sin x - 4\cos x \sin^3 x}{\cos^4 x - 6\cos^2 x \sin^2 x + \sin^4 x} = \frac{4\tan x - 4\tan^3 x}{1 - 6\tan^2 x + \tan^4 x} \tag{3.66}$$

formula for $\cot 4x$

$$\cot 4x = \frac{\cos 4x}{\sin 4x} = \frac{\cos^4 x - 6\cos^2 x \sin^2 x + \sin^4 x}{4\cos^3 x \sin x - 4\cos x \sin^3 x} = \frac{\cot^4 x - 6\cot^2 x + 1}{4\cot^3 x - 4\cot x} \tag{3.67}$$

By now, you probably know how to derive the general formulas. Please continue with the cases for n=5,6,7. Using these formulas, it is possible to calculate the explicit values of $\sin\frac{\pi}{7}$, $\cos\frac{\pi}{7}$, $\sin\frac{\pi}{9}$, $\cos\frac{\pi}{9}$, ...

Let us stop here for now. In the next post, we will return to the topic of compass-and-straightedge construction. Hope to see you again then.

Homework.

1. Continue with n=5,6,7,... and establish formulas for $\sin nx$, $\cos nx$, $\tan nx$, $\cot nx$.

2. Find explicit formulas for

$$\sin\frac{\pi}{7}; \sin\frac{2\pi}{7}; \sin\frac{3\pi}{7}; \ldots \tag{3.68}$$

$$\cos\frac{\pi}{7}; \cos\frac{2\pi}{7}; \cos\frac{3\pi}{7}; \ldots \tag{3.69}$$

3. Find explicit formulas for

$$\sin\frac{\pi}{9}; \sin\frac{2\pi}{9}; \sin\frac{3\pi}{9}; \ldots \tag{3.70}$$

$$\cos\frac{\pi}{9}; \cos\frac{2\pi}{9}; \cos\frac{3\pi}{9}; \ldots \tag{3.71}$$

4. Search on Google http://google.com about Chebyshev polynomial, find out the relationship between Chebyshev polynomial and the trigonometric multiple-angle formulas.

3.3 Power of a point to a circle

Today we will learn about the power of a point with respect to a circle.

Suppose on a plane we have a point P and a circle (O). Draw a line through P which intersects with the circle at two points U and V. Then the value of

$$PU \quad PV \tag{3.72}$$

is independent of the choice of the line PUV.

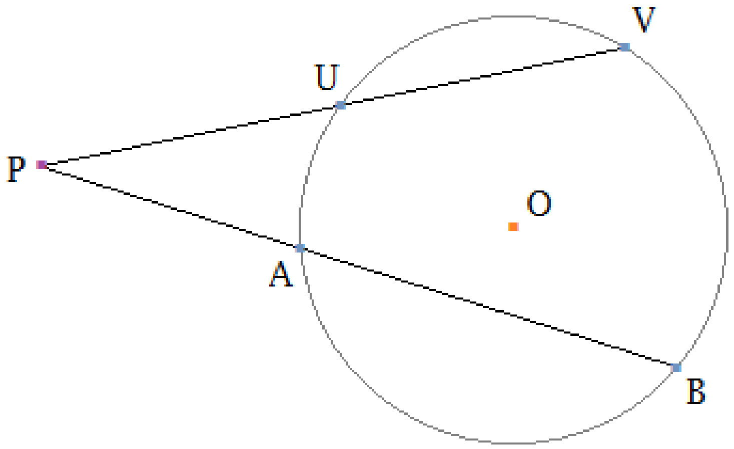

Figure 3.6: ppc1.png

This means that if we draw another line through P which cuts the circle at two other points A and B then

$$PA \quad PB = PU \quad PV: \tag{3.73}$$

This constant value is called the power of the point P with respect to the circle (O).

To prove that PU X PV is independent of the position of the line, we will use similar triangles. We will consider two separate cases: when the point P is outside the circle and when the point P is inside the circle.

When P is outside the circle (O)

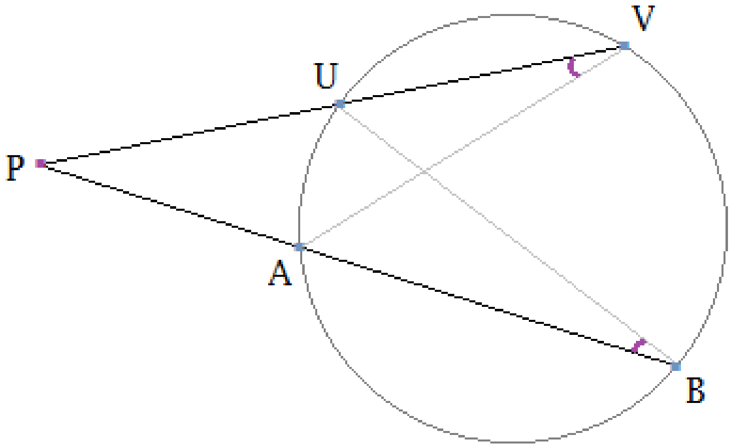

Figure 3.7: ppc2.png

We consider two triangles PUB and PAV. These two triangles are similar triangles because they have two pairs of equal angles. Thus,

$$\frac{PU}{PA} = \frac{PB}{PV}: \tag{3.74}$$

From here we obtain the required equality

$$PA \quad PB = PU \quad PV: \tag{3.75}$$

When P is inside the circle (O)

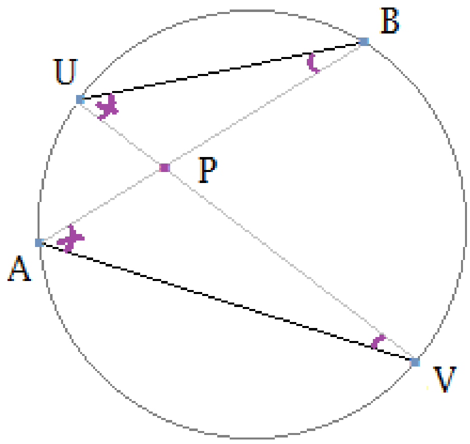

Figure 3.8: ppc3.png

When P is inside the circle, we also consider the two triangles PUB and PAV. These two triangles are similar triangles because they have equal angles. So

$$\frac{PU}{PA} = \frac{PB}{PV}: \tag{3.76}$$

This implies the constancy of the power of the point P:

$$PA \quad PB = PU \quad PV: \tag{3.77}$$

Expressing power of the point P in terms of the distance PO and the circle radius r

We will now show how to derive a formula for the power of the point P in terms of the distance PO and the radius r of the circle (O). We again consider two separate cases: when the point P is outside the circle and when the point P is inside the circle.

We will prove that:

If P is outside the circle then

$$PU \quad PV = PO^2 \quad r^2: \tag{3.78}$$

If P is inside the circle then

$$PU \quad PV = r^2 \quad PO^2: \tag{3.79}$$

Indeed, if we take U and V as two intersection points of the line PO with the circle (O) then the power of the point P can be calculated as follows:

When P is outside the circle

$$PU \quad PV = (PO \quad r)(PO + r) = PO^2 \quad r^2: \qquad (3.80)$$

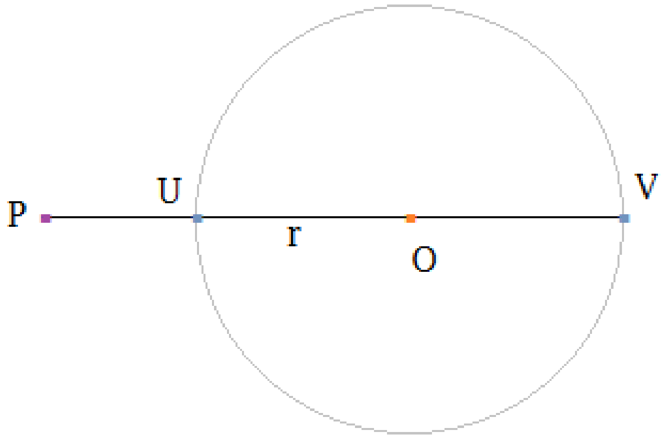

Figure 3.9: ppc4.png

When P is inside the circle

$$PU \quad PV = (r \quad PO)(r + PO) = r^2 \quad PO^2: \qquad (3.81)$$

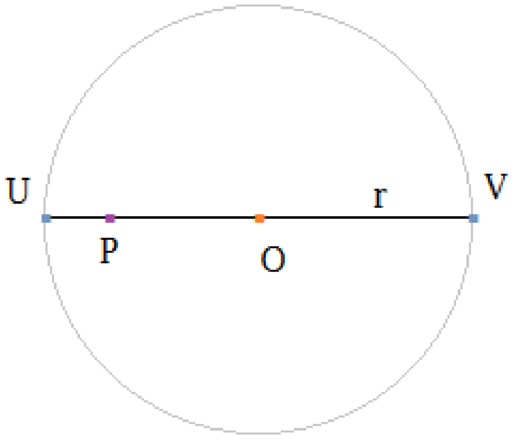

Figure 3.10: ppc5.png

So we have shown that the power of the point P can be expressed in terms of the distance PO and the radius r as

$$PU \cdot PV = \pm(PO^2 - r^2): \tag{3.82}$$

Whether the sign is a plus or a minus in the above formula depends on the position of the point P with respect to the circle. It is a plus if P is outside the circle and it is a minus if P is inside the circle. (For the special case when the point P lies on the circle then the power of P is equal to zero trivially.)

The "correct" definition of the power of a point

Actually our above definition of the power of a point is not really correct. The above definition does not concern about the sign of PU X PV making it always a positive number.

$$\vec{PU} \cdot \vec{PV} = PO^2 - r^2: \tag{3.83}$$

In this definition, the value of the power of the point P can be positive or negative, it depends on the two vectors PU -> and PV -> point to the same direction or opposite directions.

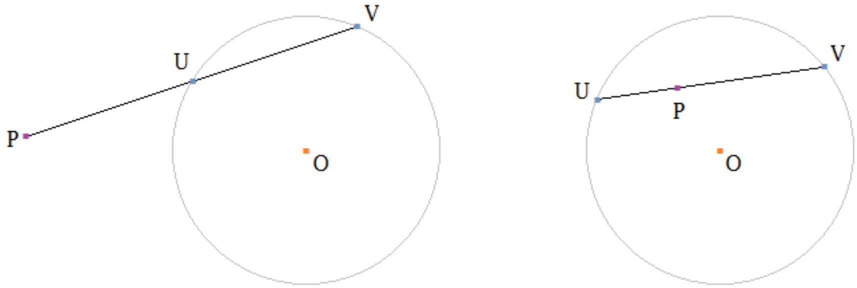

Figure 3.11: ppc6.png

When P is outside the circle, the power of P is a positive number because PU -> and PV -> have the same direction. When P is inside the circle, the power of P is a negative number because PU ->and PV -> point to opposite directions.

The power of a point is a useful bit of information that helps us to know the relative position of the point with respect to the circle. If this value is a positive number then we know that the point is outside of the circle. If this value is zero then the point must lie on the circle. And if this value is negative then we know that the point is inside the circle.

Formula of the power of a point in Cartesian coordinate

In the Cartesian coordinate system 0xy, each point P on the plane is assigned to a unique coordinate (Px,Py).

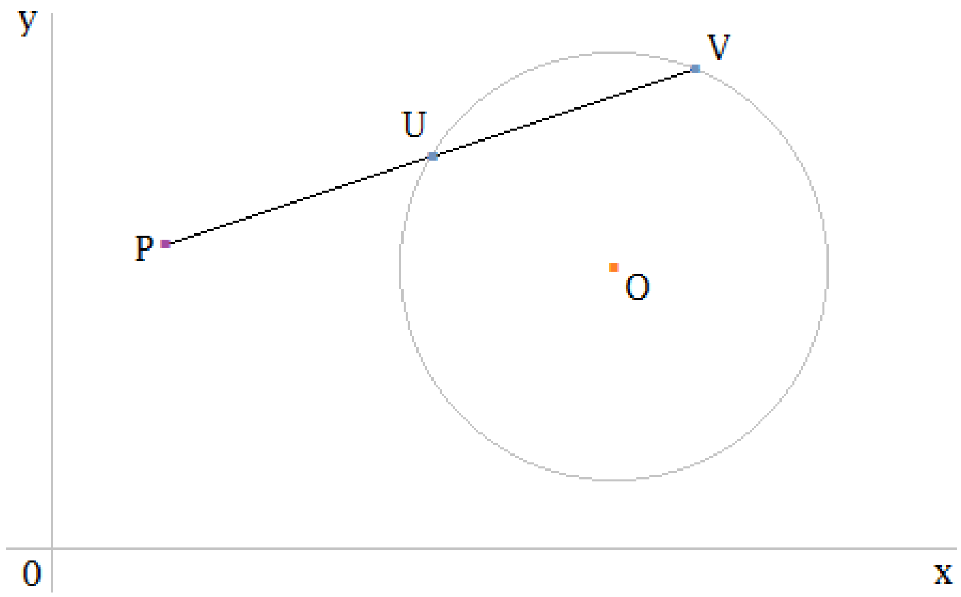

Figure 3.12: ppc7.png

We know that the equation of the circle with center O and radius r is

$$(x - O_x)^2 + (y - O_y)^2 - r^2 = 0: \tag{3.84}$$

The formula for the power of a point is ultimately related to the above equation of the circle

$$\overrightarrow{PU} \cdot \overrightarrow{PV} = PO^2 - r^2 = (P_x - O_x)^2 + (P_y - O_y)^2 - r^2: \tag{3.85}$$

This formula

$$(P_x - O_x)^2 + (P_y - O_y)^2 - r^2 \tag{3.86}$$

signifies the reason why the value of the power of a point is positive, zero, and negative when the point is outside the circle, on the circle, and inside the circle.

Today we have learned some basic facts about the power of a point to a circle. In the next post, we will learn more about its properties and its many applications.

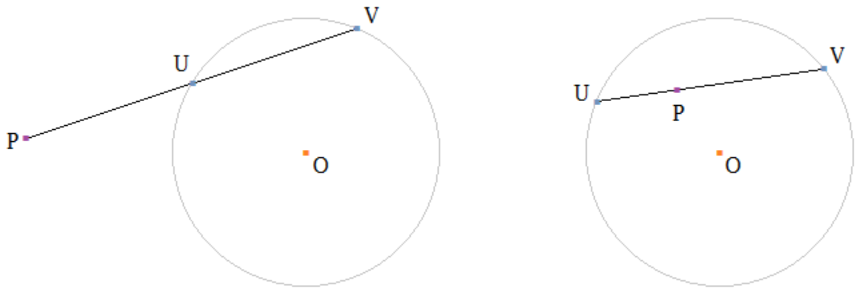

Figure 3.13: ppc8.png

Power of a point:

$$\vec{PU} \quad \vec{PV} = PO^2 \quad r^2 = (P_x \quad O_x)^2 + (P_y \quad O_y)^2 \quad r^2 \tag{3.87}$$

Before we conclude the post, let us summarize the three basic formulas for the power of a point:

$$\vec{PU} \quad \vec{PV} = PO^2 \quad r^2 = (P_x \quad O_x)^2 + (P_y \quad O_y)^2 \quad r^2: \tag{3.88}$$

Homework.

1. Suppose that the point P is outside the circle (O). Draw a tangent PT to the circle. Apply Pythagorean Theorem to show that

$$PU \quad PV = PT^2 = PO^2 \quad r^2: \tag{3.89}$$

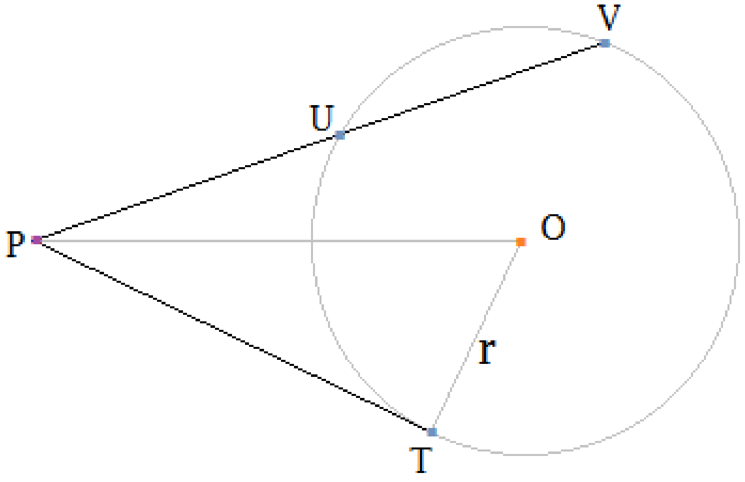

Figure 3.14: ppc9.png

2. Suppose that the point P is inside the circle (O). Draw the line UV perpendicular to PO. Again, apply Pythagorean Theorem to show that

$$PU \quad PV = PU^2 = r^2 \quad PO^2: \qquad (3.90)$$

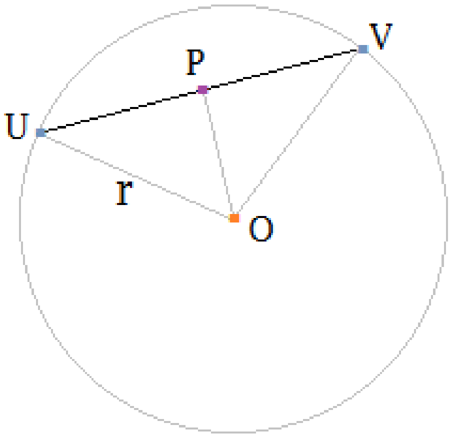

Figure 3.15: ppc10.png

3. Given two circles (O1) and (O2) intersecting at two points I and J. Show that for any point P on the line IJ, P has equal power with respect to

these two circles.

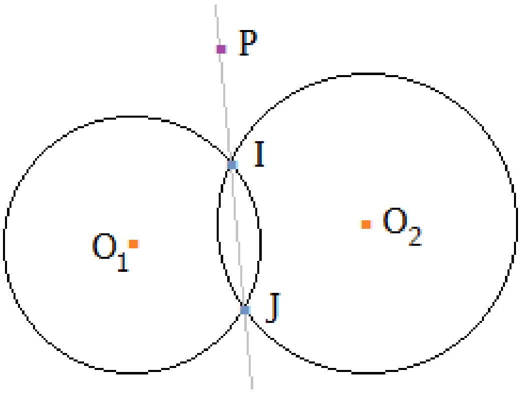

Figure 3.16: ppc11.png

4. Given two circles (O1) and (O2). Determine the locus of all the points that have equal power to these two circles.

5. Given three circles (O1), (O2) and (O3). Determine the point P such that it has equal power to all of these circles.

3.4 Radian

In our normal life, when we talk about angles, we often use the degree. For example, a right angle is equal to 90 degrees, an angle of an equilateral triangle is 60 degrees, a straight angle is 180o. However, for all trigonometric functions in mathematics, such as sin(x), cos(x), etc., the angle x is always understood as in radian.

So what is the radian?

To understand angle measurement in radians, we draw a unit circle. Unit circle is a circle with radius equal to 1. We know that by definition,   is the length of the semicircle.

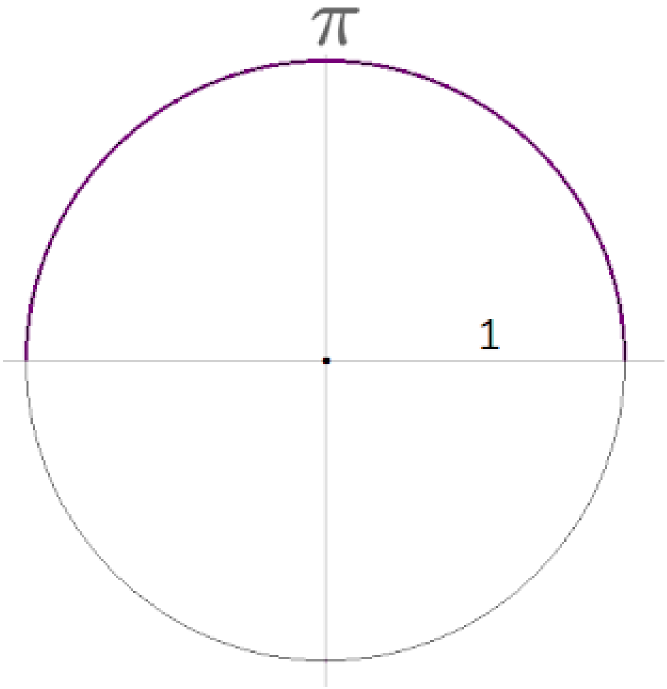

Figure 3.17: radian1.png

An angle’s measurement in radians is equal to the length of the corresponding arc of the unit circle.

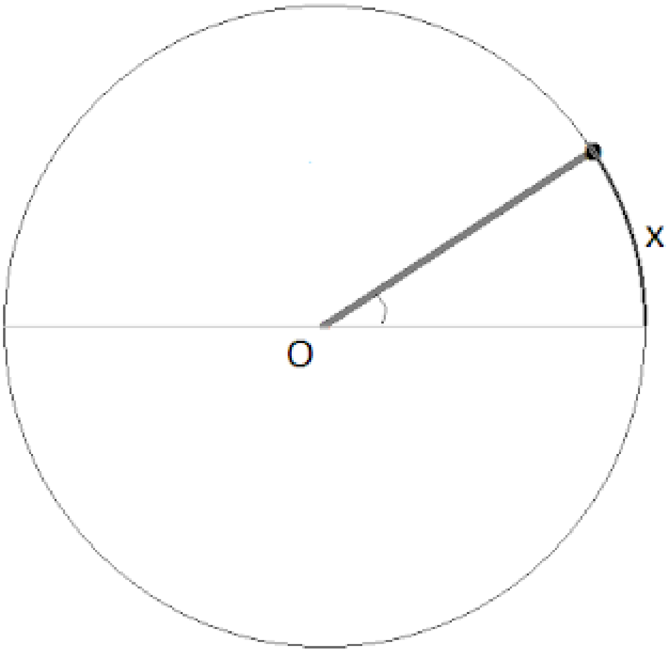

Figure 3.18: radian2.png

In radians, x is the length of the arc

Let us look at an example of a right angle. A right angle is subtended by a quarter of the circle, and the length of a quarter of the circle is $\frac{}{2}$, so a right angle is equal to $\frac{}{2}$ in radians.

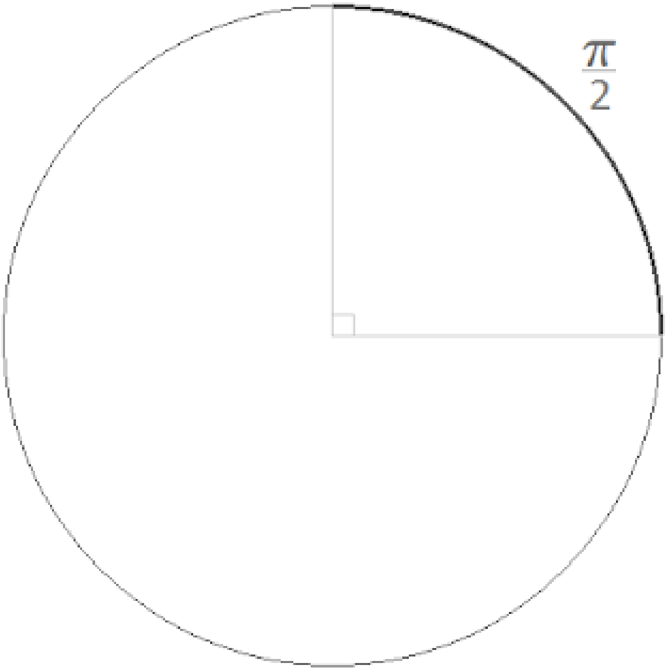

Figure 3.19: radian3.png

A straight angle (180o) occupies half of the circle, and the length of a half of the circle is , so a straight angle is equal to in radians.

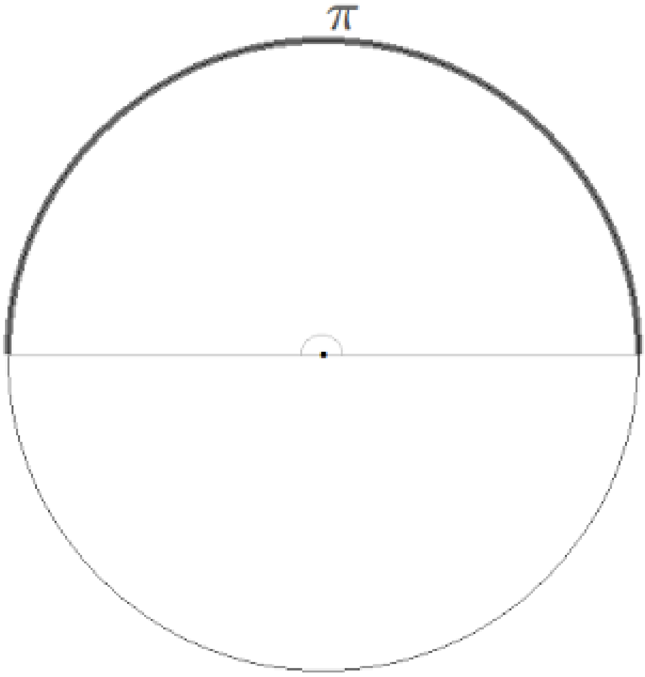

Figure 3.20: radian4.png

We can easily remember the translation from degrees to radians by the following correspondence

straight angle 180 degrees -> semicircle ->

Common angles are

$$180^o \; ! \tag{3.91}$$

$$360^o \; ! \; 2 \tag{3.92}$$

$$90^o \; ! \; \frac{}{2} \tag{3.93}$$

$$45^o \; ! \; \frac{}{4} \tag{3.94}$$

$$60^o \; ! \; \frac{}{3} \tag{3.95}$$

$$30^o \; ! \; \frac{}{6} \tag{3.96}$$

Let us stop here for now. We will return to our series on mathematical identities in our next post. Hope to see you there.

Homework.

In this homework section, we will prove the Vieta formula of the number that we mention in the previous post

$$\frac{2}{\pi} = \sqrt{\frac{1}{2}}\sqrt{\frac{1}{2}+\frac{1}{2}\sqrt{\frac{1}{2}}}\sqrt{\frac{1}{2}+\frac{1}{2}\sqrt{\frac{1}{2}+\frac{1}{2}\sqrt{\frac{1}{2}}}} \qquad (3.97)$$

In the following figure, we can see that $ZA = \sin(x)$ is a line segment which is shorter than the circle arc $ZI = x$

$$\sin(x) < x \qquad (3.98)$$

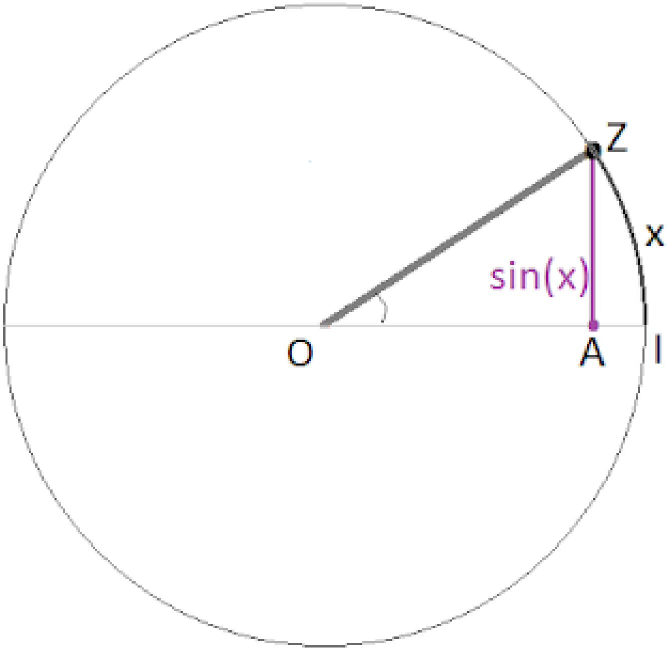

Figure 3.21: radian5.png

Especially, when the angle x is small, $\sin(x)$ is getting closer and closer to x. We will use this fact to prove the Vieta formula.

1. Use the trigonometric cos formula for double angle

$$\cos(2x) = 2\cos^2(x) - 1 \qquad (3.99)$$

to show that

$$\cos\frac{\pi}{4} = \sqrt{\frac{1}{2}} \tag{3.100}$$

$$\cos\frac{\pi}{8} = \sqrt{\frac{1}{2} + \frac{1}{2}\sqrt{\frac{1}{2}}} \tag{3.101}$$

$$\cos\frac{\pi}{16} = \sqrt{\frac{1}{2} + \frac{1}{2}\sqrt{\frac{1}{2} + \frac{1}{2}\sqrt{\frac{1}{2}}}} \tag{3.102}$$

Thus,

$$\sqrt{\frac{1}{2}} \times \sqrt{\frac{1}{2} + \frac{1}{2}\sqrt{\frac{1}{2}}} \times \sqrt{\frac{1}{2} + \frac{1}{2}\sqrt{\frac{1}{2} + \frac{1}{2}\sqrt{\frac{1}{2}}}} = \cos\frac{\pi}{4} \times \cos\frac{\pi}{8} \times \cos\frac{\pi}{16} \tag{3.103}$$

2. Use the trigonometric sin formula for double angle

$$\sin(2x) = 2\sin(x)\cos(x) \tag{3.104}$$

to show that

$$\cos\frac{\pi}{4} \times \cos\frac{\pi}{8} \times \cos\frac{\pi}{16} = \frac{\frac{1}{8}}{\sin\frac{\pi}{16}} = \frac{2}{\pi} \times \frac{\frac{\pi}{16}}{\sin\frac{\pi}{16}} \tag{3.105}$$

3. As we have discussed above, since the angle $\frac{\pi}{16}$ is very small,

$$\sin\frac{\pi}{16} \approx \frac{\pi}{16} \tag{3.106}$$

and

$$\cos\frac{\pi}{4} \times \cos\frac{\pi}{8} \times \cos\frac{\pi}{16} \approx \frac{2}{\pi} \tag{3.107}$$

4. In general, prove that

$$\cos\frac{\pi}{4} \times \cos\frac{\pi}{8} \times \cdots \times \cos\frac{\pi}{2^n} = \frac{2}{\pi} \times \frac{\frac{\pi}{2^n}}{\sin\frac{\pi}{2^n}} \tag{3.108}$$

and

$$\lim_{n\to\infty} \cos\frac{\pi}{4} \times \cos\frac{\pi}{8} \times \cdots \times \cos\frac{\pi}{2^n} = \frac{2}{\pi} \tag{3.109}$$

This is the Vieta formula of the number

$$\sqrt{\frac{1}{2}}\sqrt{\frac{1}{2}+\frac{1}{2}\sqrt{\frac{1}{2}}}\sqrt{\frac{1}{2}+\frac{1}{2}\sqrt{\frac{1}{2}+\frac{1}{2}\sqrt{\frac{1}{2}}}} = \frac{2}{\ } \qquad (3.110)$$

3.5 How to construct a regular polygon with 15 sides

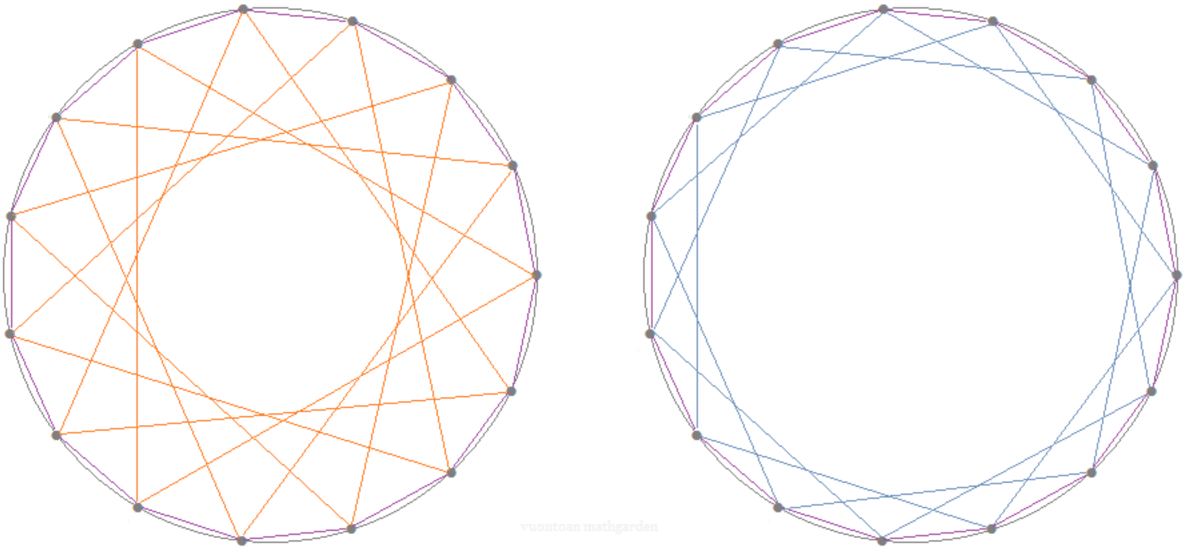

Figure 3.22: polygon1.png

To feed your curiosity, today we will look at a compass and straightedge construction of the regular polygon with 15 sides and we will show that there is a connection between this construction problem with the measuring liquid puzzle that we have learned from our previous post.

Measuring liquid puzzle

First, let us review the following brain teaser puzzle from our previous post.

Measuring liquid puzzle. Suppose you have a 3-liter jug and a 5-liter jug, how would you measure out exactly 1 liter of water?

At first glance, it seems that there are a lot of possibilities with the filling and pouring of water using the two jugs. But if we take a step back and have a careful look, we can categorize all the measuring operations into exactly 8 types:

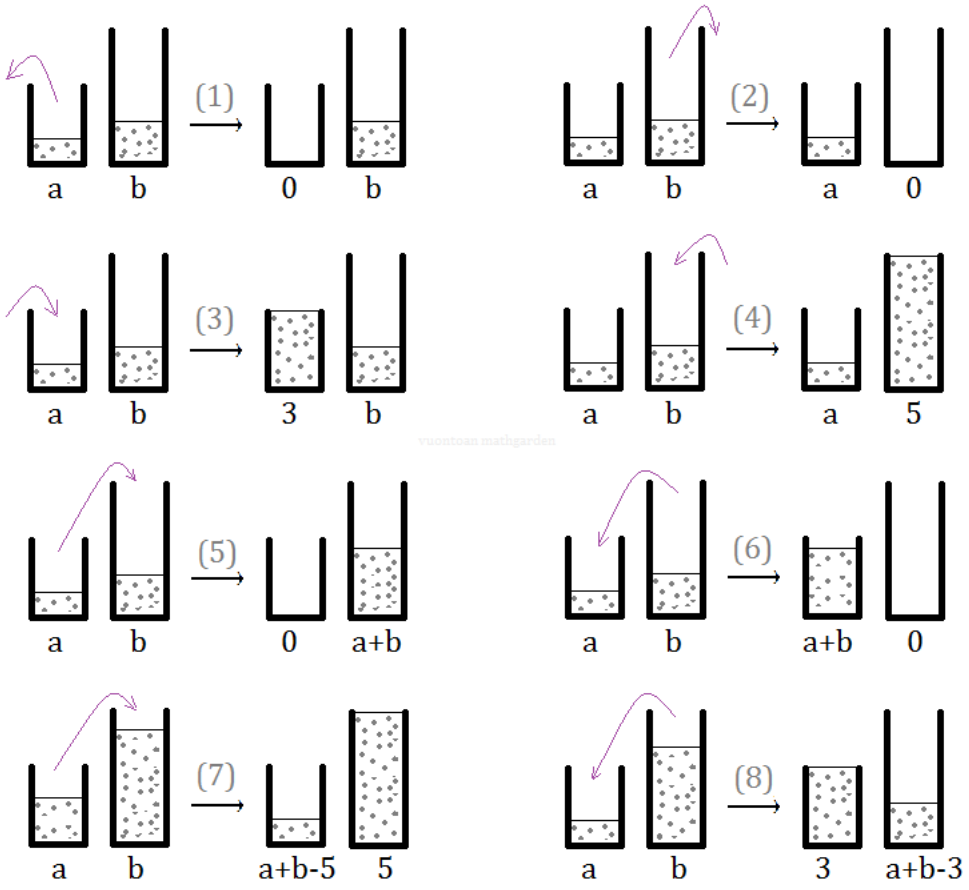

Figure 3.23: polygon2.png

We can see that the amount of water contained in the jugs will initially start with the value (0,0), and after each step of measuring operation, this value (a,b) will change into one of the following 8 possible values

$$(0; b); \quad (a; 0); \quad (3; b); \quad (a; 5); \tag{3.111}$$

$$(0; a+b); \quad (a+b; 0); \quad (a+b-5; 5); \quad (3; a+b-3): \tag{3.112}$$

Therefore, we can easily prove the following fact

The amount of water (in liter) in each of the jug is always a number of the form 3x+5y where x and y are two integers.

It means that if we want to measure out 1 liter of water then we have to write the value 1 in the form 3x+5y. So our puzzle is reduced to the problem of solving the following linear Diophantine equation

$$3x + 5y = 1: \tag{3.113}$$

This equation has infinitely many integer solutions. We can easily see that one solution is (x=2,y=-1) and another one is (x=-3,y=2). These two solutions give us the following two representations of the value 1:

$$3 \quad 2 \quad 5 \quad 1 = 1 \tag{3.114}$$

$$5 \quad 2 \quad 3 \quad 3 = 1: \tag{3.115}$$

Corresponding to these two representations, we have the following answers to our puzzle:

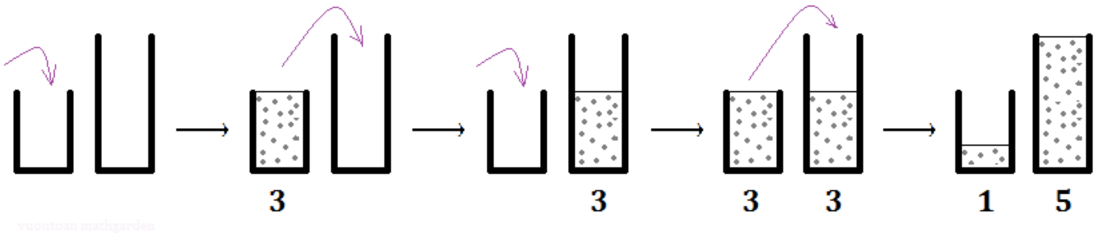

Figure 3.24: polygon3.png

First solution 3 X 2 - 5 X 1=1: Filling 3-liter jug to the full twice and pouring out to 5-liter jug making it full once, we get 1 liter remaining.

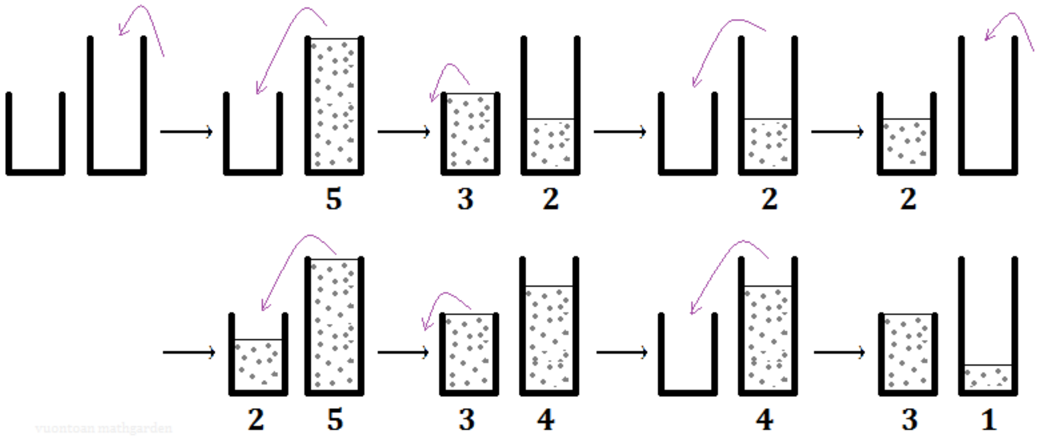

Figure 3.25: polygon4.png

Second solution 5 X 2 - 3 X 3=1: Filling 5-liter jug to the full twice and pouring out to 3-liter jug making it full three times, we get 1 liter remaining.

We have seen that our measuring liquid puzzle has a close connection with the Diophantine equation 3x+5y=1. Soon, we will see that this same Diophantine equation enables us to construct a regular polygon with 15 sides.

Regular polygon construction problem

Let us call a polygon with n sides an n-gon. A polygon with equal sides and equal angles is called a regular polygon.

The problem of constructing regular polygons by compass and straightedge is one of a few classic problems of ancient mathematics that are easy to state but incredibly difficult to solve. For a long time, we know how to construct an equilateral triangle (3-gon) and a regular pentagon (5-gon). In his famous books, the Elements, Euclid of ancient Greek presented a method of constructing a regular pentagon. But for the next two thousand years, no one had ever succeeded in constructing a regular 7-gon, a regular 9-gon, a regular 11-gon or a regular 13-gon. It was not until in 1796, Gauss, only at age 19, made the first breakthrough by successfully constructing a regular 17-gon. The problem was completely solved in 1837 with the following beautiful theorem

Gauss-Wantzel's Theorem. For an odd number n, a regular polygon of n sides can be constructed by compass and straightedge if and only if $n = p_1 \cdots p_t$ are distinct Fermat's primes.

So, what are the Fermat's primes mentioned in Gauss' theorem? Here is the definition:

Fermat's prime. A prime number is called a Fermat's prime if it has the form

$$F_k = 2^{2^k} + 1: \tag{3.116}$$

According to this definition:

k=0, $F_0 = 2^{2^0} + 1 = 2^1 + 1 = 3$ is a prime, so it is a Fermat's prime,

k=1, $F_1 = 2^{2^1} + 1 = 2^2 + 1 = 5$ is a prime, so it is a Fermat's prime,

k=2, $F_2 = 2^{2^2} + 1 = 2^4 + 1 = 17$ is a prime, so it is a Fermat's prime,

k=3, $F_3 = 2^{2^3} + 1 = 2^8 + 1 = 257$ is a prime, so it is a Fermat's prime,

k=4, $F_4 = 2^{2^4} + 1 = 2^{16} + 1 = 65537$ is a prime, so it is a Fermat's prime,

k=5, $F_5 = 2^{2^5} + 1 = 2^{32} + 1 = 4294967297 = 641 \times 6700417$ is a composite number.

Since 3 and 5 are Fermat's primes, by Gauss-Wantzel's Theorem, regular 3-gons and regular 5-gons are constructible. In addition, since 15=3 X 5, regular 15-gons are constructible. However, there is a condition in the theorem saying that the Fermat's primes have to be distinct, so 9-gon and 25-gon are not constructible by compass and straightedge.

Construction of a regular 15-gon

As we have seen above, 15 is a product of two distinct Fermat's primes (3 and 5), so by Gauss-Wantzel's Theorem, a regular 15-gon can be constructed by compass and straightedge. But how can we construct it?

Figure 3.26: polygon5.png

Let us look at a picture of a regular 15-gon. We can see that its vertices form a lot of equilateral triangles and a lot of regular pentagons.

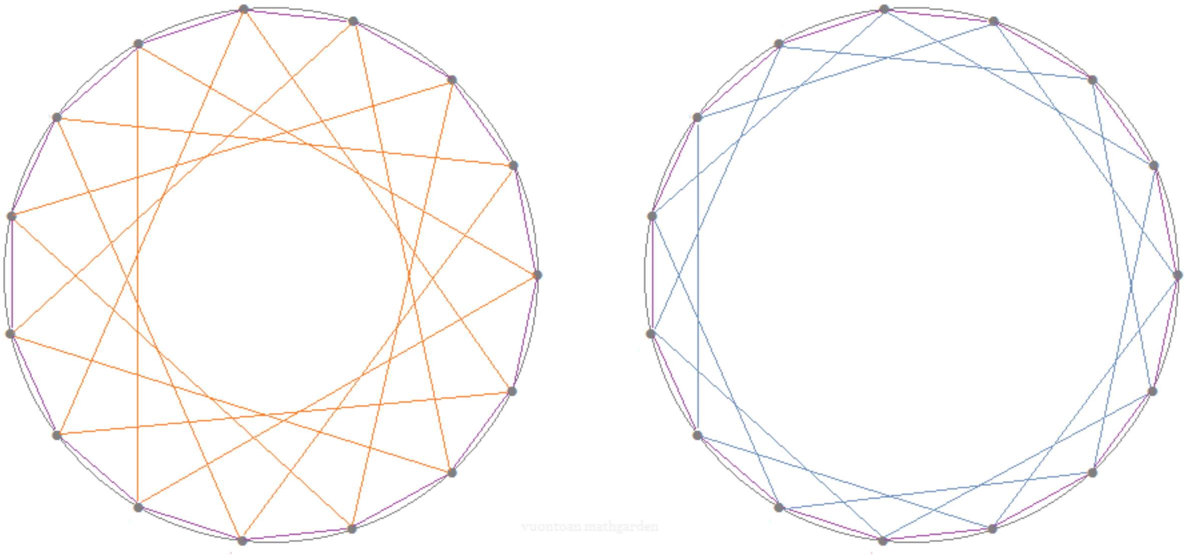

Figure 3.27: polygon6.png

This observation motivates us to construct first an equilateral triangle and a regular pentagon. Let us draw a circle, and pick a point P0 on it. We can construct an equilateral triangle A0A1A2 and a regular pentagon B0B1B2B3B4 with A0=B0=P0. Now, even though we have not constructed a regular 15-gon fully, but at least we have a part of it!

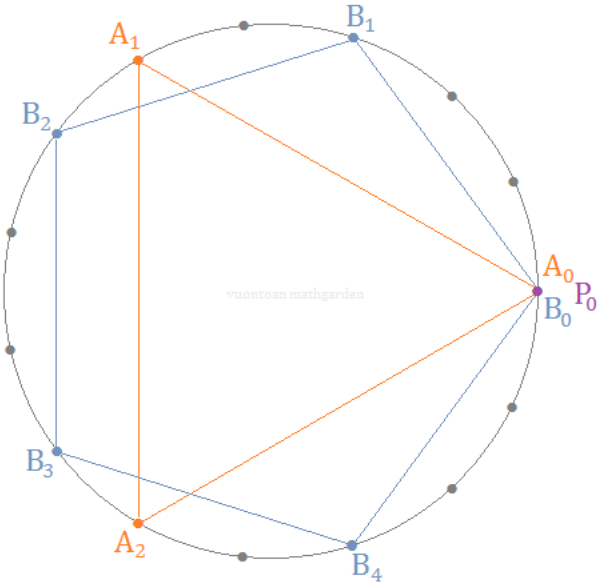

Figure 3.28: polygon7.png

Can we construct other vertices of the 15-gon? YES WE CAN!!!

Looking at the above picture, we can see that we can actually construct the whole polygon because we have already had the two sides A1B2 and B3A2. Using compass with radius A1B2 (or B3A2), from P0 we can construct P1, from P1 we can construct P2, ..., and the rest of it!

Let us now write down the steps of the construction.

Construct a circle and pick a point P0 on it. Construct an equilateral triangle P0P5P10 and a regular pentagon P0P3P6P9P12. Connect the sides P5P6 and P9P10. Draw a circle with center P0 and radius equal to P5P6, this circle intersects with the original big circle at P1 and P14. Draw a circle with center P3 and radius equal to P5P6, this circle intersects with the original big circle at P2 and P4. Other vertices P7, P8, P11, P13 can be constructed similarly.

Figure 3.29: polygon8.png

Now we know how to construct a regular 15-gon. Let us take a step back and see why this construction is possible. The crucial part of the construction is the fact that A1 and B2 are next to each other, and also B3 and A2. This fact can be explained by the Diophantine equation $3x + 5y = 1$

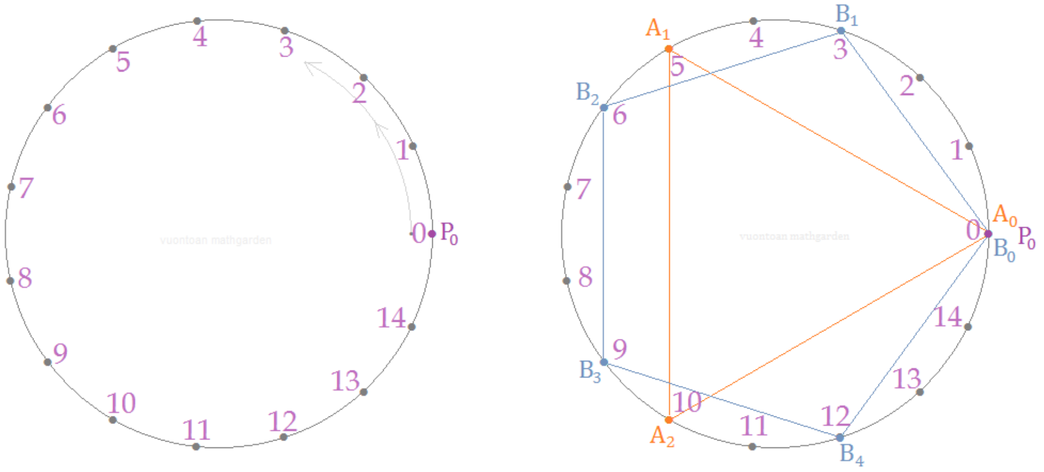

Figure 3.30: polygon9.png

Indeed, if we consider the whole circle as 15 units then each side of the equilateral triangle contains 5 units and each side of the regular pentagon contains 3 units. If we use the point P0 as the origin and measure the distance along the circle, then the point A1 is at 5 unit, the point A2 is at 10 unit. For the regular pentagon, the point B1 is at 3 unit, B2 6 unit, B3 9 unit, and B4 12 unit.

In general, the point Ai is at 5i unit and the point Bj is at 3j unit. The distance between Ai and Bj along the circle is

$$A_i B_j = |5i - 3j|. \qquad (3.117)$$

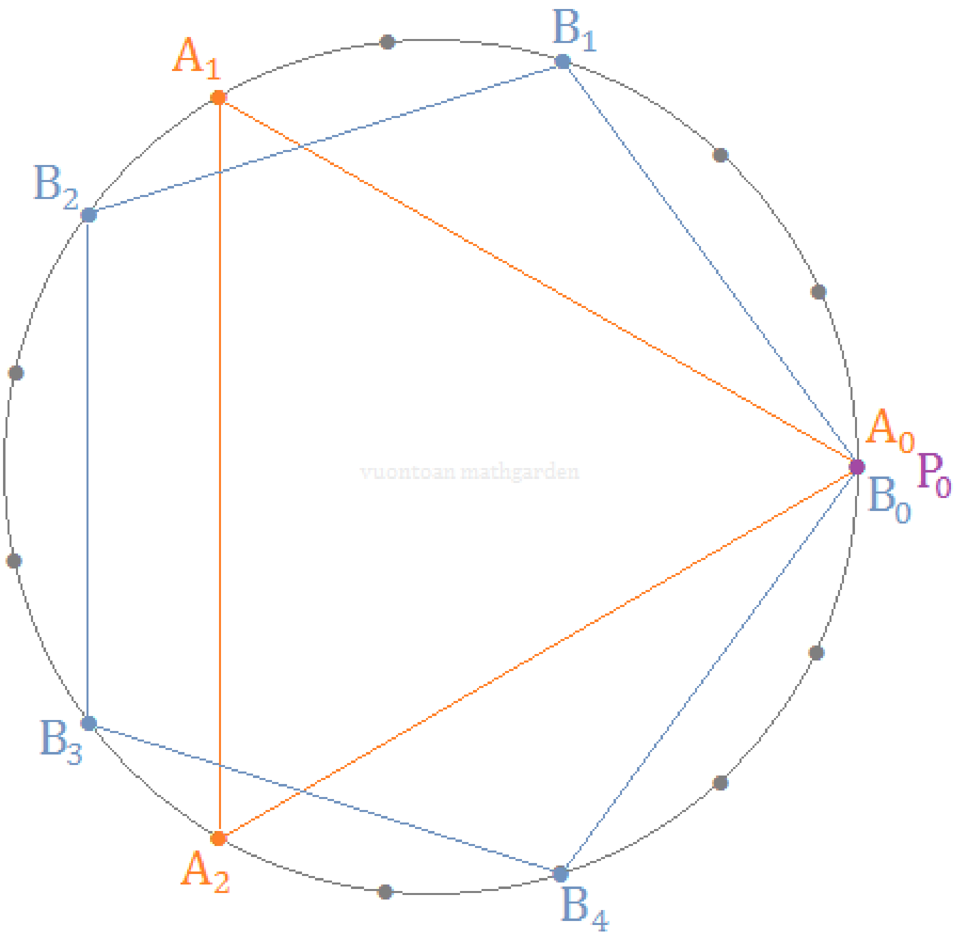

Figure 3.31: polygon10.png

Ai is at 5i unit, Bj is at 3j unit, so the distance between Ai and Bj is $A_iB_j = j5i \quad 3jj$

According to this distance formula, Ai is next to Bj if and only if the distance between Ai and Bj is 1 unit, that is

$$5i \quad 3j = \quad 1 \tag{3.118}$$

One of the solution is i=2, j=3, this gives us 5 X 2 - 3 X 3=1

this explains why A2 and B3 are next to each other and B3A2 forms a side of the 15-gon.

Another solution is i=1, j=2, 5 X 1 - 3 X 2= -1 and this explains why A1 is next to B2.

So the two sides B3A2 and A1B2 of the regular 15-gon correspond to the two integer solutions of the Diophantine equation 3x+5y=1. How amazing is that!

From here, we can easily have the following generalization

Draw a circle a pick a point P0. Draw a regular p-gon A0A1. . . Ap-1 and a regular q-gon B0B1. . . Bq-1 with A0=B0=P0. If p and q are two relatively prime numbers then there must exist Ax and By such that AxBy form a side of a regular pq-gon. It means that if a regular p-gon and a regular q-gon are constructible then a regular pq-gon is also constructible.

Let us stop here for now. In our future posts, we will look at Gauss' method of constructing regular 17-gon. Hope to see you again then.

Homework.

1. Prove the generalization mentioned at the end of the post:

Let gcd(p,q)=1. If a regular p-gon and a regular q-gon are constructible by compass and straightedge then a regular pq-gon is also constructible.

2. Go to google.com and search about Gauss' 17-gon construction.

3.6 Moivre's formula

In previous post we have learned about complex numbers. Today, we will learn about the trigonometric form of a complex number and the famous de Moivre's formula.

Let us recall that the complex numbers are created by the introduction of a very special number { the number i { with the property i2= -1.

$$i^2 = -1: \tag{3.119}$$

Complex numbers have the form

$$a + ib \tag{3.120}$$

where a and b are two real numbers. In previous post, we have learned some basic facts about complex numbers

Addition and Subtraction

$$(a + ib) + (c + id) = (a + c) + i(b + d); \tag{3.121}$$

$$(a + ib) - (c + id) = (a - c) + i(b - d): \tag{3.122}$$

Multiplication

$$(a+ib)(c+id) = ac + iad + ibc + i^2bd = (ac - bd) + i(bc + ad). \tag{3.123}$$

Division we need to use the identity

$$(a+ib)(a-ib) = a^2 - i^2b^2 = a^2 + b^2 \tag{3.124}$$

and so

$$\frac{c+id}{a+ib} = \frac{(c+id)(a-ib)}{(a+ib)(a-ib)} = \frac{(ac+bd)+i(ad-bc)}{a^2+b^2} = \frac{ac+bd}{a^2+b^2} + i\frac{ad-bc}{a^2+b^2}. \tag{3.125}$$

Complex conjugate

$$\overline{a+ib} = a - ib, \quad \overline{a-ib} = a + ib. \tag{3.126}$$

Absolute value

$$|a+ib| = \sqrt{a^2+b^2}. \tag{3.127}$$

Trigonometric form of a complex number

Today we will learn a very important fact about complex numbers, that is, any complex number z can be written in a trigonometric form as follows

$$z = r(\cos\theta + i\sin\theta), \tag{3.128}$$

where $r = |z|$.

Indeed, let $z = a + ib$, then

$$r = |z| = \sqrt{a^2+b^2}, \tag{3.129}$$

we have

$$\frac{z}{r} = \frac{a}{r} + i\frac{b}{r}. \tag{3.130}$$

Since

$$\left(\frac{a}{r}\right)^2 + \left(\frac{b}{r}\right)^2 = \frac{a^2+b^2}{r^2} = 1, \tag{3.131}$$

there exists θ such that

$$\frac{a}{r} = \cos \ ; \qquad \frac{b}{r} = \sin \ : \tag{3.132}$$

Thus,

$$\frac{z}{r} = \frac{a}{r} + i\frac{b}{r} = \cos \ + i \ \sin \ : \tag{3.133}$$

And we obtain the trigonometric form of the complex number z

$$z = r(\cos \ + i \ \sin \ ): \tag{3.134}$$

In special case when z=0 we can let r=0.

Multiplication in trigonometric form Trigonometric form is very convenient when we do multiplication for complex numbers thanks to the following identity

$$(\cos \ + i \ \sin \ )(\cos \ + i \ \sin \ ) = \cos(\ + \ ) + i \ \sin(\ + \ ): \tag{3.135}$$

If we have two complex numbers u and v, and express them in the trigonometric form

$$u = r(\cos \ + i \ \sin \ ); \tag{3.136}$$

$$v = s(\cos \ + i \ \sin \ ); \tag{3.137}$$

then their product can be easily obtained as

$$uv = rs(\cos(\ + \ ) + i \ \sin(\ + \ )): \tag{3.138}$$

Exponentiation and de Moivre's formula Similar to multiplication, exponentiation is also easy when we write the complex number in trigonometric form. If

$$u = r(\cos \ + i \ \sin \ ) \tag{3.139}$$

then

$$u^n = r^n(\cos(n \ ) + i \ \sin(n \ )): \tag{3.140}$$

The following identity is called the de Moivre's formula, this is an important formula in complex numbers

$$(\cos \ + i \ \sin \ )^n = \cos(n \ ) + i \ \sin(n \ ): \tag{3.141}$$

Now let us do some exercises.

Problem 1: Solve the quadratic equation

$$x^2 - 2x + 4 = 0 \tag{3.142}$$

and write its complex roots in trigonometric form.

Solution: We have

$$\Delta' = 1^2 - 4 = -3; \tag{3.143}$$

so the quadratic equation has complex roots

$$1 \pm i\sqrt{3}. \tag{3.144}$$

To write these complex numbers in trigonometric form, we need to calculate their absolute value

$$|1 \pm i\sqrt{3}| = \sqrt{1^2 + (\sqrt{3})^2} = \sqrt{4} = 2. \tag{3.145}$$

Thus,

$$1 \pm i\sqrt{3} = 2\left(\frac{1}{2} \pm i\frac{\sqrt{3}}{2}\right) = 2(\cos\frac{\pi}{3} \pm i\ \sin\frac{\pi}{3}). \tag{3.146}$$

Problem 2: Solve the quadratic equation

$$x^2 - x + 1 = 0 \tag{3.147}$$

and write its complex roots in trigonometric form.

Solution: We have

$$\Delta = 1^2 - 4 = -3; \tag{3.148}$$

so the quadratic equation has complex roots

$$\frac{1 \pm i\sqrt{3}}{2}. \tag{3.149}$$

To write these complex numbers in trigonometric form, we need to calculate their absolute value

$$\left|\frac{1 \pm i\sqrt{3}}{2}\right| = \sqrt{\left(\frac{1}{2}\right)^2 + \left(\frac{\sqrt{3}}{2}\right)^2} = 1. \tag{3.150}$$

Thus,

$$\frac{1-i\sqrt{3}}{2}=\frac{1}{2}-i\frac{\sqrt{3}}{2}=\cos\frac{\pi}{3}-i\sin\frac{\pi}{3}. \tag{3.151}$$

Problem 3: Solve the quadratic equation

$$x^2-3x+3=0 \tag{3.152}$$

and write its complex roots in trigonometric form.

Solution: We have

$$\Delta=(-3)^2-4\cdot 3=-3, \tag{3.153}$$

so the quadratic equation has complex roots

$$\frac{3\pm i\sqrt{3}}{2}. \tag{3.154}$$

To write these complex numbers in trigonometric form, we need to calculate their absolute value

$$\left|\frac{3\pm i\sqrt{3}}{2}\right|=\sqrt{\left(\frac{3}{2}\right)^2+\left(\frac{\sqrt{3}}{2}\right)^2}=\sqrt{3}. \tag{3.155}$$

Thus,

$$\frac{3\pm i\sqrt{3}}{2}=\sqrt{3}\left(\frac{\sqrt{3}}{2}\pm i\frac{1}{2}\right)=\sqrt{3}\left(\cos\frac{\pi}{6}\pm i\sin\frac{\pi}{6}\right). \tag{3.156}$$

Problem 4: Calculate $(1+i)^{2012}$ by two methods, using de Moivre's formula and using binomial identity, and deduce the following equality

$$\binom{2012}{0}-\binom{2012}{2}+\binom{2012}{4}-\binom{2012}{6}+\cdots+\binom{2012}{2008}-\binom{2012}{2010}+\binom{2012}{2012}=-2^{1006}. \tag{3.157}$$

Solution: In the first method, we write $1+i$ in trigonometric form and then use de Moivre's formula to calculate the exponentiation.

First, we calculate the absolute value o $1+i$:

$$|1+i|=\sqrt{1^2+1^2}=\sqrt{2}. \tag{3.158}$$

Thus,

$$1+i=\sqrt{2}\left(\frac{\sqrt{2}}{2}+i\frac{\sqrt{2}}{2}\right)=\sqrt{2}\left(\cos\frac{\pi}{4}+i\sin\frac{\pi}{4}\right). \tag{3.159}$$

Using de Moivre's formula, we calculate the exponentiation

$$(1+i)^{2012} = (\sqrt{2})^{2012}(\cos\frac{2012}{4} + i\ \sin\frac{2012}{4}) = 2^{1006}(\cos(503\ ) + i\ \sin(503\ )) = \quad 2^{1006}: \tag{3.160}$$

On the other hand, by binomial identity, we have

$$(1+i)^{2012} = 1 + \binom{2012}{1} i + \binom{2012}{2} i^2 + \binom{2012}{3} i^3 + \binom{2012}{4} i^4 + \binom{2012}{5} i^5 + ::: + \binom{2012}{2011} i^{2011} + i^{2012} \tag{3.161}$$

$$= 1 + \binom{2012}{1} i \quad \binom{2012}{2} \quad \binom{2012}{3} i + \binom{2012}{4} + \binom{2012}{5} i + ::: \quad \binom{2012}{2011} i + 1 \tag{3.162}$$

Comparing the real part of the above two results, we obtain

$$1 \quad \binom{2012}{2} + \binom{2012}{4} \quad \binom{2012}{6} + ::: + \binom{2012}{2008} \quad \binom{2012}{2010} + 1 = \quad 2^{1006}: \tag{3.163}$$

Let us stop here for now, see you again in the next post.

Homework.

1. Write these numbers in trigonometric form: $1 \quad i$, $3 + 3i$, $\sqrt{3} + 3i$, $3 \quad \sqrt{3}i$, $\quad 7 + 7i$, $3i$.

2. What is the absolute value of this complex number $\cos + i\ \sin\ $?

3. Let $u = r(\cos\ + i\ \sin\ )$ and $v = s(\cos\ + i\ \sin\ )$ calculate $u=v$.

4. Calculate $(1+i)^{2013}$ by two methods, the de Moivre's formula and the binomial identity, and then deduce some combinatorial equalities.

5. Write x in trigonometric form and find all possible values of x such that $x^4 = \quad 1$.

https://sites.google.com/site/latexgrucad/equacoes-e-subequacoes

3.8 Complex Number

Today we will learn about the complex numbers. The crucial point about complex numbers is that we accept a very special number that we will denote it by i. This number i is very special because it satisfies the following identity

$$i^2 = -1. \qquad (3.165)$$

So a complex number will have the form

$$a + ib \qquad (3.166)$$

where a and b are two real numbers. When b=0 then a+ib=a is just a normal real number, and when a=0 then a+ib=ib is called a pure imaginary number. Here are some examples of complex numbers:

$$1 + i; \quad 2 - 3i; \quad -\sqrt{3} + 4i; \quad 5i - 4; \quad 6; \quad i; \quad -3i; \quad 4 + 2i; \ldots \qquad (3.167)$$

First, let us learn about some basic arithmetic like addition, subtraction, multiplication, division of complex numbers.

Addition and Subtraction: are quite simple and trivial as follows

$$(3 + 2i) + (4 + i) = 7 + 3i; \quad (3 + 2i) - (4 + i) = -1 + i; \qquad (3.168)$$

$$(2 + i) + (3 - 4i) = 5 - 3i; \quad (2 + i) - (3 - 4i) = -1 + 5i; \qquad (3.169)$$

$$2i + (3i + 1) = 1 + 5i; \quad 2i - (3i + 1) = -1 - i; \qquad (3.170)$$

In general, we have

$$(a+ib)+(c+id)=(a+c)+i(b+d);\quad (a+ib)-(c+id)=(a-c)+i(b-d). \tag{3.171}$$

Multiplication: we need to use the identity $i^2=-1$ in multiplication, for examples,

$$(3+2i)(4+i)=12+3i+8i+2i^2=12+11i-2=10+11i; \tag{3.172}$$

$$(2+i)(3-4i)=6-8i+3i-4i^2=6-5i+4=10-5i; \tag{3.173}$$

$$2i(3i+1)=6i^2+2i=-6+2i. \tag{3.174}$$

In general, we have

$$(a+ib)(c+id)=ac+iad+ibc+i^2bd=(ac-bd)+i(bc+ad). \tag{3.175}$$

Division: let us recall the division of the radicals, suppose that we want to calculate

$$\frac{1+4\sqrt{3}}{5+2\sqrt{3}}; \tag{3.176}$$

then we will use the following identity

$$(5+2\sqrt{3})(5-2\sqrt{3})=5^2-(2\sqrt{3})^2=25-12=13. \tag{3.177}$$

We have

$$\frac{1+4\sqrt{3}}{5+2\sqrt{3}}=\frac{(1+4\sqrt{3})(5-2\sqrt{3})}{(5+2\sqrt{3})(5-2\sqrt{3})}=\frac{5-2\sqrt{3}+20\sqrt{3}-24}{25-12}=\frac{-19+18\sqrt{3}}{13}=-\frac{19}{13}+\frac{18}{13}\sqrt{3}. \tag{3.178}$$

Similarly, for complex numbers, we will use the identity

$$(a+ib)(a-ib)=a^2-i^2b^2=a^2+b^2. \tag{3.179}$$

We have

$$\frac{c+id}{a+ib} = \frac{(c+id)(a-ib)}{(a+ib)(a-ib)} = \frac{(ac+bd)+i(ad-bc)}{a^2+b^2} = \frac{ac+bd}{a^2+b^2} + i\frac{ad-bc}{a^2+b^2}. \tag{3.180}$$

Here are some examples,

$$\frac{3+2i}{4+i} = \frac{(3+2i)(4-i)}{(4+i)(4-i)} = \frac{12-3i+8i-2i^2}{16-i^2} = \frac{14+5i}{17} = \frac{14}{17}+\frac{5}{17}i, \tag{3.181}$$

$$\frac{2+i}{3-4i} = \frac{(2+i)(3+4i)}{(3-4i)(3+4i)} = \frac{6+8i+3i+4i^2}{9-16i^2} = \frac{2+11i}{25} = \frac{2}{25}+\frac{11}{25}i, \tag{3.182}$$

$$\frac{2i}{3i+1} = \frac{2i(1-3i)}{(1+3i)(1-3i)} = \frac{2i-6i^2}{1-9i^2} = \frac{6+2i}{10} = \frac{3}{5}+\frac{1}{5}i, \tag{3.183}$$

Conjugation: as we have seen above, the two complex numbers a+ib and a-ib are used together in division because their product is a real number

$$(a+ib)(a-ib) = a^2 - i^2b^2 = a^2+b^2. \tag{3.184}$$

These two complex numbers are called conjugate and they are very useful when they are used together. We will use the notation $\bar{z}$ to denote the conjugate of z, thus,

$$\overline{a+ib} = a-ib; \quad \overline{a-ib} = a+ib. \tag{3.185}$$

In special cases, the conjugate of a real number a is a, and the conjugate of ib is -ib.

Absolute value: for real numbers, we have the concept of absolute value,

$$|5| = 5; \quad |-5| = 5. \tag{3.186}$$

This concept can be extended for complex numbers. The absolute value of a complex number z=a+ib is denoted by |z| and defined as

$$|z| = |a+ib| = \sqrt{a^2+b^2}. \tag{3.187}$$

It follows that

$$|z|^2 = a^2+b^2 = (a+ib)(a-ib) = z\bar{z}. \tag{3.188}$$

Here are some examples,

$$|3+2i| = \sqrt{9+4} = \sqrt{13}; \tag{3.189}$$

$$|2-i| = \sqrt{4+1} = \sqrt{5}; \tag{3.190}$$

$$|3i| = \sqrt{0+9} = 3; \tag{3.191}$$

$$|2| = \sqrt{4+0} = 2. \tag{3.192}$$

In special cases, we have $|5| = 5$, $|-5| = 5$ and $|3i| = 3$, $|-3i| = 3$.

Fibonacci's Identity

Absolute value has the following important property

$$|u|\,|v| = |uv|. \tag{3.193}$$

This property gives rise to the following Fibonacci's identity

$$(a^2+b^2)(c^2+d^2) = (ac-bd)^2 + (ad+bc)^2. \tag{3.194}$$

Indeed, if we take u=a+ib and v=c+id then uv=(ac-bd)+i(ad+bc) and we have

$$|u| = \sqrt{a^2+b^2}; \tag{3.195}$$

$$|v| = \sqrt{c^2+d^2}; \tag{3.196}$$

$$|uv| = \sqrt{(ac-bd)^2 + (ad+bc)^2}. \tag{3.197}$$

So the identity $|u||v| = |uv|$ becomes

$$(a^2+b^2)(c^2+d^2) = (ac-bd)^2 + (ad+bc)^2. \tag{3.198}$$

If you ever forget about this identity and would like to construct it back, you can follow the following steps

First, write two arbitrary complex numbers and calculate the product

$$(a+ib)(c+id) = (ac-bd) + i(ad+bc); \tag{3.199}$$

Next, substitute the plus sign by the minus sign,

$$(a-ib)(c-id) = (ac-bd) - i(ad+bc); \tag{3.200}$$

Finally, multiply the above two equations together

$$[(a+ib)(a-ib)][(c+id)(c-id)] = [(ac-bd)+i(ad+bc)][(ac-bd)-i(ad+bc)] \tag{3.201}$$

and we obtain the required identity

$$(a^2+b^2)(c^2+d^2) = (ac-bd)^2+(ad+bc)^2. \tag{3.202}$$

Today we have learned some basic facts about complex numbers. This may surprise you but complex numbers are actually used a lot in number theory. We will learn more about complex number in the next post. Hope to see you then.

Homework.

1. Perform addition, subtraction, multiplication and division for the following pairs of complex numbers:

$$3+4i, 2+3i \tag{3.203}$$

$$-4i, 2-i, \tag{3.204}$$

$$7-i, 2+4i, \tag{3.205}$$

$$5-2i, 3+i, \tag{3.206}$$

$$4+3i, -i. \tag{3.207}$$

2. Find the complex conjugates for 5+3i, 4-2i, 1+i, -4, -1+2i, 5i, -4i.

3. Calculate the absolute values for 2+3i, 2-3i, 4+i, 4-i, 5+2i, 5-2i, 6, -6, 2-i, 2+i, 4i, -4i.

4. Calculate i3, i4, i5, i6,. . . .

Find a general formula for i^n.

5. Prove that

$$\left|\frac{u}{v}\right| = \frac{|u|}{|v|}. \tag{3.208}$$

6. Prove the following inequality

$$|u+v| \le |u|+|v|. \tag{3.209}$$

7. Show that for any complex number z, there exists such that

$$z = jzj(\cos \quad + i \; \sin \quad): \tag{3.210}$$

8. Use mathematical induction to prove the following identity

$$(\cos \quad + i \; \sin \quad)^n = \cos (n \quad) + i \; \sin (n \quad): \tag{3.211}$$

9. Prove that

$$(\cos \quad + i \; \sin \quad)(\cos \quad + i \; \sin \quad) = \cos (\quad + \quad) + i \; \sin (\quad + \quad): \tag{3.212}$$

10. Show that there exist two natural numbers a and b such that

$$a^2 + b^2 = 5^{2013}: \tag{3.213}$$

Pag. 06 (21) - Lines

LINES We will start with an example of a very simple line: y D x C 1 (Figure 1.1). For any value of x we add one to x and get y. We can draw the line by picking any two points on it, lining up a straight edge on the two points, and drawing along the straight edge. The line y D x C 1 is made of all the points that look like .x; x C 1/. Five points like that have been plotted in Figure 1.1: (-2,-1), (-1,0), (0,1), (1,2), and (2,3). Definition 1.1 A line can always be written in the form y D mx C b where m is the slope of the line, and b is the y-intercept of the line. Both m and b are numbers. There are different ways to interpret the parameters m and b.

The number m is the amount the y-value increases for each increase of 1 in the x-value.

If we pick two points on the line, then the run between those points is the change in the x-value, and the rise is the change in the y-value. The slope, m, is the rise divided by the run.

The y-intercept b is where the line hits the y-axis. This means the point .0; b/ is on the line.

Pag. 85 (101) - 3.2 ARC LENGTH AND SURFACE AREA

In this section we will learn to compute the length of curves and, having done that, to find the surface area of figures of rotation. A piece of a curve is called an arc. The key to finding the length of an arc is the differential of arc length. In the past we have had quantities like dx and dy that measure infinitesimal changes in the directions of the variables x and y. The differential of arc length is different - it does not point in a consistent direction, rather it points along a curve and so, by integrating it, we can find the length of a curve.

Examine Figure 3.5. The relationship between the change in x and y and the change in the length of the curve is Pythagorean, based on a right triangle. If we take this relationship to the infinitesimal scale, we obtain a formula for the differential of arc length.

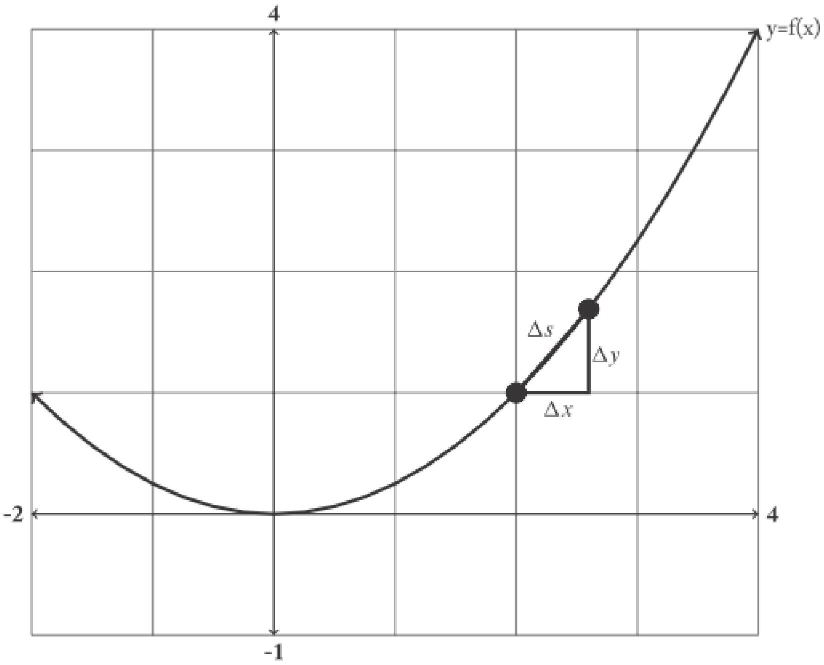

Figure 1.2: geo2.png

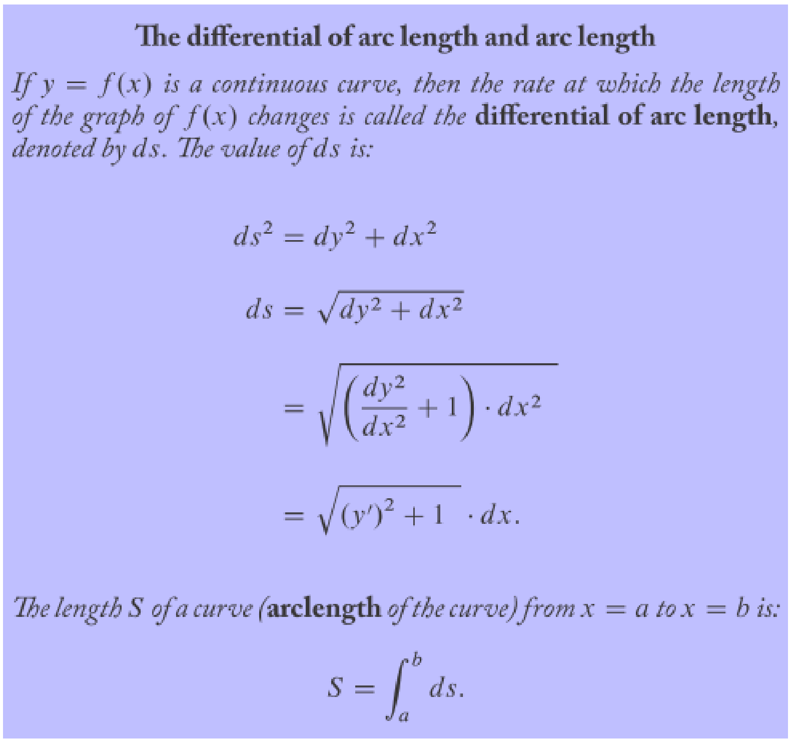
Figure 3.5:

The triangle with sides x, y, and s shows how the change in the length of the curve is related to the changes in distance in the x and y directions.



The differential of arc length and arc length

If $y = f(x)$ is a continuous curve, then the rate at which the length of the graph of $f(x)$ changes is called the **differential of arc length**, *denoted by ds. The value of ds is:*

$$ds^2 = dy^2 + dx^2$$

$$ds = \sqrt{dy^2 + dx^2}$$

$$= \sqrt{\left(\frac{dy^2}{dx^2} + 1\right) \cdot dx^2}$$

$$= \sqrt{(y')^2 + 1} \cdot dx.$$

*The length S of a curve (***arclength** *of the curve) from $x = a$ to $x = b$ is:*

$$S = \int_a^b ds.$$

Figure 1.3: geo3.png

4) C:/DATA-NovoVivo-123-2020/Books-123-2020/Calculus/Aspects of Differential Geometry I - 2015.pdf

Pag. 91 (107) - CHAPTER 3 Riemannian and Pseudo-Riemannian Geometry In Section 3.1, we introduce pseudo-Riemannian geometry. We show that the spheres of even di- mension do not admit Lorentzian metrics. We define the pseudo-Riema are perpendicular nnian measure, verify this agrees with the surface measure dS defined previously in Stokes' Theorem, and compute the volume of spheres and disks. In Section 3.2, we examine connections and their curvature. In Section 3.3, we specialize to the case of the Levi{Civita connection; this is the unique torsion-free Riemannian connection on the tangent bundle. In Section 3.4, we use the Levi{Civita connection to study geodesics. In Section 3.5, we use the Jacobi operator to establish some basic results concerning manifolds of constant sectional curvature. Section 3.6 is devoted to the proof of the Gauss{Bonnet Theorem and the study of Riemann surfaces. In Section 3.7, the generalization to higher dimensions and also to the pseudo-Riemannian setting is exhibited.

5) C:/DATA-NovoVivo-123-2020/Books-123-2020/Calculus/Aspects of Dif-

ferential Geometry II - 2015.pdf

Pag. 01 (17) - C H A P T E R 4 Additional Topics in Riemannian Geometry We continue the discussion of various topics in Riemannian geometry which was started in Chapter 3 of Book I. In Section 4.1, we discuss the geometry of curves and surfaces in Euclidean space that arise as solutions to an ordinary differential equation (ODE); this involves a nice application of the Gauss{Bonnet Theorem that is typical in the subject. In Section 4.2, we relate the scalar curvature to the growth of the volume of geodesic balls. In Section 4.3, we turn to holomorphic geometry. We present the Cauchy{Riemann equations, define almost complex structures, and state the Newlander{Nirenberg Theorem. We decompose d # and #' and introduce the spaces variation p, q. We define complex projective space. In Section 4.4, we present an introduction to Kahler geometry.

Pag. 01 (12) - IMPORTANT

1.1 Historical Background of Geometry The word geometry is derived from the Greek words geos (meaning earth) and metron (meaning measure). The ancient Egyptians, Chinese, Babylonians, Romans, and Greeks used geometry for surveying, navigation, astronomy, and other practical occupations. The Greeks sought to systematize the geometric facts they knew by establishing logical reasons for them and relationships among them. The work of men such as Thales (600 B.C.), Pythagoras (540 B.C.), Plato (390 B.C.), and Aristotle (350 B.C.) in systematizing geometric facts and principles culminated in the geom- etry text Elements, written in approximately 325 B.C. by Euclid. This most remarkable text has been in use for over 2000 years. 1.2 Undefined Terms of Geometry: Point, Line, and Plane 1.2A Point, Line, and Plane are Undefined Terms These undefined terms underlie the definitions of all geometric terms. They can be given meanings by way of descriptions. However, these descriptions, which follow, are not to be thought of as definitions. 1.2B Point A point has position only. It has no length, width, or thickness. A point is represented by a dot. Keep in mind, however, that the dot represents a point but is not a point, just as a dot on a map may represent a locality but is not the locality. A dot, unlike a point, has size. A point is designated by a capital letter next to the dot, thus point A is represented: A. 1.2C Line A line has length but has no width or thickness. A line may be represented by the path of a piece of chalk on the blackboard or by a stretched rubber band.

Pag. 159 (178) - 5. The Hydrogen Atom Based on the discussions in Chap. 4 we will now ap- ply the quantum mechanical treatment to the simplest atom, the H atom, which consists of one proton and one electron moving in the spherical symmetric Coulomb potential of the proton. These one-electron systems, such as the hydrogen atom and the ions He +, Li ++, Be +++, etc., are the only real systems for which the Schrodinger equation can be exactly (i.e., analytically) solved. For all other atoms or molecules approximations have to be made. Either the Schrodinger equation for these systems can be solved numerically (which offers a mathematical solution within the accuracy of the computer program, but generally gives little insight into the physical nature of the approximation), or the real atoms are described by approximate models that can be calculated analytically. In any case, for all multielectron systems, one has to live with approximations, either in the numerical solution of the exact atomic model or for the exact solution of the approximate model. A closer inspection of the spectrum of the hydrogen atom and other atoms reveals, however, that at higher spectral resolution the lines show a substructure that cannot be described by the Schrodinger theory, but is due to new effects, such as fine structure, hyperfine structure or the anomalous Zeeman effect. Therefore, even for the simple hydrogen atom the quantum mechanical model of an electron in the Coulomb field of the proton has to be modified by introducing new properties of electron and proton, such as electron spin or proton spin and their mutual interactions. These effects, which are small compared to the Coulomb energy, are included in a relativistic theory, based on the Dirac equation, which is called quantum electrodynamics. The Schrodinger equation can be regarded as the fundamental equation of nonrelativistic quantum theory. The treatment of the hydrogen atom illustrates in a very clear way the basic ideas of quantum mechanics,it explains the physical interpretation of quantum numbers, the description of the Zeeman effect and the fine structure by the model of angular momentum vector couplings and gives a better understanding of the more complex many-electron systems that will be discussed in the next chapter. 5.1 Schrodinger Equation for One-electron Systems

Pag. 201 (220) - 6. Atoms with More Than One Electron In atoms with more than one electron additional problems arise that are caused by mutual electrostatic and magnetic interactions between the electrons. In addition, we are now confronted with new symmetry principles that are valid if two electrons are exchanged. These stem from the fact that electrons cannot be distinguished from each other. We will first study these phenomena for the helium atom, which represents the simplest system with two electrons. This will help us understand the building up principle for the structure of electron shells for larger atoms. We will see that the electron configurations for all atoms can be obtained from the minimum energy principle, the correct coupling of the different angular momenta of the electrons and the observation of certain symmetry rules. This results in the determination of all possible energy states of the atoms and the characterization of these states by quantum numbers.

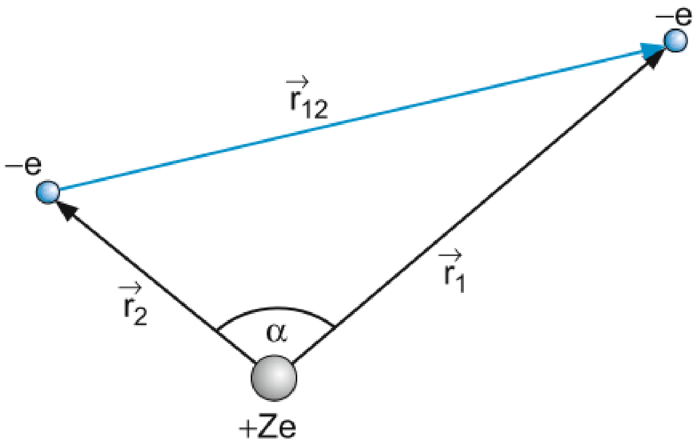

Figure 1.6: The Helium Atom.png

1.2 Geometry - Differential Geometry - Geodesic curve on a surface

1) C:/DATA-NovoVivo-123-2020/Books-123-2020/Applied Calculus of Variations for Engineers, Third edition/0367376091.pdf
Pag.141 (160) -

Chapter 8 Differential geometry Differential geometry is a classical mathematical area that has become very important for engineering applications in the recent decades. This importance is based on the rise of computer-aided visualization and geometry generation technologies. The chapter will address the fundamental problem of differential geometry, the finding of geodesic curves, that has practical implications in manufacturing. Development of non-mathematical surfaces used in ships and airplanes has serious financial impact in reducing material waste and improving the quality of the surfaces. While the discussion in this chapter will focus on analytically solvable problems, the methods and concepts we introduce will provide a foundation applicable in various engineering areas. 8.1 The geodesic problem Finding a geodesic curve on a surface is a classical problem of differential geometry. Variational calculus seems uniquely applicable to this problem. Let us consider a parametrically given surface

$$\underline{r} = x(u,v)\underline{i} + y(u,v)\underline{j} + z(u,v)\underline{k}. \tag{1.1}$$

Let two points on the surface be

$$\underline{r}_0 = x(u_0,v_0)\underline{i} + y(u_0,v_0)\underline{j} + z(u_0,v_0)\underline{k}.$$

and

$$\underline{r}_1 = x(u_1,v_1)\underline{i} + y(u_1,v_1)\underline{j} + z(u_1,v_1)\underline{k}.$$

The shortest path on the surface between these two points is the geodesic curve. Consider the square of the arc length

$$ds^2 = (dx)^2 + (dy)^2 + (dz)^2,$$

and compute the differentials related to the parameters,

$$ds^2 = E(u,v)(du)^2 + 2F(u,v)du dv + G(u,v)(dv)^2$$

Here the so-called first fundamental quantities are defined as

$$E(u,v) = \left(\frac{\partial x}{\partial u}\right)^2 + \left(\frac{\partial y}{\partial u}\right)^2 + \left(\frac{\partial z}{\partial u}\right)^2 = |\underline{r}'_u|^2,$$

and

$$F(u,v) = \frac{\partial x}{\partial u}\frac{\partial x}{\partial v} + \frac{\partial y}{\partial u}\frac{\partial y}{\partial v} + \frac{\partial z}{\partial u}\frac{\partial z}{\partial v} = \underline{r}'_u \cdot \underline{r}'_v,$$

and

$$G(u,v) = \left(\frac{\partial x}{\partial v}\right)^2 + \left(\frac{\partial y}{\partial v}\right)^2 + \left(\frac{\partial z}{\partial v}\right)^2 = |\underline{r}'_u|^2,$$

Assume that the equation of the geodesic curve in the parametric space is described by

$$v = v(u).$$

Then the geodesic curve is the solution of the variational problem

$$I(v) = \int_{u_0}^{u_1} \sqrt{E(u,v) + 2F(u,v)\frac{dv}{du} + G(u,v)\left(\frac{dv}{du}\right)^2}\, du$$

= extremum with boundary conditions

$$v(u_0) = v_0,$$

and

$$v(u_1) = v_1.$$

The corresponding Euler-Lagrange differential equation is

$$\frac{E_v + 2v' F_v + v'^2 G_v}{2\sqrt{E(u,v) + 2F(u,v)v' + G(u,v)v'^2}} - \frac{d}{du}\frac{F + Gv'}{\sqrt{E(u,v) + 2F(u,v)v' + G(u,v)v'^2}} = 0,$$

with the notation of

$$E_v = \frac{\partial E}{\partial v}, F_v = \frac{\partial F}{\partial v}, G_v = \frac{\partial G}{\partial v},$$

and

$$v' = \frac{dv}{du}.$$

The equation is rather difficult in general, and exploitation of special cases arising from the particular surface definitions is advised.

When the first fundamental quantities are only functions of the u parameter, the equation simplifies to

$$\frac{F + Gv'}{\sqrt{E(u,v) + 2F(u,v)v' + G(u,v)v'^2}} = c_1.$$

A further simplification is based on the practical case when the u and v parametric lines defining the surface are orthogonal. In this case

$$F = 0,$$

and the equation may easily be integrated as

$$v = c_1 \int \frac{\sqrt{E}}{\sqrt{G^2 - c_1^2 G}} du + c_2.$$

The integration constants may be resolved from the boundary conditions. When the first fundamental quantities are only functions of the v parameter, and the F = 0 assumption still holds, the equation becomes

$$\frac{Gv'^2}{\sqrt{E+Gv'^2}} - \sqrt{E+Gv'^2} = c_1.$$

Reordering and another integration bring

$$v = c_1 \int \frac{\sqrt{E^2 - c_1^2 E}}{\sqrt{G}}\,du + c_2.$$

1) C:/DATA-NovoVivo-124-2020/Books-124-20220/Important/ Projective Geometry - Volume 1 - 2007.djvu

Pag. 15(24) - CHAPTER I THEOREMS OF ALIGNMENT AND THE PRINCIPLE OF DUALITY 6. The assumptions of alignment. In the following treatment of projective geometry we have chosen the point and the line as unde- undefined elements. We consider a class (cf2, p. 2) the elements of which we call points, and certain undefined classes of points which we call lines. Here the words point and line are to be regarded as mere symbols devoid of all content except as implied in the as- assumptions (presently to be made) concerning them, and which may represent any elements for which the latter may he valid propositions. In other words, these elements are not to be considered as having properties in common with the points and lines of ordinary Euclidean geometry, except in so far as such properties are formal logical conse- consequences of explicitly stated assumptions. We shall in the future generally use the capital letters of the alphabet, as A, B, C, P, etc., as names for points, and the small let- letters, as a, b, c, I, etc., as names for lines. If A and B denote the same point, this will be expressed by the relation A = B; if they repre- represent distinct points, by the relation A =$ B. If A = B, it is sometimes said that A coincides with B, or that A is coincident with B. The same remarks apply to two lines, or indeed to any two elements of the same kind. All the relations used are defined in general logical terms, mainly by means of the relation of belonging to a class and the notion of one-to-one correspondence. In case a point is an element of one of the classes of points which we call lines, we shall express this relation by any one of the phrases: the point is on cr lies on or is a point of the line, or is united with the line; the line passes through or con- contains or is united with the point. We shall often find it convenient to use also the phrase the line is on the point to express this relation. Indeed, all the assumptions and theorems in this chapter will be stated consistently in this way. The reader will quickly become ac- accustomed to this " on " language, which is introduced with the purpose 15 16 THEOREMS OF ALIGNMENT AND DUALITY [Chap.i of exhibiting in its most elegant form one of the most far-reaching theorems of projective geometry (Theorem 11). Two lines which have a point in common are said to intersect in or to meet in that point, or to he on a common point. Also, if two distinct points lie on the same line, the line is said to join the points. Points which are on the same line are said to be collinear ; points which are not on the same line are said to be noncollinear. Lines which are on the same point (i.e. contain the same point) are said to be copunctal, or concurrent.[1] Concerning points and lines we now make the following assumpassumptions : The Assumptions of Alignment, A : A 1. If A and B are distinct points, there is at least one line on loth A and B. A 2. If A and B are distinct points, there is not more than one line on both A and B. A3. If A, B, C are points not all on the same line, and D and E (D ≠ E) are points such that B, C, D are on a line and C, A, E

Pag. 6(25) - Fig. 3

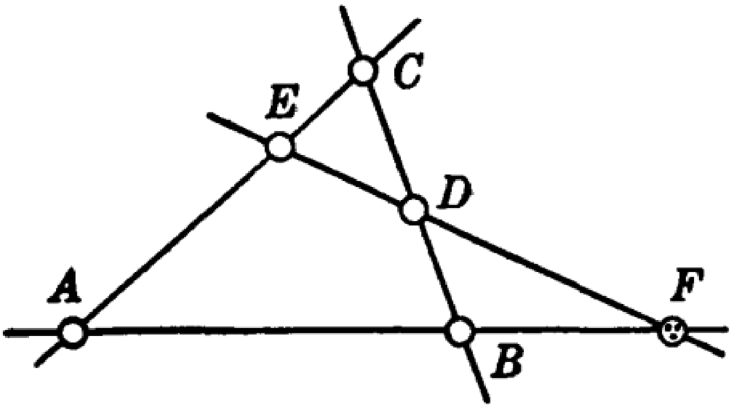

Figure 1.7: pg01.png

are on a line, there is a point F such that A, B, F are on a line and also D, E, F are on a line (fig. 3)[2]. It should be noted that this set of assumptions is satisfied by the triple system 1), p. 3, and also by the system of quadruples (2), p. 6, as well as by the points and lines of ordinary Euclidean geometry with the notion ‘points at infinity" (cf. paragrafo 3, p.8), and by The figures are to be regarded as a concrete representation of our science, in which the undefined "points" and "lines" of the science are represented by points and lines of ordinary Euclidean geometry (this requires the notion of ideal points; cf. x 3, p. 8). Their function is not merely to exhibit one of the many possible concrete representations, but also to help keep in mind the various rela- relations in question. In using them, however, great care must be exercised not to use any properties of such figures that are not formal logical consequences of the assumptions; in other words, care must be taken that all deductions are made formally from the assumptions and theorems previously derived from the assumptions. Obs.: Veja livro todo!!!

---

[1] The object of this paragraph is simply to define the terms in common use in terms of the general logical notion of belonging to a class. In later portions of this book we may omit the explicit definition of such common terms when such definition is obvious.

[2] The figures are to be regarded as a concrete representation of our science, in which the undefined "points" and "lines" of the science are represented by points and lines of ordinary Euclidean geometry (this requires the notion of ideal points; cf. x 3, p. 8). Their function is not merely to exhibit one of the many possible concrete representations, but also to help keep in mind the various rela- relations in question. In using them, however, great care must be exercised not to use any properties of such figures that are not formal logical consequences of the assumptions; in other words, care must be taken that all deductions are made formally from the assumptions and theorems previously derived from the assumptions.

Pag. 119 (132) - CHAPTER IV EUCLIDEAN PLANE GEOMETRY 55. Geometries of the Euclidean type. We come now to the extension of the definition of congruence which was promised in xx 39 and 46. This requires the consideration of groups which are not self-conjugate under the afnne group. Not being self-conjugate, these groups are not determined uniquely by the affine group, and hence our definitions will contain a further arbitrary element. Definition. Let I be an arbitrary but fixed involution on lm. This involution shall be called the absolute or orthogonal involution. The group of all projective collineations leaving I invariant shall be called a parabolic[3] metric group. The transformations of the group shall be called similarity transformations. Two figures conjugate under the group shall be said to be similar. The geometry corresponding to the group shall be called the parabolic metric geometry. The absolute involution is supposed to be fixed throughout the rest of the discussion, but of course there are as many parabolic metric groups as there are choices of I. We nevertheless speak of the para- parabolic metric group in order to emphasize the fact that we are fixing attention on one group. In case the plane in which we are working is a real plane and the absolute involution is without double points, the parabolic metric geometry is the Euclidean geometry. It is for this reason that we refer to the parabolic metric geometries as geometries of the Euclidean type. The investigations in the following sections are arranged in order of increasing specialization. First we consider a perfectly general involution, I, in a projective plane satisfying A, E, P, HQ. Then we consider a particular type of involution in an ordered plane, and finally limit the plane to be the real plane. When the plane and the involution are fully specialized, it is a theorem x(70) that the real plane is contained in a complex plane in which the absolute involution has double points. Thus the theorems on the general type of involution (where the possible existence of double points is taken into account) come to have a new application.

---

[3] The reason for the term "parabolic" in this connection is explained in a later chapter, where the elliptic and hyperbolic metric groups are defined.

56. Orthogonal lines

Definition. Two lines are said to be orthogonal or perpendicular to each other if and only if they meet lm in conjugate points of the absolute involution.

Pag. 120 (133) - Lemma. Let 0 and I[be two points not collinear with either double point of the absolute involution. There is one and only one conic, C^2, having 0 as center, passing through P1 and having the pairs of the absolute involution as pairs of conjugate points. Proof Let P2 be the harmonic conjugate of Py with respect to 0 and the point at infinity, PX1 of the line OPV Any conic containing P1 and having 0 as center must contain P2, by the definition of center. Let X be a variable point of L, and Y the conjugate of X in the absolute involution. Any of the triangles OXY must be self-polar to any conic satisfying the required conditions. But if P is the point of intersection of the lines PXX and P2Y, and Q the point of intersection of PXX and OY, ...

Pag. 104 (116) - 7.3 Curvilinear Coordinates Curvilinear coordinates were first systematically developed by the physicist, mathematician, and engineer Gabriel Lame (1795{1870) in his treatise Lecons sur les coordonnes curvilignes et leurs diverses applications of 1859. He used transformations to curvilinear coordinates in solving certain problems of heat conduction and elasticity. This proved to be a powerful idea: many problems in geometry, partial differential equations, multiple integrals, etc., become much simpler when cast in coordinate systems that reflect their symmetries.
Pag.95 (107) - 7.2.2 Barycentric Coordinates on Triangles

Pag. 123 (135) - 7.4.6 Geometrical Figures and their Shadows A deeper insight into projective transformations of the plane can be obtained from an elegant geometrical model that intuitively explains how parallel lines may be transformed into intersecting lines, or vice{versa. Consider a three{ dimensional Euclidean space in which two non{parallel planes | an \object" plane O and \image" plane I | are chosen together with a point \light source" or center of projection c that does not lie on O or I (see Fig. 7.10).

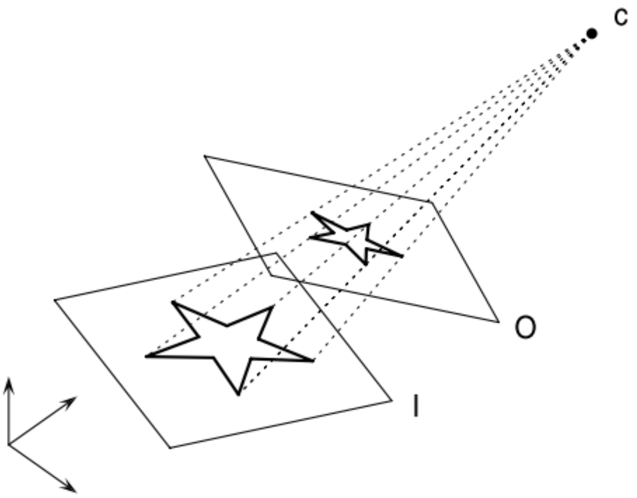

Figure 1.19: ph01.png - Visualization of a plane projective transformation by means of a central projection of an object plane O to an image plane I from a center of projection c.

We imagine the object plane O to be translucent, with a geometrical figure A drawn on it in black ink. The point light source at c then casts a shadow A' of A onto the image plane I, such that the finite points of A and A' exhibit an (almost) one{to{one correspondence. The mapping of A to A' is called a central projection, and we are obliged to say \almost" for the following reasons.

Consider the plane I // through the center of projection c that is parallel to the image plane I. This plane cuts the object plane O in a certain (affine) line l O . Clearly, no point of the line l O on O casts a finite shadow point on I, since rays from c to each point of this line are all parallel to I. Thus, we say that the affine line l O on O is mapped[4] to the line at infinity on I. Conversely, consider the plane O // through c that is parallel to the object plane. It cuts the image plane in a certain (affine) line l I , and we ask: what points of the object plane are mapped to this line l I on the image plane? If we consider a point p on I that approaches l I , the location at which the ray from c to p pierces the object plane recedes indefinitely along that plane, since this ray approaches parallelism with O. Thus, we say that the line l I on I is the \shadow" of the line at infinity on O. Figure 7.11 illustrates these concepts. From the above reasoning, it should be evident that almost all intersecting lines on O are mapped to intersecting lines on I. However, when two lines on O happen to intersect at a point on l O , they will be mapped to parallel lines on I. Conversely, parallel lines on O are mapped to intersecting lines on I | their intersections lie on the line l I.

---

[4] For obvious reasons, the line lO is often called the \vanishing line" on O.

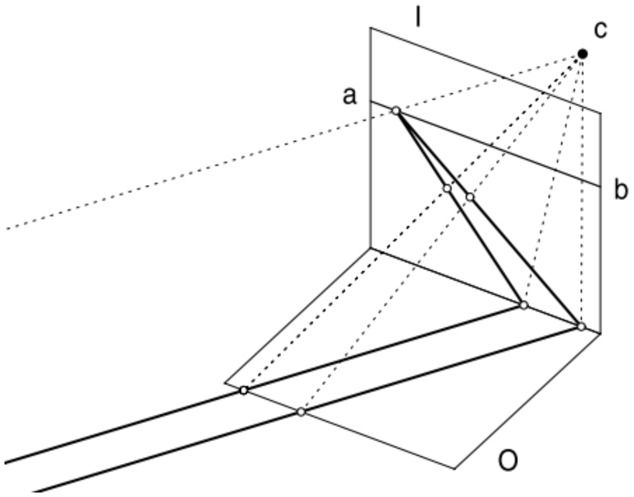

Figure 1.20: ph02.png - Parallel lines on the object plane O, extended indefinitely, meet at a point on the line ab when projected from the center c onto the image plane I. The line ab, defined by the intersection of I with a plane O// through c that is parallel to O, is the image on I of the \line at infinity" on O.

A central projection of an object plane O from a finite center c onto a non{parallel image plane I defines the most general form of two{dimensional projective transformation. When c recedes to infinity, the rays connecting it to points of O become parallel, and we then have a parallel projection | which corresponds to an affine transformation of the plane, since points at infinity on O are then mapped[5] to points at infinity on I. Finally, the case in which the image plane I and object plane O are parallel defines a shape–preserving affine transformation, namely, a simple scaling of the plane. The model described above offers an intuitive geometrical understanding of the projective transformations that were introduced in purely algebraic terms in § 7.4.4. It should be apparent that, in general, such transformations preserve the incidence relations (intersections, tangencies, etc.) in a geometrical figure — but they alter its size and shape. This can be seen, for example, in the case of the conics in Fig. 7.12, which imparts an intuitive interpretation to the statement that “the parabola is tangent to the line at infinity.”

---

[5] Unlike general projective transformations, this implies that parallel lines remain parallel under affine transformations.

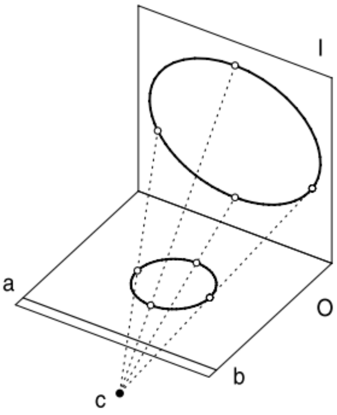

Figure 1.21: ph03a.png

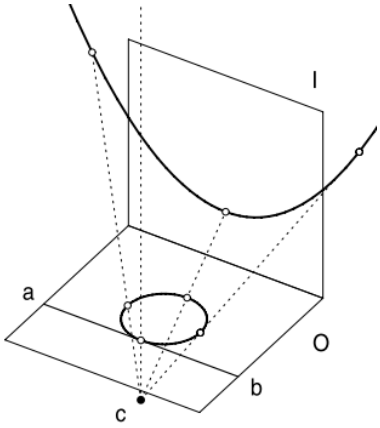

Figure 1.22: ph03b.png

Figure 1.23: Projective image of a circle. The “vanishing line” ab is the intersection of the object plane O with a plane through c that is parallel to the image plane I. The circle is mapped into an ellipse or a parabola according to whether ab lies outside the circle or touches it (not shown is the case where the vanishing line ab cuts the circle into two segments, which are mapped into the two branches of a hyperbola).

The equivalence of higher–order curves under projective transformations was perhaps first recognized by Sir Isaac Newton. In his *Enumeratio linearum tertii ordinis*, concerned with the classification of cubic curves (see also § 9.2) he includes [432] the following paragraphs on *genesis curvarum per umbras* — i.e., the generation of curves by shadows: “If the shadows of curves caused by a luminous point, be projected on an infinite plane, the shadows of conic sections will always be conic sections; those of curves of the second genus will always be of the second genus; those of the third genus will always be of the third genus; and so on ad infinitum . . . And in the same manner as the circle, projecting its shadow, generates all the conic sections, so the five divergent parabolas, by their shadows, generate all other curves of the second genus. And thus some of the more simple curves of other genera might be found, which would form all curves of the same genus by the projection of their shadows on a plane." In Newton's terminology[6] (borrowed from Descartes) conics are curves of the \first genus" while cubics are of the \second genus." His \divergent parabolas" are cubics described by an equation of the form

$$y^2 = ax^3 + bx^2 + cx + d \tag{1.2}$$

,

and he identifies five different types according to the root structure of the cubic on the right (namely: three simple real roots; a double root and a simple root either greater or smaller than it; one triple root; and one real root with two complex conjugate roots). Thus, Newton is claiming that any cubic may be regarded as the projective image of a curve of the above type. The desire of Renaissance artists for greater \realism" in their paintings was the cultural pretext for the development of projective geometry. This led to a deeper grasp of the \perspective" projection of a three{dimensional scene onto a plane (the canvas) from a specified point (eye position), as seen in Fig. 7.13. Paolo Uccello (1379{1435) of Florence was perhaps the first to fully master the method | his perspective rendering of a chalice appears on the cover of the journal Computer Aided Geometric Design.

Pag. 24(43) - 1.11 Gaussian Derivative Operator (DroG) In the preceding paragraphs, we have already highlighted the problem of differen- tiation which introduces a attenuation of the signal noise ratio. With the smoothing operators described (see Sect.9.12.6 Vol. I) based on Gaussian filtering, the noise is attenuated. The DroG operator has the function of combining the noise reduction activities in the image and then executing the derivative with respect to the coordinate axes for edge detection. Remembering the associative property of the convolution operator, the gradient operator g DroG, based on the Gaussian derivative, is obtained by first applying the

Gaussian smoothing operator hG and then differentiating with the hD filter. The DroG operator in the horizontal component (indicated with r) is thus obtained:

3) C:/DATA-NovoVivo-125-2020/Books-125-2020/Handbook of Image Processing and Computer Vision-3-Volumes/Handbook of Image Processing and Computer Vision-Volume 3-From Pattern to Object 2020.pdf

Pag. 561(580) - 6.5.5 BS Method Based on Gaussian Mixture Model (GMM) So far methods have been considered where the background update model is based on the recent pixel history. Only with the Gaussian moving average method was the background modeled with the statistical parameters of average and variance of each pixel of the last images with the assumption of a unimodal Gaussian distribution. No spatial correlation was considered with the pixels in the vicinity of the one being processed. To handle more complex application contexts where the background scene includes structures with small movements not to be regarded as moving objects (for example, small leaf movements, trees, temporarily generated shadows, . . .) different methods have been proposed based on models of background with multimodal Gaussian distribution [31].

1.9 Energia escura

Date: 20200327

1) Energia escura: mapa da pistas sobre o quee, mas leva a novos enigmas indexEnergia escura: mapa da pistas sobre o quee, mas leva a novos enigmas

Figure 1.27: ee01.jpg - Energia Escura

Uma nova pesquisa trouxe mais informações sobre a misteriosa energia que preenche o espaço, mas alguns de seus dados entram em choque com teorias atualmente aceitas.

A energia escura é um dos maiores mistérios da ciência atualmente. Sabemos muito pouco sobre ela, afora ser invisível, preencher todo o universo e afastar as galáxias. Ela está fazendo nosso cosmos se expandir a uma taxa acelerada. Mas o que é ela? Uma das explicações mais simples é que é uma \constante cosmológica" { resultado da energia do próprio espaço vazio {, uma ideia introduzida por Albert Einstein.

Muitos físicos não estão satisfeitos com essa explicação, no entanto. Eles querem uma descrição mais fundamental de sua natureza. É algum novo tipo de campo de energia ou fluido exótico? Ou é um sinal de que as equações da gravidade de Einstein são de alguma forma incompletas? Além do mais, não entendemos realmente a atual taxa de expansão do universo.

Agora, nosso projeto { o Levantamento Espectroscópico de Oscilações Bariônicas Estendidas (eBOSS, na sigla em inglês) { apresentou algumas respostas. Nosso trabalho foi lançado como uma série de 23 publicações, algumas das quais ainda estão sendo revisadas por pares, descrevendo o maior mapa cosmológico tridimensional já criado.

Máquina do tempo

Atualmente, a única maneira de sentir a presença de energia escura é com observações do universo distante. Quanto mais distantes estão as galáxias, mais jovens elas aparecem para nós. Isso ocorre porque a luz que emitem levou milhões ou bilhões de anos para alcançar nossos telescópios. Graças a esse tipo de máquina do tempo, podemos medir diferentes distâncias no espaço em diferentes momentos cósmicos, ajudando-nos a descobrir a rapidez com que o universo está se expandindo.

Usando o telescópio Sloan Digital Sky Survey (SDSS), medimos mais de 2 milhões de galáxias e quasares { objetos extremamente brilhantes e distantes alimentados por buracos negros { nas últimas duas décadas. Esse novo mapa cobre cerca de 11 bilhões de anos de história cósmica que era essencialmente inexplorada, ensinando-nos sobre energia escura como nunca antes.

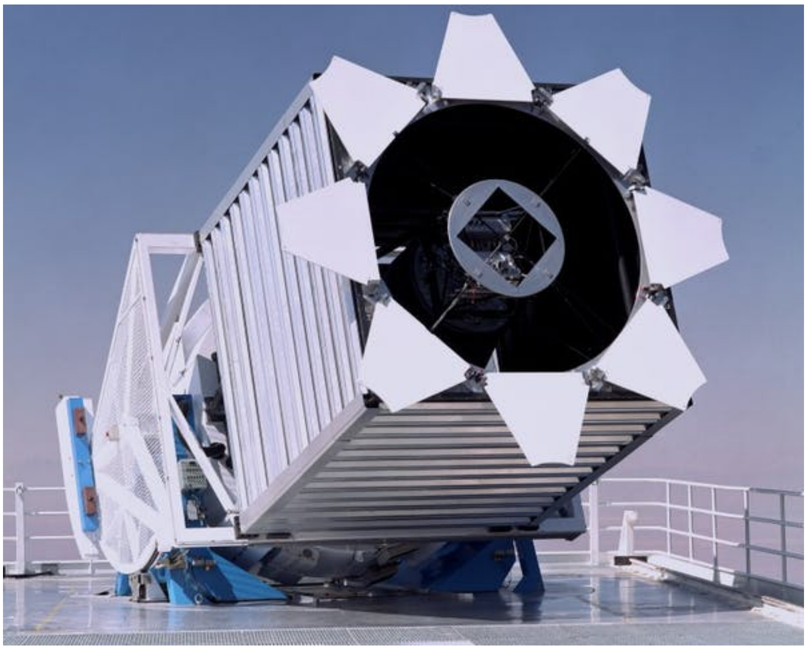

Figure 1.28: ee02.jpg - Energia Escura - Telescópio

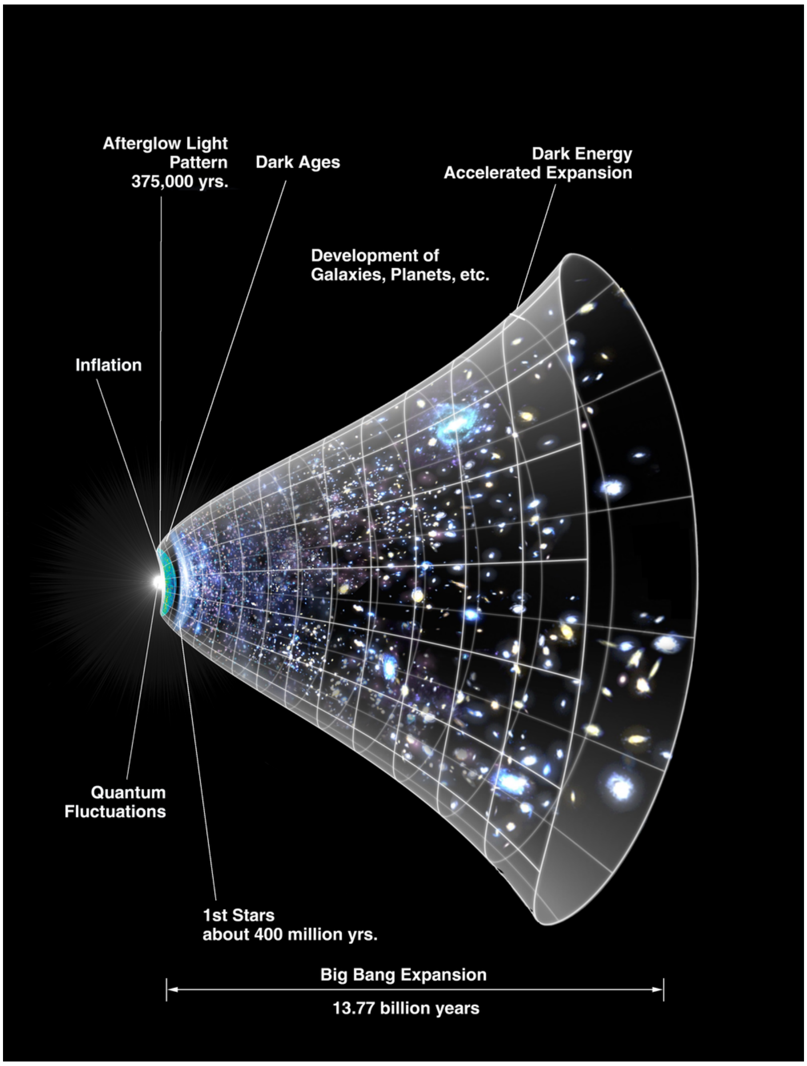
Nossos resultados mostram que cerca de 69% da energia do nosso universo e energia escura. Eles também demonstram, mais uma vez, que a forma mais simples de energia escura de Einstein { a constante cosmológica { concorda mais com nossas observações.

Quando se combina as informações do nosso mapa com outras investigações cosmológicas, como o fundo cósmico de micro-ondas { a luz remanescente do Big Bang {, todos parecem preferir a constante cosmológica a explicações mais exóticas da energia escura. Expansão cósmica em disputa

Os resultados também fornecem uma visão melhor de algumas controvérsias recentes sobre a taxa de expansão do universo atual e sobre a geometria do espaço.

A combinação de nossas observações com estudos do universo em sua infância revela rachaduras em nossa descrição de sua evolução. Em particular, nossa medição da taxa atual de expansão do universo é cerca de 10% menor que o valor encontrado usando métodos diretos para medir distâncias a galáxias próximas. Ambos os métodos afirmam que o resultado é correto e muito preciso. Portanto, a diferença não pode ser simplesmente um acaso estatístico.



Afterglow Light Pattern 375,000 yrs.
Dark Ages
Dark Energy Accelerated Expansion
Development of Galaxies, Planets, etc.
Inflation
Quantum Fluctuations
1st Stars about 400 million yrs.
Big Bang Expansion
13.77 billion years

Figure 1.29: ee03.png - Energia Escura - Telescópio

A precisão do eBOSS aumenta essa crise. Não há uma explicação amplamente aceita para essa discrepância. Pode ser que alguém tenha cometido um erro sutil em um desses estudos. Ou pode ser um sinal de que precisamos de uma nova física. Uma possibilidade empolgante é que uma forma de matéria anteriormente desconhecida do universo primitivo tenha deixado um rastro em nossa história. Isso é conhecido como \energia escura precoce", que se pensa estar presente quando o universo era jovem, o que poderia ter modificado a taxa de expansão cósmica. Espaço plano

Estudos recentes do fundo cósmico de micro-ondas sugeriram que a geometria do espaço pode ser curvada em vez de simplesmente plana, o que é consistente com a teoria mais aceita do Big Bang. Mas nosso estudo concluiu que o espaço é realmente plano.IMPORTANT

Mesmo após esses importantes avanços, os cosmólogos de todo o mundo permanecerão intrigados com a aparente simplicidade da energia escura, a planura do espaço e os valores controversos da taxa de expansão atual. Existe apenas um caminho a seguir na busca de respostas { a criação de mapas maiores e mais detalhados do universo. Vários projetos têm como objetivo medir pelo menos dez vezes mais galáxias do que nós.

Se os mapas do eBOSS foram os primeiros a explorar uma lacuna anteriormente perdida de 11 bilhões de anos de nossa história, a nova geração de telescópios criará uma versão de alta resolução no mesmo período de tempo. É emocionante pensar no fato de que futuras pesquisas poderão resolver os mistérios restantes sobre a expansão do universo na próxima década. Mas seria igualmente emocionante se elas revelassem mais surpresas.

Julian Bautistaé pesquisador da Universidade de Portsmouth (Reino Unido).

c) https://theconversation.com/dark-energy-map-gives-clue-about-what-it-is-but-deepens-dispute-about-the-cosmic-expansion-rate-143200

Dark energy: map gives clue about what it is { but deepens dispute about the cosmic expansion rate

Dark energy is one of the greatest mysteries in science today. We know very little about it, other than it is invisible, it fills the whole universe, and it pushes galaxies away from each other. This is making our cosmos expand at an accelerated rate. But what is it? One of the simplest explanations is that it is a \cosmological constant" { a result of the energy of empty space itself { an idea introduced by Albert Einstein.

Many physicists aren't satisfied with this explanation, though. They want a more fundamental description of its nature. Is it some new type of energy field or exotic fluid? Or is it a sign that Einstein's equations of gravity are somehow incomplete? What's more, we don't really understand the universe's current rate of expansion.

Now our project - the extended Baryon Oscillation Spectroscopic Survey (eBOSS) - has come up with some answers. Our work has been released as a series of 23 publications, some of which are still being peer reviewed, describing the largest three-dimensional cosmological map ever created.

Currently, the only way we can feel the presence of dark energy is with observations of the distant universe. The farther galaxies are, the younger they appear to us. That's because the light they emit took millions or even billions of years to reach our telescopes. Thanks to this sort of time-machine, we can measure different distances in space at different cosmic times, helping us work out how quickly the universe is expanding.

Using the Sloan Digital Sky Survey telescope, we measured more than two million galaxies and quasars { extremely bright and distant objects that are powered by black holes { over the last two decades. This new map covers around 11 billion years of cosmic history that was essentially unexplored, teaching us about dark energy like never before.

Our results show that about 69% of our universe's energy is dark energy. They also demonstrate, once again, that Einstein's simplest form of dark energy - the cosmological constant - agrees the most with our observations.

When combining the information from our map with other cosmological probes, such as the cosmic microwave background { the light left over from the big bang { they all seem to prefer the cosmological constant over more exotic explanations of dark energy. Cosmic expansion in dispute

The results also provide a better insight into some recent controversies about the expansion rate of the universe today and about the geometry of space.

Combining our observations with studies of the universe in its infancy reveals cracks in our description of its evolution. In particular, our measurement of the current rate of expansion of the universe is about 10% lower than the value found using direct methods of measuring distances to nearby galaxies. Both these methods claim their result is correct and very precise, so their difference cannot simply be a statistical fluke.

The precision of eBOSS enhances this crisis. There is no broadly accepted explanation for this discrepancy. It may be that someone made a subtle mistake in one of these studies. Or it may be a sign that we need new physics. One exciting possibility is that a previously unknown form of matter from the early universe might have left a trace on our history. This is known as \early dark energy", thought to be present when the universe was young, which could have modified the cosmic expansion rate.

Recent studies of the cosmic microwave background suggested that the geometry of space may be curved instead of being simply flat { which is consistent with the most accepted theory of the big bang. But our study concluded that space is indeed flat.

Even after these important advances, cosmologists over the world will remain puzzled by the apparent simplicity of dark energy, the flatness of space and the controversial values of the expansion rate today. There is only one way forward in the quest for answers { making larger and more detailed maps of the universe. Several projects are aiming to measure at least ten times more galaxies than we did.

If the maps from eBOSS were the first to explore a previously missing gap of 11 billion years of our history, the new generation of telescopes will make a high-resolution version of the same period of time. It is exciting to think about the fact that future surveys may be able to resolve the remaining mysteries about the universe's expansion in the next decade or so. But it would be equally exciting if they revealed more surprises.

2) Matéria escura: o enigma se aprofunda indexMatéria escura: o enigma se aprofunda

Análise de 20 anos de dados mostra que enigmáticos sinais eletromagnéticos de galáxias próximas { a maior possibilidade de se identificar a matéria escura { não estão associados a ela.

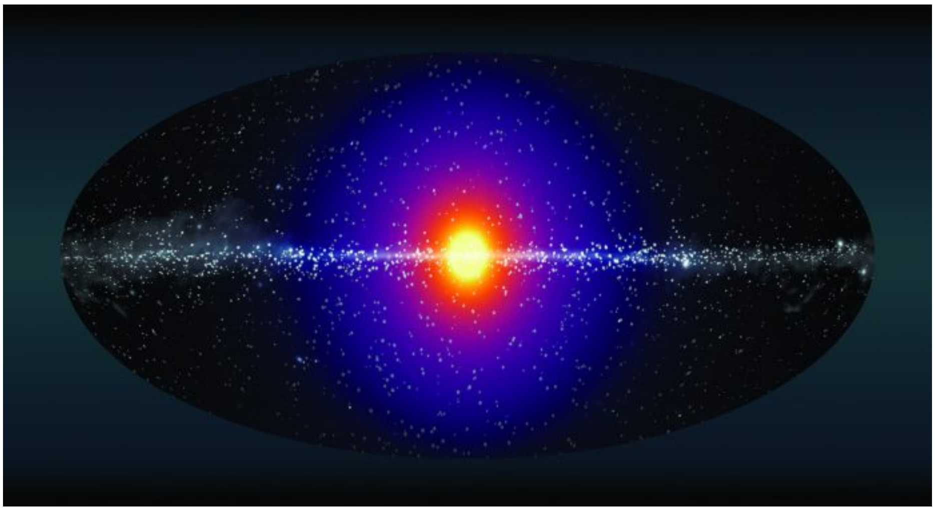

Figure 1.30: ee04.jpg - Matéria Escura - A matéria escura em decaimento deveria produzir um halo brilhante e esférico de emissão de raios X ao redor do centro da Via Láctea, passível de ser detectado quando se olha para regiões em branco da galáxia. Crédito: concepção artística de C. Dessert, N. L. Rodd, B. R. Safdi, Z. Rostomian (Berkeley Lab), com base em dados do telescópio espacial Fermi de raios gama

Nada menos do que 85% do universo é composto de matéria escura, mas não sabemos exatamente o que ela é.

Um novo estudo americano, com pesquisadores da Universidade de Michigan, do Lawrence Berkeley National Laboratory (Berkeley Lab) e da Universidade da Califórnia em Berkeley, descartou que a matéria escura seja responsável por misteriosos sinais eletromagnéticos anteriormente observados de galáxias próximas. Antes desse trabalho, publicado na revista “Science”, havia grandes esperanças de que tais sinais dariam aos físicos evidências concretas para ajudar a identificar a matéria escura.

A matéria escura não pode ser observada diretamente porque não absorve, reflete ou emite luz, mas os pesquisadores sabem que ela existe devido ao efeito que tem sobre a matéria visível. Precisamos da matéria escura para explicar as forças gravitacionais que mantêm as galáxias unidas, por exemplo.

Os físicos sugeriram que a matéria escura é um primo intimamente relacionado do neutrino, chamado neutrino estéril. Os neutrinos – partículas subatômicas sem carga e que raramente interagem com a matéria – são liberados durante as reações nucleares que ocorrem no interior do Sol. Eles têm uma pequena quantidade de massa, mas essa massa não é explicada pelo Modelo Padrão de Física de Partículas. Os físicos sugerem que o neutrino estéril, uma partícula hipotética, poderia explicar essa massa e também ser matéria escura.

Instabilidade

Os pesquisadores devem ser capazes de detectar o neutrino estéril porque ele é instável, diz Ben Safdi, professor assistente de física da Universidade de Michigan e coautor do estudo. Decai em neutrinos comuns e radiação eletromagnética. Para detectar a matéria escura, os físicos examinam galáxias em busca dessa radiação eletromagnética na forma de emissão de raios X.

Em 2014, um estudo descobriu excesso de emissão de raios X de galáxias próximas e aglomerados de galáxias. A emissão parece ser consistente com a que surgiria da decomposição da matéria escura estéril de neutrinos, disse Safdi.

Agora, uma metanálise de dados brutos de objetos na Via Láctea obtidos pelo telescópio espacial de raios X XMM-Newton, da Agência Espacial Europeia (ESA), durante um período de 20 anos não encontrou evidências de que o neutrino estéril seja o que compreende a matéria escura.

“Esse trabalho de 2014 e seu acompanhamento confirmaram que o sinal gerou um interesse significativo nas comunidades de astrofísica e física de partículas devido à possibilidade de saber, pela primeira vez, exatamente o que é a matéria escura em nível microscópico”, disse Safdi. “Nossa descoberta não significa que a matéria escura não seja um neutrino estéril, mas significa que – ao contrário do que foi afirmado em 2014 – não há evidências experimentais ate o momento que apontem para sua existência." Linha estudada

Os telescopios de raios X baseados no espaco, como o XMM-Newton, apontam para ambientes ricos em materia escura a fim de procurar essa fraca radiacao eletromagnetica na forma de sinais de raios X. A descoberta de 2014 denominou a emissao de raios X de \linha de 3,5 keV" (keV significa quilo eletron-volt) por causa de onde o sinal apareceu nos detectores de raios X.

Os pesquisadores estudaram essa linha na Via Lactea usando 20 anos de dados de arquivo obtidos pelo telescopio espacial de raios X XMM-Newton. Os fsicos sabem que a materia escura se acumula em torno das galaxias. Portanto, quando trabalhos anteriores analisaram galaxias proximas e aglomerados de galaxias, cada uma dessas imagens teria capturado alguma coluna do halo da materia escura da Via Lactea.

A equipe usou essas imagens para observar a parte \mais sombria" da Via Lactea. Isso melhorou significativamente a sensibilidade de analises anteriores a procura de materia escura esteril de neutrinos, disse Safdi.

\Para onde quer que olhemos, deve haver algum fluxo de materia escura do halo da Via Lactea" por causa da localizacao do Sistema Solar na galaxia, disse Nicholas Rodd, do Berkeley Lab. \Exploramos o fato de que vivemos em um halo de materia escura" no estudo, ele acrescentou. Sem evidências

Christopher Dessert, aluno de doutorado da Universidade de Michigan e coautor do estudo, disse que os aglomerados de galaxias onde a linha de 3,5 keV foi observada tambem têm grandes sinais de fundo, que servem como rudo nas observacoes e dificultariam a identificacao de sinais especficos que podem estar associados a materia escura.

\A razao pela qual estamos olhando atraves do halo de materia escura galactica da Via Lactea e que o fundo e muito menor", disse Dessert.

Por exemplo, o XMM-Newton capturou imagens de objetos isolados, como estrelas, na Via Lactea. Os pesquisadores capturaram essas imagens e mascararam os objetos de interesse original, deixando ambientes escuros e puros para procurar o brilho da decomposicao da materia escura. A combinacao de 20 anos de tais observacoes permitiu sondar a materia escura de neutrino esteril a nveis sem precedentes.

Se os neutrinos estereis eram materia escura, e se o seu decaimento levasse a uma emissao da linha de 3,5 keV, Safdi e seus colegas pesquisadores deveriam ter observado essa linha em suas analises. Mas eles nao encontraram evidências de materia escura esteril de neutrinos.

\Embora este trabalho, infelizmente, jogue agua fria no que parecia ser a primeira evidência da natureza microscopica da materia escura, ele abre uma nova abordagem para procurar materia escura que poderia levar a uma

descoberta em futuro proximo", disse Safdi.

3) Dark energy: new experiment may solve one of the universe's greatest mysteries. indexDark energy: new experiment may solve one of the universe's greatest mysteries Date: 20191028

As an astronomer, there is no better feeling than achieving \first light" with a new instrument or telescope. It is the culmination of years of preparations and construction of new hardware, which for the first time collects light particles from an astronomical object. This is usually followed by a sigh of relief and then the excitement of all the new science that is now possible.

On October 22, the Dark Energy Spectroscopic Instrument (DESI) on the Mayall Telescope in Arizona, US, achieved first light. This is a huge leap in our ability to measure galaxy distances { enabling a new era of mapping the structures in the universe. As its name indicates, it may also be key to solving one of the biggest questions in physics: what is the mysterious force dubbed \dark energy" that makes up the 70% of the universe?

The cosmos is clumpy. Galaxies live together in groups of a few to tens of galaxies. There are also clusters of a few hundreds to thousands of galaxies and superclusters that contain many such clusters.

This hierarchy of the universe has been known from the first maps of the universe, which looked like a \stickman" in graphs by the pioneering Centre for Astrophysics (CfA) Redshift Survey. These striking images were the first glimpse of large-scale structures in the universe, some spanning hundreds of millions of light years across.

The CfA survey was laboriously constructed one galaxy at a time. This involved measuring the spectrum of the galaxy light { a splitting of the light by wavelength, or colour { and identifying the fingerprints of certain chemical elements (mostly hydrogen, nitrogen and oxygen).

These chemical signatures are systematically shifted to longer redder wavelengths due to the expansion of the universe. This \red shift" was first detected by the astronomer Vesto Slipher and gave rise to the now famous Hubble's Law { the observation that more distant galaxies appear to be moving away at a faster rate. This means that galaxies that are close by appear to be moving away relatively slowly by comparison { they are less redshifted than galaxies far away. Therefore, measuring the redshift of a galaxy is a way to measure its distance.

Crucially, the exact relationship between redshift and distance depends on the expansion history of the Universe which can be calculated theoretically using our theory of gravity and our assumptions of the matter and energy density of the universe.

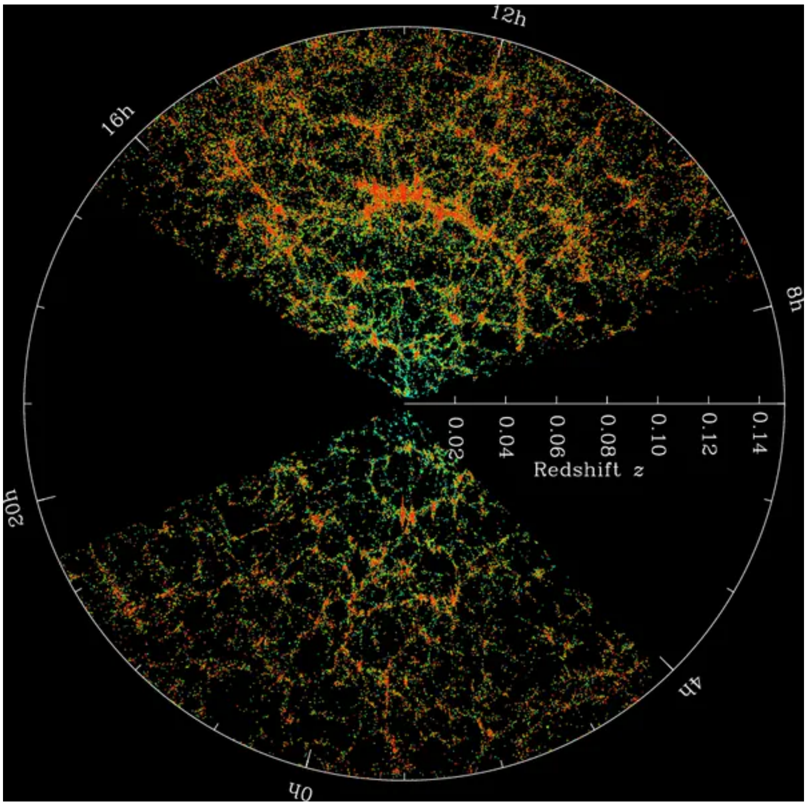

Figure 1.31: ee05.png - Dark Energy - SDSS map

All these assumptions were ultimately tested at the turn of the century with the combination of new observations of the universe, including new 3D maps from larger redshift surveys. In particular, the Sloan Digital Sky Survey (SDSS) was the first dedicated redshift survey telescope to measure over a million galaxy redshifts, mapping the large scale structure in the universe to unprecedented detail.

The SDSS maps included hundreds of superclusters and filaments and helped make an unexpected discovery { dark energy. They showed that the matter density of the universe was much less than expected from the Cosmic Microwave Background, which is the light left over from the Big Bang. That meant there must be an unknown substance, dubbed dark energy, driving an accelerated expansion of the Universe and become increasingly devoid of matter. The puzzle

The combination of all these observations heralded a new era of cosmological understanding with a universe consisting of 30% matter and 70% dark energy. But despite the fact that most physicists have now accepted that there is such a thing as dark energy, we still do not know its exact form.

There are several possibilities though. Many researchers believe that the energy of the vacuum simply has some particular value, dubbed a \cosmological constant". Other options include the possibility that Einstein's hugely successful theory of gravity is incomplete when applied on the huge scale of the entire universe.

New instruments like DESI will help take the next step in resolving the mystery. It will measure tens of millions of galaxy redshifts, spanning a huge volume of the universe up to ten billion light years from Earth. Such an amazing, detailed map should be able to answer a few key questions about dark energy and the creation of the large scale structures in the universe.

For example, it should be able to tell us if dark energy is just a cosmological constant. To do this it will measure the ratio of pressure that dark energy puts on the universe to the energy per unit volume. If dark energy is a cosmological constant, this ratio should be constant in both cosmic time and location. For other explanations, however, this ratio would vary. Any indication that it is not a constant would be revolutionary and spark intense theoretical work.

DESI should also be able to constrain, and even kill, many theories of modified gravity, possibly providing an emphatic confirmation of Einstein's Theory of General Relativity on the largest scales. Or the opposite { and again that would spark a revolution in theoretical physics.

Another important theory that will be tested with DESI is Inflation, which predicts that tiny random quantum fluctuations of energy density in the primordial universe were exponentially expanded during a short period of intense growth to become the seeds of the large scale structures we see today.

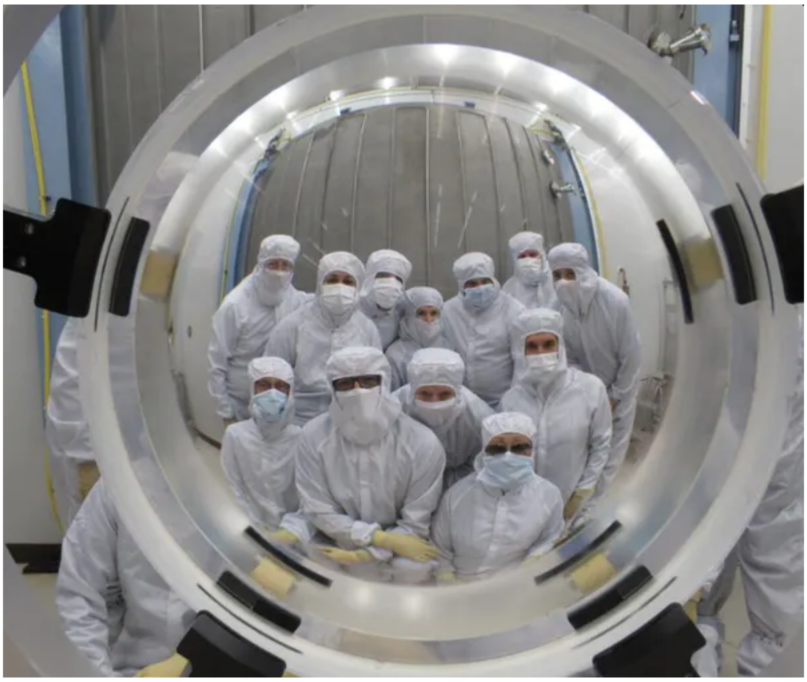

Figure 1.32: ee06.png - A team at a vendor in Santa Rosa Calif poses behind a DESI lens. VIAVI Solutions

DESI is only one of several next generation dark energy missions and experiments coming in the next decade, so there's certainly reason to be optimistic that we could soon solve the mystery of dark energy. New satellite missions like Euclid, and massive ground based observatories like the Large Synoptic Survey Telescope, will also offer insights.

There will also be other redshift instruments like DESI including 4MOST at the European Southern Observatory. Together, these will provide hundreds of millions of redshifts across the whole sky leading to an unimaginable map of our cosmos.

It seems a long time ago now when I wrote my PhD thesis based on just 700 galaxy redshifts. It really goes to show it's an exciting time to be an astronomer.

4) How fast is the universe really expanding? New measurements help tackle the mystery indexHow fast is the universe really expanding? New measurements help tackle the mystery September 12, 2019 2.01pm EDT

Advances in astronomical observation over the past century have allowed scientists to construct a remarkably successful model of how the cosmos works. It makes sense { the better we can measure something, the more we learn. But when it comes to the question of how fast our universe is expanding, some new cosmological measurements are making us ever more confused.

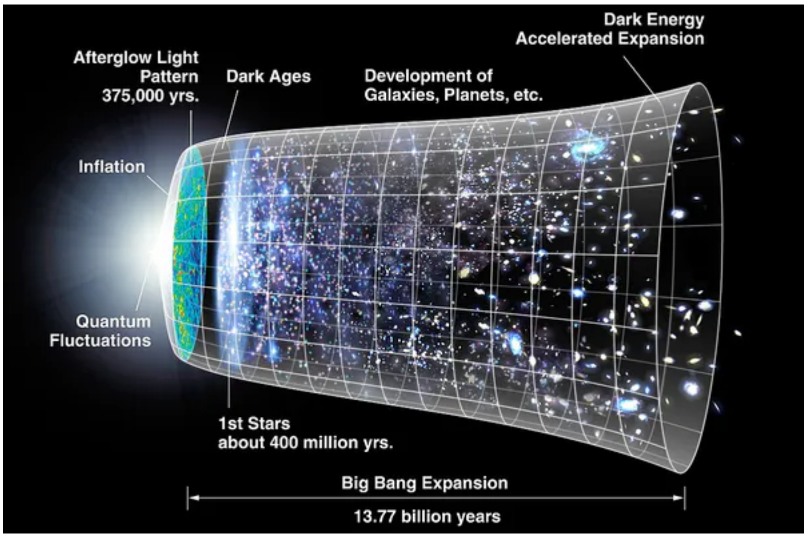
Since the 1920s we've known that the universe is expanding { the more distant a galaxy is, the faster it is moving away from us. In fact, in the 1990s, the rate of expansion was found to be accelerating. The current expansion rate is described by something called \Hubble's Constant" { a fundamental cosmological parameter.

Until recently, it seemed we were converging on an accepted value for Hubble's Constant. But a mysterious discrepancy has emerged between values measured using different techniques. Now a new study, published in Science, presents a method that may help to solve the mystery. The problem with precision

Hubble's Constant can be estimated by combining measurements of the distances to other galaxies with the speed they are moving away from us. By the turn of the century, scientists agreed that the value was about 70 kilometres per second per megaparsec { one megaparsec is just over 3m light years. But in the last few years, new measurements have shown that this might not be a final answer.

If we estimate Hubble's Constant using observations of the local, present-day universe, we get a value of 73. But we can also use observations of the afterglow of the Big Bang { the \cosmic microwave background" { to estimate Hubble's Constant. But this \early" universe measurement gives a lower value of around 67.

Worryingly, both of the measurements are reported to be precise enough that there must be some sort of problem. Astronomers euphemistically refer to this as \tension" in the exact value of Hubble's Constant.



Dark Energy
Accelerated Expansion
Afterglow Light
Pattern
375,000 yrs.
Dark Ages
Development of
Galaxies, Planets, etc.
Inflation
Quantum
Fluctuations
1st Stars
about 400 million yrs.
Big Bang Expansion
13.77 billion years

Figure 1.33: ee07.png - Universe's expansion. NASA/WMAP

If you're the worrying kind, then the tension points to some unknown systematic problem with one or both of the measurements. If you're the excitable kind, then the discrepancy might be a clue about some new physics that we didn't know about before. Although it has been very successful so far, perhaps our cosmological model is wrong, or at least incomplete. Distant versus local

To get to the bottom of the discrepancy, we need a better linking of the distance scale between the very local and very distant universe.

The new paper presents a neat approach to this challenge. Many estimates of the expansion rate rely on the accurate measurement of distances to objects. But this is really hard to do: we can't just run a tape measure across the universe.

One common approach is to use \Type 1a" supernovas (exploding stars). These are incredibly bright, so we can see them at great distance. As we know how luminous they should be, we can calculate their distance by comparing their apparent brightness with their known luminosity.

To derive Hubble's Constant from the supernova observations, they must be calibrated against an absolute distance scale because there is still a rather large uncertainty in their total brightness. Currently, these \anchors" are very nearby (and so very accurate) distance markers, such as Cepheid Variable stars, which brighten and dim periodically.

If we had absolute distance anchors further out in the cosmos, then the supernova distances could be calibrated more accurately over a wider cosmic range. Far-flung anchors

The new work has dropped a couple of new anchors by exploiting a phenomenon called gravitational lensing. By looking at how light from a background source (like a galaxy) bends due to the gravity of a massive object in front of it, we can work out the properties of that foreground object.

NASA and ESA
STScI-PRC15-08a

Figure 1.34: ee08.png - A large cluster galaxy (centre of the box) has split the light from an exploding background supernova into four yellow images/dots. NASA/HUbble

The team has studied two galaxies that are lensing the light from two other background galaxies. The distortion is so strong that multiple images of each background galaxy are projected around the foreground deflectors (such as in the image above). The components of light making up each of those images will have travelled slightly different distances on their journey to Earth as the light bends around the foreground deflector. This causes a delay in the arrival time of light across the lensed image.

If the background source has a fairly constant brightness, we don't notice that time delay. But when the background source itself varies in brightness, we can measure the difference in light arrival time. This work does exactly that.

The time delay across the lensed image is related to the mass of the foreground galaxy deflecting the light, and its physical size. So when we combine the measured time delay with the mass of the deflecting galaxy (which we know) we get an accurate measure of its physical size.

Like a penny held at arms length, we can then compare the apparent size of the galaxy to the physical size to determine the distance, because an object of fixed size will appear smaller when it is far away. The authors present absolute distances of 810 and 1230 megaparsecs for the two deflecting galaxies, with about a 10-20% margin of error.

Treating these measurements as absolute distance anchors, the authors go on to reanalyse the distance calibration of 740 supernovas from a well-established data set used to determine Hubble's Constant. The answer they got was just over 82 kilometres per second per megaparsec.

This is quite high compared to the numbers mentioned above. But the key point is that with only two distance anchors the uncertainty in this value is still quite large. Importantly, though, it is statistically consistent with the value measured from the local universe. The uncertainty will be reduced by hunting for – and measuring – distances to other strongly lensed and time-varying galaxies. They are rare, but upcoming projects like the Large Synoptic Survey Telescope should be capable of detecting many such systems, raising hopes of reliable values.

The result provides another piece of the puzzle. But more work is needed: it still doesn't explain why the value derived from the cosmic microwave background is so low. So the mystery remains, but hopefully not for too long.

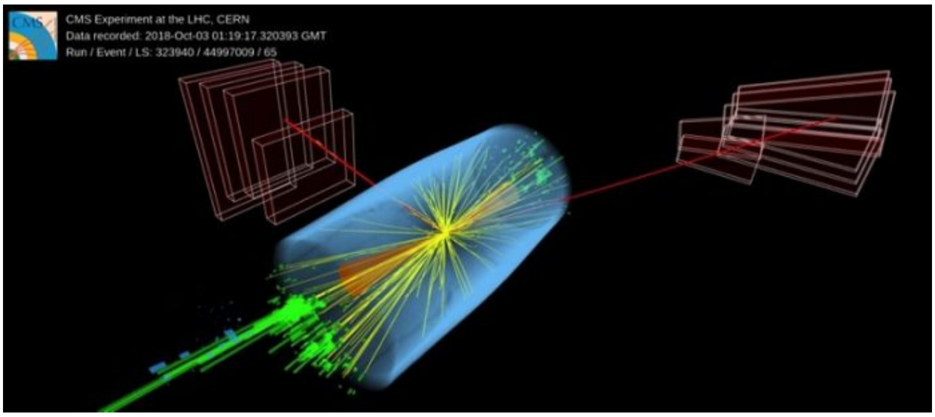
5) Cientistas observam 'partícula de Deus' em nova interação. Date: 20200806

Primeira detecção de interação do bóson de Higgs com um múon é considerada uma importante transposição de fronteira científica Texto:Inovação Tecnológica (com informações da Agência Fapesp) 05/08/2020



CMS Experiment at the LHC, CERN
Data recorded: 2018-Oct-03 01:19:17.320393 GMT
Run / Event / LS: 323940 / 44997009 / 65

Figure 1.35: Higgs01.png - Imagem real de um evento registrado pelo detector CMS do LHC. As duas linhas vermelhas correspondem ao par de múons formados pelo decaimento do bóson de Higgs. Crédito: Cern/divulgação

A primeira medida da interação do bóson de Higgs com o múon foi anunciada na segunda-feira, 3 de agosto, pela organização que controla o LHC (Grande Colisor de Hádrons).

Isso é importante porque abre caminho para o estudo de como o campo de Higgs – responsável por "dar materialidade à matéria", ou seja, dar-lhe massa – com as partículas mais leves que compõem o chamado Modelo Padrão da Física.

O múon é uma partícula semelhante ao elétron, com carga elétrica -1 e spin 1/2. Sua massa, embora muitas vezes superior à do elétron, é bem menor do que as massas das partículas com as quais o Higgs já havia interagido nos experimentos anteriores realizados no LHC.

O resultado, considerado um dos mais importantes obtidos desde a descoberta experimental do próprio bóson de Higgs em 2012, foi alcançado pela equipe internacional do CMS (Compact Muon Solenoid), um dos detectores do LHC. Análises trabalhosas

"O evento físico foi registrado em 2018, mas teve que passar por análises extremamente trabalhosas antes de ser reconhecido de maneira inequívoca. O fato de o CMS ter obtido essa medida complexa é mais uma demonstração do alcance do detector para explorar os detalhes do mecanismo de Higgs", disse à Agência Fapesp o físico Sérgio Novaes, professor titular da Universidade Estadual Paulista (Unesp) e líder do Sprace (São Paulo Research and Analysis Centre), um grupo de pesquisa atuante no LHC, apoiado pela Fapesp.

"Depois da descoberta do bóson de Higgs, as colaborações internacionais do Cern confirmaram experimentalmente as predições do Modelo Padrão quanto ao acoplamento dele com todas as partículas pesadas. Essa comparação foi estendida agora ao múon, um resultado bem mais difícil de alcançar," explicou Novaes.

Segundo o Modelo Padrão, é o campo de Higgs que fornece massa a todas as partículas conhecidas. O bóson de Higgs é o quantum, ou quantidade mínima de energia, desse campo.

No contexto experimental, o bóson de Higgs é obtido por meio da energia gerada em colisões de prótons. Como sua massa é muito grande, ele é instável e decai rapidamente em outras partículas mais leves. Por meio dos diferentes canais de decaimento, é possível calcular as forças de interação entre o campo de Higgs e as partículas resultantes.

E comparar os resultados com as previsões do Modelo Padrão permite testar a teoria e lança luz sobre o processo pelo qual as partículas fundamentais adquirem massa. Façanha científica

\O Higgs acopla-se a todas as partículas fundamentais com uma intensidade proporcional à massa dessas partículas. Assim, a interação é mais forte, e por isso mais fácil de medir, quando as partículas são bastante pesadas. É o caso dos bósons W e Z, intermediários da interação fraca, e dos férmions quarks top e bottom e lépton tau { sendo todos estes férmions partículas de terceira geração, cujo acoplamento com o Higgs já havia sido detectado anteriormente. O múon é um lépton de segunda geração, muito mais leve do que as partículas mencionadas. A detecção de seu acoplamento com o Higgs foi uma grande façanha científica," explicou Novaes.

A chance de um bóson de Higgs decair em múons é de uma em 5 mil, aproximadamente. Além disso, quando o decaimento realmente acontece, o par de múons resultante fica \escondido" no meio de mil outros pares de múons, gerados pelo decaimento de outras partículas envolvidas no processo. É preciso isolar e identificar cada um desses pares para saber se corresponde ou não ao resultado esperado.

\O acoplamento com o múon era considerado a próxima fronteira a ser explorada para o entendimento da interação do bóson de Higgs com as partículas mais leves. Essa fronteira foi agora transposta," comemorou Novaes. Source:

1a) Pag. 37(57) - 2.6 MOHR'S CIRCLES FOR 30 STRESS ANALYSIS
Pag. 39(59) - Figure 2.20

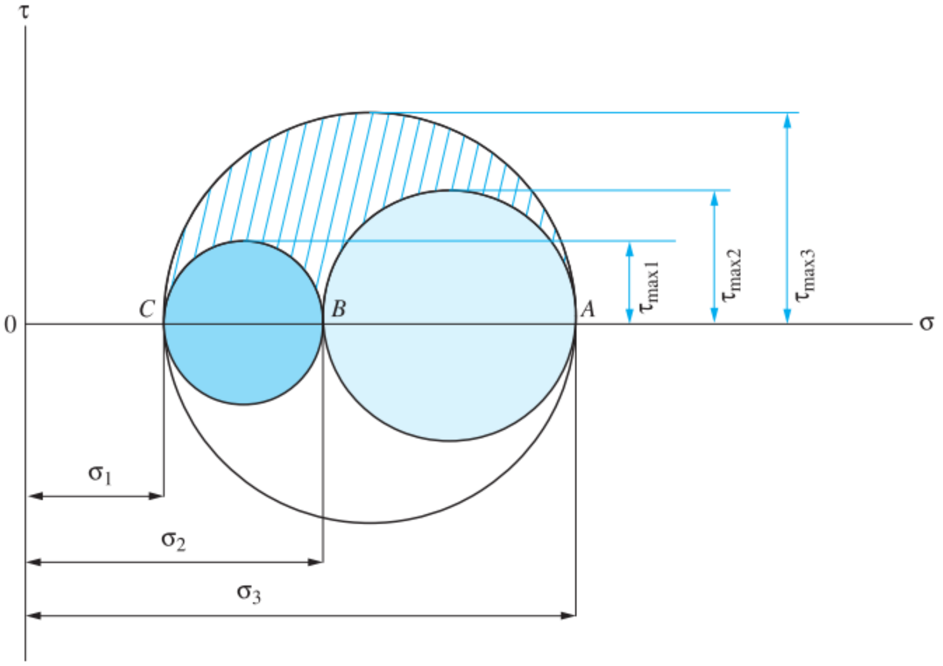

Figure 1.36: F01.png - The 3D representation of Mohr's circle.

1b) Pag. 51(71) - The element with these normal stresses in an octahedron where the eight surfaces are symmetric with respect to the principal axes. The directional cosines of the normal of these surfaces, relative to the principal axes, are eight combinations of $\frac{1}{\sqrt{3}}$ (e.g., one set is $\frac{1}{\sqrt{3}}$, $\frac{1}{\sqrt{3}}$, $\frac{1}{\sqrt{3}}$; another is $\frac{1}{\sqrt{3}}$, $\frac{1}{\sqrt{3}}$, $\frac{1}{\sqrt{3}}$, etc).

The octahedron is as shown in Fig. 3.1. The shear stresses on these surfaces are also equal, called the octahedral shear stresses, and are given by

$$_{oct} = \frac{1}{3}\sqrt{(\;_1 \quad _2)^2 + (\;_2 \quad _3)^2 + (\;_3 \quad _1)^2} \tag{1.5}$$

Again, for the simple tensile test, yield occurs when$_1$ = $_{ys}$ and $_2$ = $_3$ = 0. From Eq. (3.7-6), this gives an octahedral shear stress at yield of

$$(\ _{oct})_y = \frac{\sqrt{2}}{3}\ _{ys} \tag{1.6}$$

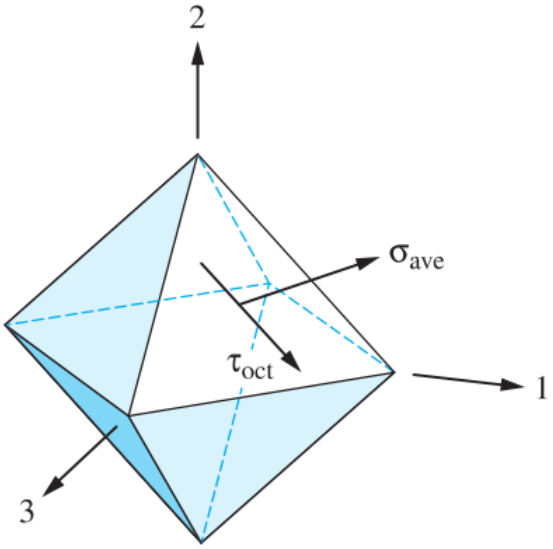

Figure 1.37: F02.png - Octahedral surfaces containing octahedral shear stresses (shown relative to the principal axes, with only one set of stresses displayed).

Equating Eqs. (3.7-6) and (3.7-7) results in Eq. (3.7-3) again, proving that the maximum-octahedral-shear-stress theory is identical to the maximum-distortion-energy theory. The maximum-shear-stress theory equates the maximum shear stress for a general state of stress to the maximum shear stress obtained when the tensile specimen yields. If the principal stresses are ordered such that $_1 \quad _2 \quad _3$, the maximum shear stress is given by:0.5($_1 \quad _3$) (see Sec. 2.3, Eq. 2.3-25). The maximum shear stress obtained when the tensile specimen yields is:0.5 $_{ys}$:
Thus; the condition for elastic failure for the maximum shear stress theory is [7]

---

[7] Plane stress problems are encountered quite often where the principal stresses are found from Eq. (2.3-23), which is

$$_p = \frac{_x + _y}{2} \qquad \sqrt{\left(\frac{_x \quad _y}{2}\right)^2 + \ ^2_{xy}}$$

This yields only two of the three principal stresses. The third principal stress for plane is

$$ {}_1 \quad {}_3 = \quad {}_{ys} \tag{1.7} $$

The criteria just discussed concern the elastic failure of material. Such failure may occur locally in a member and may do no real damage if the volume of material affected is so small or so located as to have only negligible influence on the form and strength of the member as a whole. Whether or not such local overstressing is significant depends upon the properties of the material and the conditions of service. Fatigue properties, resistance to impact, and mechanical functioning are much more likely to be affected than static strength, and a degree of local overstressing that would constitute failure in a high-speed machine part might be of no consequence whatever in a bridge member. A brittle material cannot be considered to have definitely failed until it has broken, which can occur either through a tensile fracture, when the maximum tensile stress reaches the ultimate strength, or through what appears to be a shear fracture, when the maximum compressive stress reaches a certain value. The fracture occurs on a plane oblique to the maximum compressive stress but not, as a rule, on the plane of maximum shear stress, and so it cannot be considered to be purely a shear failure (see Ref. 14). The results of some tests on glass and Bakelite (Ref. 26) indicate that for these brittle materials either the maximum stress or the maximum strain theory affords a satisfactory criterion of rupture while neither the maximum shear stress nor the constant energy of distortion theory does. These tests also indicate that strength increases with rate of stress application and that the increase is more marked when the location of the most stressed zone changes during the loading (pressure of a sphere on a flat surface) than when this zone is fixed (axial tension). Another failure theory that is applicable to brittle materials is the Coulomb-Mohr theory of failure. Brittle materials have ultimate compressive strengths ${}_{uc}$ greater than their ultimate tensile strengths ${}_{ut}$ and therefore both a uniaxial tensile test and a uniaxial compressive test must be run to use the Coulomb-Mohr theory. First we draw on a single plot both Mohr's stress circle for the tensile test at the instant of failure and Mohr's stress circle for the compressive test at the instant of failure; then we complete a failure envelope simply by drawing a pair of tangent lines to the two circles, as shown in Fig. 3.2. Failure under a complex stress situation is expected if the largest of the three Mohr circles for the given situation touches or extends outside the envelope just described. If

---

zero. Once the three principal stresses are determinid, they can be ordered according to

$$ 1 \quad 2 \quad 3 $$

and the Eq. (3.7-8) can be employed.

all normal stresses are tensile, the results coincide with the maximum stress theory. For a

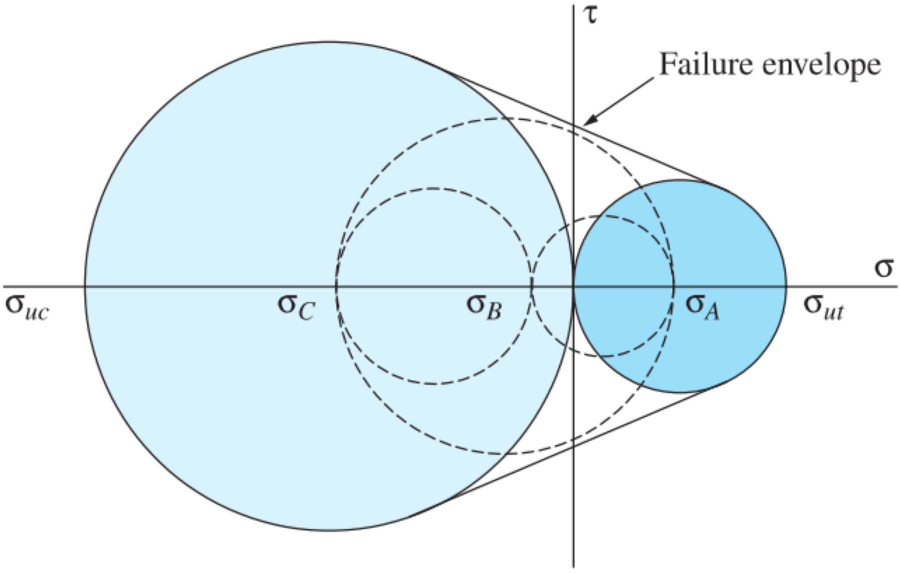

Figure 1.38: F03.png - Failure envelope

condition where the three principal stresses are $_A$, $_B$, and $_C$, as shown in Fig. 3.2, failure is being approached but will not take place unless the dashed circle passing through $_A$ and $_C$ reaches the failure envelope. The accurate prediction of the breaking strength of a member composed of brittle metal requires a knowledge of the effect of form and scale, and these effects are expressed by the rupture factor (see Sec. 3.11). In addition, what has been said here concerning brittle metals applies also to any essentially isotropic brittle material. Thus far, our discussion of failure has been limited to isotropic materials. For wood, which is distinctly anisotropic, the possibility of failure in each of several ways and direc- tions must be taken into account, viz.: (1) by tension parallel to the grain, which causes fracture; (2) by tension transverse to the grain, which causes fracture; (3) by shear parallel to the grain, which causes fracture; (4) by compression parallel to the grain, which causes gradual buckling of the fibers usually accompanied by a shear displacement on an oblique plane; and (5) by compression transverse to the grain, which causes sufficient deformation to make the part unfit for service. The unit stress producing each of these types of failure must be ascertained by suitable tests (Ref. 2). Another anisotropic class of material of consequence is that of the composites. It is well-known that composite members (see Sees. 7.3, 8.2, and definitions), such as steel reinforced concrete beams, more effectively utilize the more expensive, higher-strength materials in high-stress areas and the less expensive, lower-strength materials in the low-stress areas. Composite materials accomplish the same effect at microstructural and macrostructural levels. Composite materials come in many forms, but are generally formulated by embedding a reinforcement material in the form of fibers, flakes, particles, or laminations, in a randomly or orderly oriented fashion within a base matrix of polymeric, metallic, or ceramic material. For more detail properties of composites, see Ref. 60.

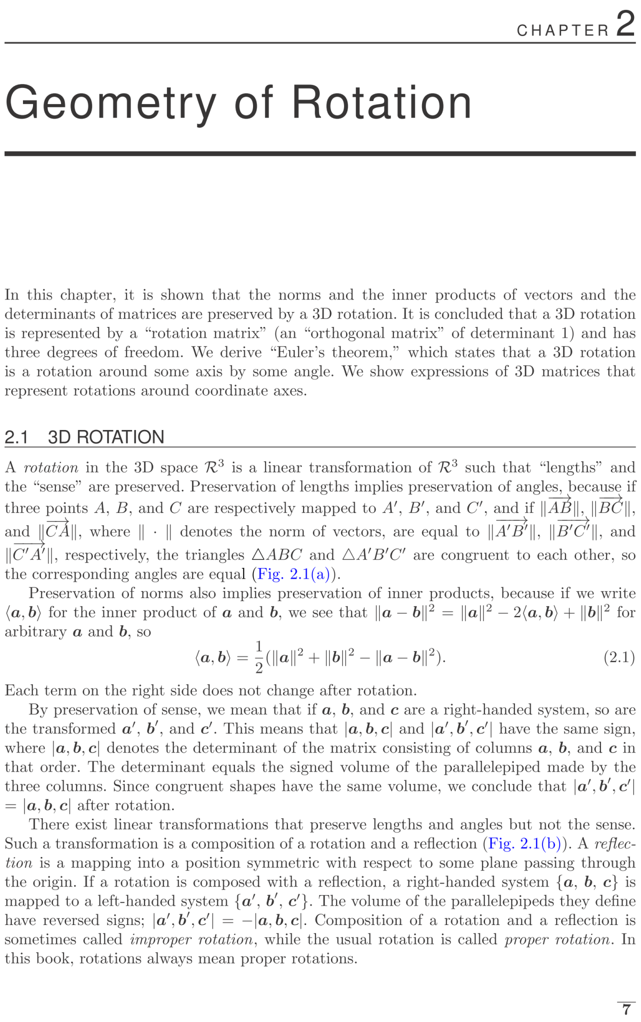
Pag. 07 (18) - Chapter 2 - Geometry of Rotations IMPORTANT



CHAPTER 2

Geometry of Rotation

In this chapter, it is shown that the norms and the inner products of vectors and the determinants of matrices are preserved by a 3D rotation. It is concluded that a 3D rotation is represented by a "rotation matrix" (an "orthogonal matrix" of determinant 1) and has three degrees of freedom. We derive "Euler's theorem," which states that a 3D rotation is a rotation around some axis by some angle. We show expressions of 3D matrices that represent rotations around coordinate axes.

2.1 3D ROTATION

A *rotation* in the 3D space $\mathcal{R}^3$ is a linear transformation of $\mathcal{R}^3$ such that "lengths" and the "sense" are preserved. Preservation of lengths implies preservation of angles, because if three points A, B, and C are respectively mapped to A', B', and C', and if $\|\overrightarrow{AB}\|$, $\|\overrightarrow{BC}\|$, and $\|\overrightarrow{CA}\|$, where $\|\cdot\|$ denotes the norm of vectors, are equal to $\|\overrightarrow{A'B'}\|$, $\|\overrightarrow{B'C'}\|$, and $\|\overrightarrow{C'A'}\|$, respectively, the triangles $\triangle ABC$ and $\triangle A'B'C'$ are congruent to each other, so the corresponding angles are equal (Fig. 2.1(a)).

Preservation of norms also implies preservation of inner products, because if we write $\langle \boldsymbol{a}, \boldsymbol{b} \rangle$ for the inner product of $\boldsymbol{a}$ and $\boldsymbol{b}$, we see that $\|\boldsymbol{a}-\boldsymbol{b}\|^2 = \|\boldsymbol{a}\|^2 - 2\langle \boldsymbol{a}, \boldsymbol{b} \rangle + \|\boldsymbol{b}\|^2$ for arbitrary $\boldsymbol{a}$ and $\boldsymbol{b}$, so

$$\langle \boldsymbol{a}, \boldsymbol{b} \rangle = \frac{1}{2}(\|\boldsymbol{a}\|^2 + \|\boldsymbol{b}\|^2 - \|\boldsymbol{a}-\boldsymbol{b}\|^2). \tag{2.1}$$

Each term on the right side does not change after rotation.

By preservation of sense, we mean that if $\boldsymbol{a}$, $\boldsymbol{b}$, and $\boldsymbol{c}$ are a right-handed system, so are the transformed $\boldsymbol{a}'$, $\boldsymbol{b}'$, and $\boldsymbol{c}'$. This means that $|\boldsymbol{a}, \boldsymbol{b}, \boldsymbol{c}|$ and $|\boldsymbol{a}', \boldsymbol{b}', \boldsymbol{c}'|$ have the same sign, where $|\boldsymbol{a}, \boldsymbol{b}, \boldsymbol{c}|$ denotes the determinant of the matrix consisting of columns $\boldsymbol{a}$, $\boldsymbol{b}$, and $\boldsymbol{c}$ in that order. The determinant equals the signed volume of the parallelepiped made by the three columns. Since congruent shapes have the same volume, we conclude that $|\boldsymbol{a}', \boldsymbol{b}', \boldsymbol{c}'| = |\boldsymbol{a}, \boldsymbol{b}, \boldsymbol{c}|$ after rotation.

There exist linear transformations that preserve lengths and angles but not the sense. Such a transformation is a composition of a rotation and a reflection (Fig. 2.1(b)). A *reflection* is a mapping into a position symmetric with respect to some plane passing through the origin. If a rotation is composed with a reflection, a right-handed system $\{\boldsymbol{a}, \boldsymbol{b}, \boldsymbol{c}\}$ is mapped to a left-handed system $\{\boldsymbol{a}', \boldsymbol{b}', \boldsymbol{c}'\}$. The volume of the parallelepipeds they define have reversed signs; $|\boldsymbol{a}', \boldsymbol{b}', \boldsymbol{c}'| = -|\boldsymbol{a}, \boldsymbol{b}, \boldsymbol{c}|$. Composition of a rotation and a reflection is sometimes called *improper rotation*, while the usual rotation is called *proper rotation*. In this book, rotations always mean proper rotations.

B'
A
A'
C'
O

(a) (b)

FIGURE 2.1 (a) Lengths and angles of vectors and the orientation of the space are preserved by a rotation in the 3D space $\mathcal{R}^3$. (b) The mapping is a composition of a rotation and a reflection if the orientation of the space is reversed, even though lengths and angles are preserved.

Thus, we can say that a rotation is a linear mapping $\boldsymbol{R}$ such that for arbitrary vectors $\boldsymbol{a}$, $\boldsymbol{b}$, and $\boldsymbol{c}$

$$\|\boldsymbol{Ra}\| = \|\boldsymbol{a}\|, \qquad |\boldsymbol{Ra}, \boldsymbol{Rb}, \boldsymbol{Rc}| = |\boldsymbol{a}, \boldsymbol{b}, \boldsymbol{c}| \tag{2.2}$$

hold. This implies that $\langle \boldsymbol{Ra}, \boldsymbol{Rb} \rangle = \langle \boldsymbol{a}, \boldsymbol{b} \rangle$ for arbitrary vectors $\boldsymbol{a}$, and $\boldsymbol{b}$.

2.2 ORTHOGONAL MATRICES AND ROTATION MATRICES

Let $\{\boldsymbol{e}_1, \boldsymbol{e}_2, \boldsymbol{e}_3\}$ be the standard basis of $\mathcal{R}^3$, where $\boldsymbol{e}_i$ denotes the unit vector whose ith component is 1, the other components being 0. Suppose they are rotated to vectors $\{\boldsymbol{r}_1, \boldsymbol{r}_2, \boldsymbol{r}_3\}$, respectively, by a rotation (Fig. 2.2). Then, this rotation is represented by a 3×3 matrix

$$\boldsymbol{R} = \begin{pmatrix} \boldsymbol{r}_1 & \boldsymbol{r}_2 & \boldsymbol{r}_3 \end{pmatrix}, \tag{2.3}$$

having these vectors as columns, since $\boldsymbol{r}_i = \boldsymbol{Re}_i$ holds from the definition of the vector $\boldsymbol{e}_i$.

The basis $\{\boldsymbol{e}_1, \boldsymbol{e}_2, \boldsymbol{e}_3\}$ is orthonormal, i.e., consisting of mutually orthogonal unit vectors. Since norms and angles are preserved by a rotation, $\{\boldsymbol{r}_1, \boldsymbol{r}_2, \boldsymbol{r}_3\}$ is also an orthonormal system. A matrix with orthonormal columns is called an *orthogonal matrix*. Since $\{\boldsymbol{r}_1, \boldsymbol{r}_2, \boldsymbol{r}_3\}$ has the same sense as $\{\boldsymbol{e}_1, \boldsymbol{e}_2, \boldsymbol{e}_3\}$, the matrix $\boldsymbol{R}$ has determinant 1. An orthogonal matrix of determinant 1 is called a *rotation matrix*. Thus, *a rotation is represented by a rotation matrix*. If $\{\boldsymbol{r}_1, \boldsymbol{r}_2, \boldsymbol{r}_3\}$ of Eq. (2.3) are a left-handed system, $\boldsymbol{R}$ has determinant -1. As pointed out earlier, a linear mapping specified by an orthogonal matrix of determinant -1 is a composition of a rotation and a reflection, i.e., an improper rotation. Thus, an orthogonal matrix represents either a proper rotation or an improper rotation.

The condition that $\{\boldsymbol{r}_1, \boldsymbol{r}_2, \boldsymbol{r}_3\}$ of Eq. (2.3) are an orthonormal system is written as

$$\langle \boldsymbol{r}_i, \boldsymbol{r}_j \rangle = \delta_{ij}, \tag{2.4}$$

where δ_{ij} is the *Kronecker delta*, taking on 1 for $i = j$ and 0 otherwise. It follows from Eq. (2.3) that

$$\begin{aligned} \boldsymbol{R}^\top \boldsymbol{R} &= \begin{pmatrix} \boldsymbol{r}_1^\top \\ \boldsymbol{r}_2^\top \\ \boldsymbol{r}_3^\top \end{pmatrix} \begin{pmatrix} \boldsymbol{r}_1 & \boldsymbol{r}_2 & \boldsymbol{r}_3 \end{pmatrix} = \begin{pmatrix} \langle \boldsymbol{r}_1, \boldsymbol{r}_1 \rangle & \langle \boldsymbol{r}_1, \boldsymbol{r}_2 \rangle & \langle \boldsymbol{r}_1, \boldsymbol{r}_3 \rangle \\ \langle \boldsymbol{r}_2, \boldsymbol{r}_1 \rangle & \langle \boldsymbol{r}_2, \boldsymbol{r}_2 \rangle & \langle \boldsymbol{r}_2, \boldsymbol{r}_3 \rangle \\ \langle \boldsymbol{r}_3, \boldsymbol{r}_1 \rangle & \langle \boldsymbol{r}_3, \boldsymbol{r}_2 \rangle & \langle \boldsymbol{r}_3, \boldsymbol{r}_3 \rangle \end{pmatrix} \\ &= \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} = \boldsymbol{I}, \end{aligned} \tag{2.5}$$

O
$\boldsymbol{r}_3$
$\boldsymbol{r}_2$

FIGURE 2.2 If the basis vectors $\{\boldsymbol{e}_1, \boldsymbol{e}_2, \boldsymbol{e}_3\}$ of the 3D space $\mathcal{R}^3$ are rotated to $\{\boldsymbol{r}_1, \boldsymbol{r}_2, \boldsymbol{r}_3\}$, respectively, the rotation is represented by a 3×3 matrix $\boldsymbol{R} = \left(\boldsymbol{r}_1\ \boldsymbol{r}_2\ \boldsymbol{r}_3\right)$ having these vectors as columns.

where $\boldsymbol{I}$ is the identity matrix and $\top$ denotes transpose. Thus, we conclude that a matrix $\boldsymbol{R}$ is orthogonal if and only if $\boldsymbol{R}^\top\boldsymbol{R} = \boldsymbol{I}$ and that a matrix $\boldsymbol{R}$ represents a rotation if and only if $\boldsymbol{R}^\top\boldsymbol{R} = \boldsymbol{I}$ and $|\boldsymbol{R}| = 1$.

Recall that the determinant $|\boldsymbol{R}| = |\boldsymbol{r}_1, \boldsymbol{r}_2, \boldsymbol{r}_3|$ equals the signed volume of the parallelepiped defined by the columns $\boldsymbol{r}_1$, $\boldsymbol{r}_2$, and $\boldsymbol{r}_3$. An orthonormal system defines a cube of size 1. Hence, for an orthogonal matrix $\boldsymbol{R}$, the determinant is $|\boldsymbol{R}| = \pm 1$. It follows that we can say that $\boldsymbol{R}$ is a rotation matrix if and only if $\boldsymbol{R}^\top\boldsymbol{R} = \boldsymbol{I}$ and $|\boldsymbol{R}| > 0$.

The identity $\boldsymbol{R}^\top\boldsymbol{R} = \boldsymbol{I}$ of Eq. (2.5) implies that $\boldsymbol{R}^\top$ *equals the inverse* $\boldsymbol{R}^{-1}$:

$$\boldsymbol{R}\boldsymbol{R}^\top = \boldsymbol{R}\boldsymbol{R}^{-1} = \boldsymbol{I}. \tag{2.6}$$

Since $\boldsymbol{R}\boldsymbol{R}^\top = (\boldsymbol{R}^\top)^\top\boldsymbol{R}^\top$, we see that $\boldsymbol{R}^\top$ is also an orthogonal matrix. The columns of the transpose $\boldsymbol{R}^\top$ are the rows of $\boldsymbol{R}$, so *the columns and rows of an orthogonal matrix are both orthonormal systems*. Since the determinant is unchanged by transpose, we have $|\boldsymbol{R}^\top| = |\boldsymbol{R}|$. Hence, if $\boldsymbol{R}$ is a rotation matrix, so is $\boldsymbol{R}^\top$. Geometrically, $\boldsymbol{R}^\top$ $(= \boldsymbol{R}^{-1})$ represents the inverse of rotation $\boldsymbol{R}$.

Equation (2.4) consists of six identities in the elements for (i, j) = (1,1), (2,2), (3,3), (1,2), (2,3), (3,1), which constrain the nine elements of $\boldsymbol{R}$. Hence, we can freely specify only $9 - 6 = 3$ elements. Namely, *a rotation matrix has three degrees of freedom* (the inequality $|\boldsymbol{R}| > 0$ does not affect the degree of freedom). Thus, a 3D rotation can be specified by at least three parameters, though not necessarily in a unique manner.

2.3 EULER'S THEOREM

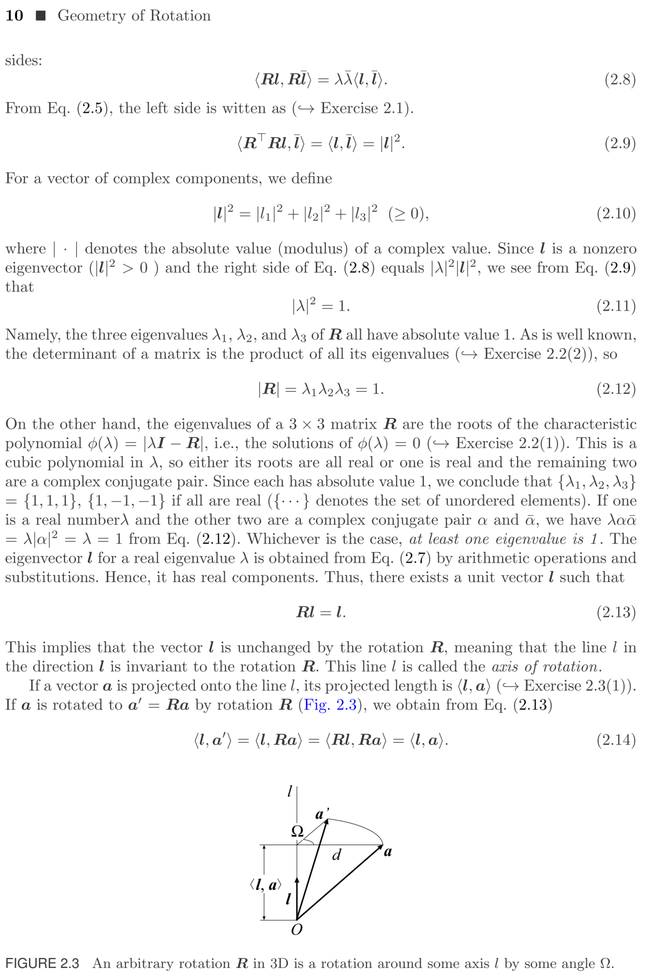
We now derive "Euler's theorem," which states that an arbitrary rotation $\boldsymbol{R}$ in 3D is a rotation around some axis l by some angle Ω.

Let λ be an eigenvalue of $\boldsymbol{R}$, and $\boldsymbol{l}$ the corresponding unit eigenvector:

$$\boldsymbol{R}\boldsymbol{l} = \lambda\boldsymbol{l}. \tag{2.7}$$

The eigenvalue may have a complex value, and the eigenvector $\boldsymbol{l}$ may have complex components. Consider the inner product of Eq. (2.7) and its complex conjugate $\boldsymbol{R}\bar{\boldsymbol{l}} = \bar{\lambda}\bar{\boldsymbol{l}}$ on both

Figure 1.254: 3D-Rotations-03.png



10 ■ Geometry of Rotation

sides:

$$\langle \boldsymbol{Rl}, \boldsymbol{R\bar{l}} \rangle = \lambda\bar{\lambda}\langle \boldsymbol{l}, \bar{\boldsymbol{l}} \rangle. \tag{2.8}$$

From Eq. (2.5), the left side is witten as (↪ Exercise 2.1).

$$\langle \boldsymbol{R}^\top \boldsymbol{Rl}, \bar{\boldsymbol{l}} \rangle = \langle \boldsymbol{l}, \bar{\boldsymbol{l}} \rangle = |\boldsymbol{l}|^2. \tag{2.9}$$

For a vector of complex components, we define

$$|\boldsymbol{l}|^2 = |l_1|^2 + |l_2|^2 + |l_3|^2 \ \ (\geq 0), \tag{2.10}$$

where $|\cdot|$ denotes the absolute value (modulus) of a complex value. Since $\boldsymbol{l}$ is a nonzero eigenvector ($|\boldsymbol{l}|^2 > 0$) and the right side of Eq. (2.8) equals $|\lambda|^2|\boldsymbol{l}|^2$, we see from Eq. (2.9) that

$$|\lambda|^2 = 1. \tag{2.11}$$

Namely, the three eigenvalues λ_1, λ_2, and λ_3 of $\boldsymbol{R}$ all have absolute value 1. As is well known, the determinant of a matrix is the product of all its eigenvalues (↪ Exercise 2.2(2)), so

$$|\boldsymbol{R}| = \lambda_1\lambda_2\lambda_3 = 1. \tag{2.12}$$

On the other hand, the eigenvalues of a 3×3 matrix $\boldsymbol{R}$ are the roots of the characteristic polynomial $\phi(\lambda) = |\lambda\boldsymbol{I} - \boldsymbol{R}|$, i.e., the solutions of $\phi(\lambda) = 0$ (↪ Exercise 2.2(1)). This is a cubic polynomial in λ, so either its roots are all real or one is real and the remaining two are a complex conjugate pair. Since each has absolute value 1, we conclude that $\{\lambda_1, \lambda_2, \lambda_3\} = \{1, 1, 1\}$, $\{1, -1, -1\}$ if all are real ($\{\cdots\}$ denotes the set of unordered elements). If one is a real numberλ and the other two are a complex conjugate pair α and $\bar{\alpha}$, we have $\lambda\alpha\bar{\alpha} = \lambda|\alpha|^2 = \lambda = 1$ from Eq. (2.12). Whichever is the case, *at least one eigenvalue is 1*. The eigenvector $\boldsymbol{l}$ for a real eigenvalue λ is obtained from Eq. (2.7) by arithmetic operations and substitutions. Hence, it has real components. Thus, there exists a unit vector $\boldsymbol{l}$ such that

$$\boldsymbol{Rl} = \boldsymbol{l}. \tag{2.13}$$

This implies that the vector $\boldsymbol{l}$ is unchanged by the rotation $\boldsymbol{R}$, meaning that the line l in the direction $\boldsymbol{l}$ is invariant to the rotation $\boldsymbol{R}$. This line l is called the *axis of rotation*.

If a vector $\boldsymbol{a}$ is projected onto the line l, its projected length is $\langle \boldsymbol{l}, \boldsymbol{a} \rangle$ (↪ Exercise 2.3(1)). If $\boldsymbol{a}$ is rotated to $\boldsymbol{a}' = \boldsymbol{Ra}$ by rotation $\boldsymbol{R}$ (Fig. 2.3), we obtain from Eq. (2.13)

$$\langle \boldsymbol{l}, \boldsymbol{a}' \rangle = \langle \boldsymbol{l}, \boldsymbol{Ra} \rangle = \langle \boldsymbol{Rl}, \boldsymbol{Ra} \rangle = \langle \boldsymbol{l}, \boldsymbol{a} \rangle. \tag{2.14}$$

FIGURE 2.4 Rotation around the z-axis by angle γ.

The distance d between the endpoint of vector $\boldsymbol{a}$ and the line l is $d = \|\boldsymbol{a} - \langle \boldsymbol{l}, \boldsymbol{a}\rangle \boldsymbol{l}\|$ (↪ Exercise 2.3(2)). For the vector $\boldsymbol{a}' = \boldsymbol{Ra}$ after the rotation, we have

$$\begin{aligned} d' &= \|\boldsymbol{a}' - \langle \boldsymbol{l}, \boldsymbol{a}'\rangle \boldsymbol{l}\| = \|\boldsymbol{Ra} - \langle \boldsymbol{l}, \boldsymbol{Ra}\rangle \boldsymbol{l}\| = \|\boldsymbol{Ra} - \langle \boldsymbol{l}, \boldsymbol{Ra}\rangle \boldsymbol{Rl}\| \\ &= \|\boldsymbol{R}(\boldsymbol{a} - \langle \boldsymbol{l}, \boldsymbol{a}\rangle \boldsymbol{l})\| = \|\boldsymbol{a} - \langle \boldsymbol{l}, \boldsymbol{a}\rangle \boldsymbol{l}\| = d. \end{aligned} \tag{2.15}$$

Hence, for any vector $\boldsymbol{a}$, its projected length onto the line l and the distance d from the line l are both unaffected by the rotation $\boldsymbol{R}$. Thus, we obtain the following *Euler's theorem*: *any rotation* $\boldsymbol{R}$ *in 3D is a rotation around some axis* l *by some angle* Ω.

2.4 AXIAL ROTATIONS

Among rotations around axes, the most fundamental ones are those around the coordinate axes. In the following, the axis is regarded as oriented and the angle of rotation is regarded as positive or negative according to the right-hand rule.

First, consider the rotation around the z-axis by angle γ. If we rotate the basis vectors $\{\boldsymbol{e}_1, \boldsymbol{e}_2, \boldsymbol{e}_3\}$ around the z-axis by angle γ (Fig. 2.4), they are rotated, respectively, to

$$\boldsymbol{r}_1 = \begin{pmatrix} \cos\gamma \\ \sin\gamma \\ 0 \end{pmatrix}, \qquad \boldsymbol{r}_2 = \begin{pmatrix} -\sin\gamma \\ \cos\gamma \\ 0 \end{pmatrix}, \qquad \boldsymbol{r}_3 = \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}. \tag{2.16}$$

As stated in Sec. **2.2**, the corresponding rotation matrix $\boldsymbol{R}_z(\gamma)$ has these as columns in the form

$$\boldsymbol{R}_z(\gamma) = \begin{pmatrix} \cos\gamma & -\sin\gamma & 0 \\ \sin\gamma & \cos\gamma & 0 \\ 0 & 0 & 1 \end{pmatrix}. \tag{2.17}$$

Similarly, we obtain the rotation matrices around the x-axis by angle α and around the y-axis by angle β in the form (Fig. 2.5).

$$\boldsymbol{R}_x(\alpha) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos\alpha & -\sin\alpha \\ 0 & \sin\alpha & \cos\alpha \end{pmatrix}, \qquad \boldsymbol{R}_y(\beta) = \begin{pmatrix} \cos\beta & 0 & \sin\beta \\ 0 & 1 & 0 \\ -\sin\beta & 0 & \cos\beta \end{pmatrix}. \tag{2.18}$$

2.5 SUPPLEMENTAL NOTE

As stated in Introduction, 3D rotation plays a central role in analysis of dynamics of rigid bodies and angular momentum of elementary particles, and hence it has mostly been discussed by physicists. Classical textbooks still widely read today include [8, 10, 32]. 3D

rotation is also an important topic of computer vision research in relation to analysis of cameras and 3D scenes [17].

2.6 EXERCISES

2.1. Show that for an arbitrary matrix $\boldsymbol{A}$ and arbitrary vectors $\boldsymbol{x}$ and $\boldsymbol{y}$ the following identity holds:

$$\langle \boldsymbol{x}, \boldsymbol{A}\boldsymbol{y} \rangle = \langle \boldsymbol{A}^\top \boldsymbol{x}, \boldsymbol{y} \rangle. \tag{2.19}$$

2.2. (1) Show that an eigenvalue λ of matrix $\boldsymbol{A}$ is a root of the characteristic polynomial $\phi(\lambda) = |\lambda \boldsymbol{I} - \boldsymbol{A}|$.

(2) Show that the eigenvalues λ_1, λ_2, and λ_3 of matrix $\boldsymbol{A}$ satisfy the following identities:

$$\mathrm{tr}\boldsymbol{A} = \lambda_1 + \lambda_2 + \lambda_3, \qquad |\boldsymbol{A}| = \lambda_1 \lambda_2 \lambda_3. \tag{2.20}$$

2.3. (1) Show that the (signed) length of the projection of vector $\boldsymbol{a}$ onto line l having the unit direction vector $\boldsymbol{u}$ is given by $\langle \boldsymbol{u}, \boldsymbol{a} \rangle$ (Fig. 2.6).

FIGURE 2.6 Projection of a vector $\boldsymbol{a}$ starting from a point on a line l onto the line l.

(2) Show that the distance between line l having the unit direction vector $\boldsymbol{u}$ and the endpoint of vector $\boldsymbol{a}$ starting from a point on l is given by $\|\boldsymbol{a} - \langle \boldsymbol{u}, \boldsymbol{a} \rangle \boldsymbol{u}\|$.

Pag. 02 (23) - On the geographic projection of the surface of a sphere - Euler (nota de rodape). Source: C:/DATA-NovoVivo-127-2020/Books-127-2020/EULER/E491en.pdf

Pag. 18(39) - Fuller called this configuration a Dymaxion projection[1]. The projection is based on a subdivision grid that runs either parallel or perpendicular to the edges of the square and triangular faces. After pointing out the disadvantages of current projections, including the popular Mercator projection, Fuller goes on to say: \Another expedient has been to resolve the earth's surface into a polyhedron, projecting gnomonically to the facets of the polyhedron, the idea being that the sections of the polyhedron can be assembled on a flat surface to give a truer picture of the earth's surface and of directions and distance."[2] In essence, Fuller claims that a gnomonically projected[3] map placed onto the faces of a polyhedron, the cuboctahedron in this case, provides a truer representation of areas, boundaries, directions, and distances than any plane surface map heretofore known. By using the cuboctahedron as the base polyhedron for his projection, all vertices lie on one of four great circles. Fuller makes three invention claims in his patent. The Dymaxion map is a projected map of square and triangular sections where edges are represented by projected great circles with a uniform cartographic scale;

---

[1] In the 1930s, Fuller was advised to find a better name for his 4D house invention, and with the help of an advertising wordsmith, Waldo Warren, the word \Dymaxion" was coined by selecting suitable syllables from Fuller's account of his design ideas. The roots of this name are \dynamism", \maximum", and \ions". Buckminster Fuller, The Dymaxion World of Buckminster Fuller, ed. Robert Marks, New York: Doubleday, 1973

[2] (Fuller 1946, p.1, col. 1, para. 2)

[3] Gnomonic or gnomic projection is a map projection obtained by projecting points on

12 In the 1930s, Fuller was advised to find a better name for his 4D house invention, and with the help of an advertising wordsmith, Waldo Warren, the word \Dymaxion" was coined by selecting suitable syllables from Fuller's account of his design ideas. The roots of this name are \dynamism", \maximum", and \ions". Buckminster Fuller, The Dymaxion World of Buckminster Fuller, ed. Robert Marks. New York: Doubleday, 1973.IMPORTANT 13 (Fuller 1946, p.1, col. 1, para. 2) 14 Gnomonic or gnomic projection is a map projection obtained by projecting points on the surface of a sphere from a sphere's center to a plane that is tangent to the sphere or a projection from the center of a sphere to the surface that surrounds an object (such as a sphere around a polyhedra). In a gnomonic projection, great circles are mapped to straight lines.

Pag. 58(79) - Cells in a spherical tessellation have wall-point relationships, and it's possible to con- vert a triangular tessellation with wall-point neighbors into a hexagonal one with only wall neighbors simply by defining eachpoint's Voronoi cell.[4] Voronoi cells are polygons that define an area (of points) that is closer to a designated point than to any other. If the original points are evenly spaced, or nearly so, the Voronoi cells will resemble a grid of hexagons. Randall and Heikes illustrate this in Figure 3.8(a). The Voronoi cells in green define the points (areas) closest to each of the points in the following triangular grid. The spherical versions of both grids are shown in (b).[5] When a Voronoi tessellation is made of a fully subdivided icosahedron, such as the one shown in Figure 3.9, the result is mostly hexagonal cells, but pentagonal cells also result.

---

the surface of a sphere from a sphere's center to a plane that is tangent to the sphere or a projection from the center of a sphere to the surface that surrounds an object (such as a sphere around a polyhedra). In a gnomonic projection, great circles are mapped to straight lines.

[4] Voronoi diagrams are named after Russian mathematician, Georgy Feodosevich Voronoy (1868{1908). However, they were recognized much earlier by Rene Descartes (1596{1650) and used by Lejeune Dirichlet (1805{1859). Voronoi tessellations are also called Dirichlet tessellations.

[5] Climate model color illustrations in this section courtesy of Ross Heikes.

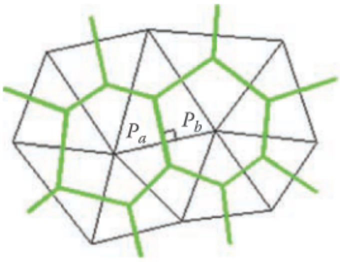

Figure 1.1: ds02a.png - Hexagonal Voronoi cells from triangular tessellations.

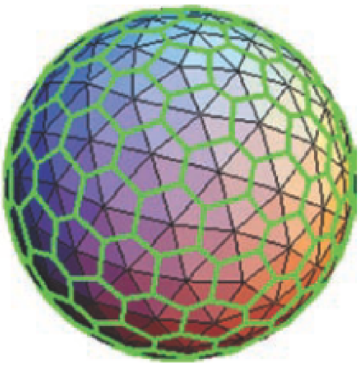

Figure 1.2: ds02b.png - Hexagonal Voronoi cells from triangular tessellations.

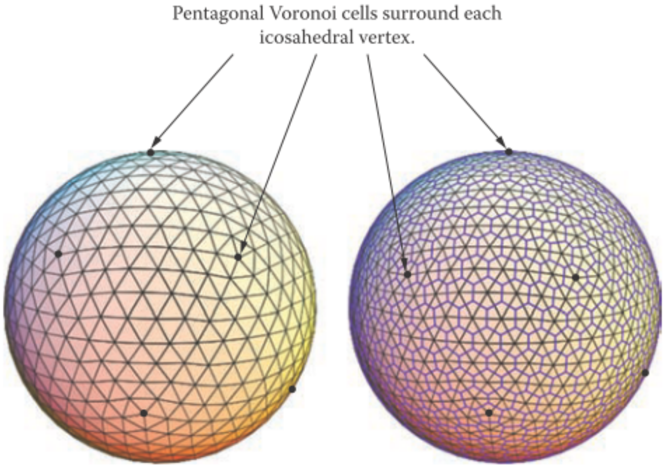

Figure 1.3: ds03.png - Hexagonal Voronoi cells from triangular tessellations.

One pentagonal cell surrounds each of the icosahedron's 12 vertices. Some are pointed out in the figure. Each hexagonal and pentagonal cell is quasi-isotropic because their areas are nearly equal. Both spheres in Figure 3.9 are oriented and scaled the same for comparison. When it comes to climate modeling, hexagonal geodesic grids offer many benefits over other grid systems. They are largely isotropic and do not suffer from oversampling near the poles like longitude/latitude grids. The poles are no different than any other area in the hexagonal grid. All cells in the grid are equal wall-neighbors. There are no point neighbors, as in other grid systems. Hexagonal geodesic grids can also accommodate different resolutions where the atmosphere might be represented by a coarse hexagonal grid, and land-surface areas represented by a finer grid as seen at the right. Randall says coupling the atmosphere and ocean models with multiple hexagonal grids simplifies modeling because the atmospheric state is \interpolated down" from large hexagonal cells to smaller ones below and fluxes are \averaged up" from small cells to larger ones. Hexagonal geodesic grids can also be warped or morphed to meet local needs. Although hexagonal geodesic grids are more complicated to implement than rectangular longitude/latitude grids, their benefits far outweigh the additional work needed to set them up and use them in climate models. Figure 3.10 shows typical climate modeling output based on a geodesic grid.

Pag.91 (112) - 4.9 Loxodromes Latitude and longitude are so familiar we can be fooled when navigating. Consider the use of a compass. A compass performs a very specific function; it always points in the same direction-north.[6] Think of it this way: when you change directions, the compass still points north. In effect, you are turning under the compass; the compass continues pointing in the same direction. The value of a compass is that it allows you to maintain a course over a long distance by ensuring that you cross every meridian (longitude) at the same angle. This course is called a rhumb line or a loxodrome, from the Greek words loxos (oblique) and dromos (running, from dramein: to run). A loxodrome is a line on a sphere of constant bearing that cuts across all meridians at any constant angle except a right one. A loxodrome is also called a spherical spiral and it

---

[6] A compass is influenced by many factors. The magnetic north pole is not exactly located at the geographic north pole. Electrical currents (nearby wires), and large ferrous metal sources near the compass (engines, pipes, etc.) influence which way the compass needle points.

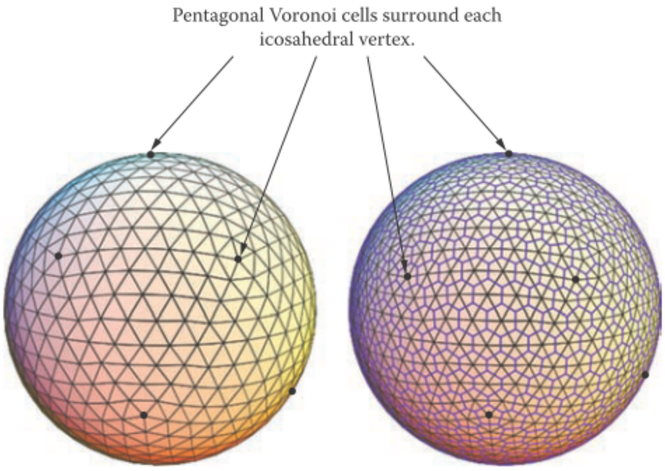

Figure 1.4: ds04.png - Loxodrome courses 56° and 84.2° with a great circle route.

displays as a logarithmic spiral on a polar projection. If the course is not due north-south or east-west, a loxodromic spiral will eventually spiral to either the north or south pole and then endlessly loop that pole in smaller and smaller circles. A loxodrome displays as a straight line on a Mercator map. When plotted on any other map projection, it is a curved line. A loxodrome is a great circle, only if it is along the equator or a meridian. A rhumb line course between two points that is not along the equator or a meridian is always longer than the great circle route between the same two points. And there are an infinite number of rhumb lines between any two nonpolar points that are not on the same latitude or longitude. They only differ in the number of times they encircle the earth. Figure 4.10 shows rhumb lines or loxodromes between two sample points, 1 and 2, and how they compare to a direct great circle route, shown with a bold line. In Figure 4.10(a), the loxodrome takes the most direct route from point 1 to point 2 by following compass course 56°. In (b), the loxodrome follows a different course of 84.2°. It still leads to point 2, but has to circle the earth one time to do so. In both illustrations, the great circle route between the two points is the shortest route possible. Notice, too, if you miss your destination on any rhumb course other than along the equator, you will eventually end up at the north or south pole. Can we ever use a compass to follow a great circle route, if using a compass to navigate any direction other than due north-south or east-west puts us on a rhumb line or loxodrome? The answer is a qualified yes. You can approximate the great circle route by taking a series of short rhumb line courses.

You would travel a particular compass course for a while before changing to another course, and then another, until you arrived at your destination. To do this, the navigator divides the overall track between his starting and ending points into a series of small segments. Between each segment is a waypoint, a location where he or she will change course slightly. The length of a course segment is about the distance the navigator expects to travel in a day, if by ship, or in an hour or so, if by plane, depending on the plane's speed. On a ship, the course change might take place at the same time every day. For instance, navigators might change at local noon, the time when navigators traditionally used their sextants to determine their latitude by the sun's noon-time meridian passage. Today, airplanes and ships are equipped with autopilots, and course corrections are made automatically from time to time in order to stay close to a theoretic great circle course. The more rhumb lines or legs the course is divided into, the closer individual rhumb lines will approximate the great circle route. When a great circle and rhumb line course are shown together on a Mercator map, the great circle route appears as a curved line, while the rhumb line is straight. On a sphere, they appear just the opposite, the great circle being the shortest "straight line" course, while the rhumb line is the longer curved course between points unless the points are directly north or south of each other or along the equator. To give an example of just how dramatic the difference between navigating a rhumb line and great circle course can be, consider a trip between London, England, and Anchorage, Alaska. The latitude-longitude of London's Heathrow International Airport is 51° 28' 15.72"N, 0° 27' 30.98"W. Anchorage International Airport is located at 61° 10' 14.69"N, 149° 59' 33.66"W. The great circle distance between them, the most direct route, passes over Greenland and near the north pole, and is 4,475 miles (7,201 km). The rhumb line bearing to Anchorage from London is about 276°(almost due west by compass) and the distance is 5,731 miles (9,223 km). Clearly, the rhumb line distance is longer, almost 28 percent longer. These differences cannot be ignored by airlines or shipping companies. The time and fuel-cost implications are considerable. Obs.: Ortodromia é a linha que une dois pontos à superfície da Terra, à qual corresponde o caminho mais curto entre eles. Este é o sentido normalmente atribuído no âmbito da navegação marítima ou aérea. Formalmente, uma ortodromia é a deformação do círculo máximo quando plotado sobre uma representação planisférica da Terra. Já numa superfície esférica, a ortodromia cobre a seção de um círculo máximo que divide um elipsoide de revolução em dois hemisférios. Cartograficamente é uma linha torsa, isto é, uma linha que não pode ser assente sobre um plano.

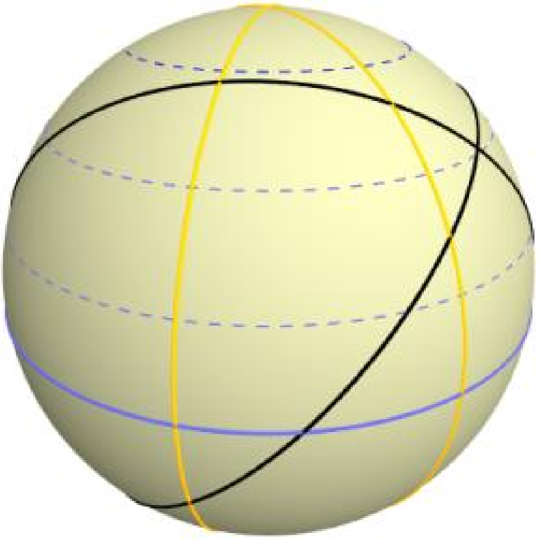

Figure 1.5: ds05.jpg - Ortodrómicas traçadas sobre uma esfera.

A ortodromia e a navegação Entre dois pontos quaisquer da superfície terrestre podem traçar-se dois tipos de rotas distintas: a ortodromia, que minimiza a distância entre eles; e a loxodromia, que mantém constante o rumo, isto é, o ângulo entre o caminho seguido e os meridianos. Caso os pontos estejam separados por um arco de 180° (isto é, sejam antípodas), existe uma infinidade de rotas ortodrómicas que os ligam, pelo que, esquecendo outras considerações, em qualquer direção que se partir, se a rota for mantida, chega-se igualmente ao outro ponto. A ortodromia pura tem o inconveniente de necessitar de correções constantes de rumo, já que o ângulo com cada meridiano é sempre diferente, excepto quando a viagem se faça sobre o Equador ou ao longo de um meridiano.

Em navegação marítima, a ortodromia só é utilizada em circunstâncias especiais e em trajetos muito longos, quando o fator tempo seja decisivo, o que não acontece na navegação aérea. Em qualquer dos casos, a sua aplicação prática é concretizada através de um conjunto de segmentos de loxodromia, isto é, de segmentos a rumo constante entre pontos intermédios escolhidos ao longo da rota. Outro inconveniente deste tipo de trajeto reside no facto de as ortodromias entre pontos distantes atingirem muitas vezes latitudes elevadas, onde a ocorrência de gelo e de condições atmosféricas adversas é frequente. Nestes casos, é sempre possível optar-se por uma rota mista, constituída por dois segmentos de ortodromia, que ligam os pontos de partida e de chegada a um certo paralelo limite, e um segmento de loxodromia intermédio, ao rumo este ou oeste, ao longo desse paralelo.

Rhumb line
https://en.wikipedia.org/wiki/Rhumb-line

Figure 1.6: ds06.png - Ortodromicas tracadas sobre uma esfera.

The effect of following a rhumb line course on the surface of a globe was first discussed by the Portuguese mathematician Pedro Nunes in 1537, in his Treatise in Defense of the Marine Chart, with further mathematical development by Thomas Harriot in the 1590s.

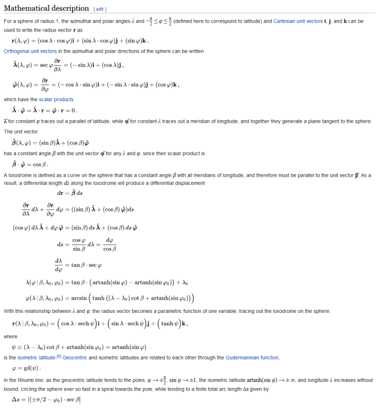
A rhumb line can be contrasted with a great circle, which is the path of shortest distance between two points on the surface of a sphere. On a great circle, the bearing to the destination point does not remain constant. If one were to drive a car along a great circle one would hold the steering wheel fixed, but to follow a rhumb line one would have to turn the wheel, turning it more sharply as the poles are approached. In other words, a great circle is locally "straight" with zero geodesic curvature, whereas a rhumb line has non-zero geodesic curvature.

Meridians of longitude and parallels of latitude provide special cases of the rhumb line, where their angles of intersection are respectively 0o and 90o. On a north-south passage the rhumb line course coincides with a great circle, as it does on an east-west passage along the equator.

On a Mercator projection map, any rhumb line is a straight line; a rhumb line can be drawn on such a map between any two points on Earth without going off the edge of the map. But theoretically a loxodrome can extend beyond the right edge of the map, where it then continues at the left edge with the same slope (assuming that the map covers exactly 360 degrees of longitude).

Rhumb lines which cut meridians at oblique angles are loxodromic curves which spiral towards the poles.[1] On a Mercator projection the north and south poles occur at infinity and are therefore never shown. However the full loxodrome on an infinitely high map would consist of infinitely many line segments between the two edges. On a stereographic projection map, a loxodrome is an equiangular spiral whose center is the north or south pole.

All loxodromes spiral from one pole to the other. Near the poles, they are close to being logarithmic spirals (which they are exactly on a stereographic projection, see below), so they wind around each pole an infinite number of times but reach the pole in a finite distance. The pole-to-pole length of a loxodrome (assuming a perfect sphere) is the length of the meridian divided by the cosine of the bearing away from true north. Loxodromes are not defined at the poles.



Mathematical description [edit]

For a sphere of radius 1, the azimuthal and polar angles λ and $-\frac{\pi}{2} \le \varphi \le \frac{\pi}{2}$ (defined here to correspond to latitude) and Cartesian unit vectors $\mathbf{i}$, $\mathbf{j}$, and $\mathbf{k}$ can be used to write the radius vector $\mathbf{r}$ as

$$\mathbf{r}(\lambda,\varphi) = (\cos\lambda\cdot\cos\varphi)\mathbf{i} + (\sin\lambda\cdot\cos\varphi)\mathbf{j} + (\sin\varphi)\mathbf{k}\,.$$

Orthogonal unit vectors in the azimuthal and polar directions of the sphere can be written

$$\hat{\boldsymbol{\lambda}}(\lambda,\varphi) = \sec\varphi\frac{\partial\mathbf{r}}{\partial\lambda} = (-\sin\lambda)\mathbf{i} + (\cos\lambda)\mathbf{j}\,,$$

$$\hat{\boldsymbol{\varphi}}(\lambda,\varphi) = \frac{\partial\mathbf{r}}{\partial\varphi} = (-\cos\lambda\cdot\sin\varphi)\mathbf{i} + (-\sin\lambda\cdot\sin\varphi)\mathbf{j} + (\cos\varphi)\mathbf{k}\,,$$

which have the scalar products

$$\hat{\boldsymbol{\lambda}}\cdot\hat{\boldsymbol{\varphi}} = \hat{\boldsymbol{\lambda}}\cdot\mathbf{r} = \hat{\boldsymbol{\varphi}}\cdot\mathbf{r} = 0\,.$$

$\hat{\lambda}$ for constant φ traces out a parallel of latitude, while $\hat{\boldsymbol{\varphi}}$ for constant λ traces out a meridian of longitude, and together they generate a plane tangent to the sphere.

The unit vector

$$\hat{\boldsymbol{\beta}}(\lambda,\varphi) = (\sin\beta)\hat{\boldsymbol{\lambda}} + (\cos\beta)\hat{\boldsymbol{\varphi}}$$

has a constant angle β with the unit vector $\hat{\boldsymbol{\varphi}}$ for any λ and φ, since their scalar product is

$$\hat{\boldsymbol{\beta}}\cdot\hat{\boldsymbol{\varphi}} = \cos\beta\,.$$

A loxodrome is defined as a curve on the sphere that has a constant angle β with all meridians of longitude, and therefore must be parallel to the unit vector $\hat{\boldsymbol{\beta}}$. As a result, a differential length ds along the loxodrome will produce a differential displacement

$$d\mathbf{r} = \hat{\boldsymbol{\beta}}\,ds$$

$$\frac{\partial\mathbf{r}}{\partial\lambda}\,d\lambda + \frac{\partial\mathbf{r}}{\partial\varphi}\,d\varphi = ((\sin\beta)\,\hat{\boldsymbol{\lambda}} + (\cos\beta)\,\hat{\boldsymbol{\varphi}})ds$$

$$(\cos\varphi)\,d\lambda\,\hat{\boldsymbol{\lambda}} + d\varphi\,\hat{\boldsymbol{\varphi}} = (\sin\beta)\,ds\,\hat{\boldsymbol{\lambda}} + (\cos\beta)\,ds\,\hat{\boldsymbol{\varphi}}$$

$$ds = \frac{\cos\varphi}{\sin\beta}\,d\lambda = \frac{d\varphi}{\cos\beta}$$

$$\frac{d\lambda}{d\varphi} = \tan\beta\cdot\sec\varphi$$

$$\lambda(\varphi\,|\,\beta,\lambda_0,\varphi_0) = \tan\beta\cdot\left(\operatorname{artanh}(\sin\varphi) - \operatorname{artanh}(\sin\varphi_0)\right) + \lambda_0$$

$$\varphi(\lambda\,|\,\beta,\lambda_0,\varphi_0) = \arcsin\Big(\tanh\left((\lambda-\lambda_0)\cot\beta + \operatorname{artanh}(\sin\varphi_0)\right)\Big)$$

With this relationship between λ and φ, the radius vector becomes a parametric function of one variable, tracing out the loxodrome on the sphere:

$$\mathbf{r}(\lambda\,|\,\beta,\lambda_0,\varphi_0) = \Big(\cos\lambda\cdot\operatorname{sech}\psi\Big)\mathbf{i} + \Big(\sin\lambda\cdot\operatorname{sech}\psi\Big)\mathbf{j} + \Big(\tanh\psi\Big)\mathbf{k}\,,$$

where

$$\psi \equiv (\lambda-\lambda_0)\cot\beta + \operatorname{artanh}(\sin\varphi_0) = \operatorname{artanh}(\sin\varphi)$$

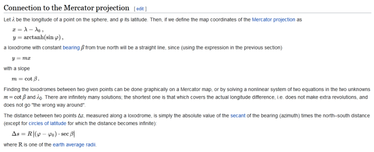
is the isometric latitude.[5] Geocentric and isometric latitudes are related to each other through the Gudermannian function,

$$\varphi = \operatorname{gd}(\psi)\,.$$

In the Rhumb line, as the geocentric latitude tends to the poles, $\varphi \to \pm\frac{\pi}{2}$, $\sin\varphi \to \pm 1$, the isometric latitude $\operatorname{artanh}(\sin\varphi) \to \pm\infty$, and longitude λ increases without bound, circling the sphere ever so fast in a spiral towards the pole, while tending to a finite total arc length Δs given by

$$\Delta s = \left|(\pm\pi/2 - \varphi_0)\cdot\sec\beta\right|$$

Figure 1.7: ds07.png



Connection to the Mercator projection [edit]

Let λ be the longitude of a point on the sphere, and φ its latitude. Then, if we define the map coordinates of the Mercator projection as

$$x = \lambda - \lambda_0\,,$$
$$y = \operatorname{arctanh}(\sin\varphi)\,,$$

a loxodrome with constant bearing β from true north will be a straight line, since (using the expression in the previous section)

$$y = mx$$

with a slope

$$m = \cot\beta\,.$$

Finding the loxodromes between two given points can be done graphically on a Mercator map, or by solving a nonlinear system of two equations in the two unknowns $m = \cot\beta$ and λ_0. There are infinitely many solutions; the shortest one is that which covers the actual longitude difference, i.e. does not make extra revolutions, and does not go "the wrong way around".

The distance between two points Δs, measured along a loxodrome, is simply the absolute value of the secant of the bearing (azimuth) times the north–south distance (except for circles of latitude for which the distance becomes infinite):

$$\Delta s = R\left|(\varphi - \varphi_0)\cdot\sec\beta\right|$$

where R is one of the earth average radii.

Figure 1.8: ds08.png

Its use in navigation is directly linked to the style, or projection of certain navigational maps. A rhumb line appears as a straight line on a Mercator projection map.[1]

The name is derived from Old French or Spanish respectively: "rumb" or "rumbo", a line on the chart which intersects all meridians at the same angle.[1] On a plane surface this would be the shortest distance between two points. Over the Earth's surface at low latitudes or over short distances it can be used for plotting the course of a vehicle, aircraft or ship.[1] Over longer distances and/or at higher latitudes the great circle route is significantly shorter than the rhumb line between the same two points. However the inconvenience of having to continuously change bearings while travelling a great circle route makes rhumb line navigation appealing in certain instances.

The point can be illustrated with an East-West passage over 90 degrees of longitude along the equator, for which the great circle and rhumb line distances are the same at 5,400 nautical miles (10,000 km). At 20 degrees north the great circle distance is 4,997 miles (8,042 km) while the rhumb line distance is 5,074 miles (8,166 km), about 1,5 percent further. But at 60 degrees north the great circle distance is 2,485 miles (3,999 km) while the rhumb line is 2,700 miles (4,300 km), a difference of 8,5 percent. A more extreme case is the air route between New York City and Hong Kong, for which the rhumb line path is 9,700 nautical miles (18,000 km). The great circle route over the North Pole is 7,000 nautical miles (13,000 km), or 5,5 hours less flying time at a typical cruising speed.

Some old maps in the Mercator projection have grids composed of lines of latitude and longitude but also show rhumb lines which are oriented directly towards north, at a right angle from the north, or at some angle from the north which is some simple rational fraction of a right angle. These rhumb lines would be drawn so that they would converge at certain points of the map: lines going in every direction would converge at each of these points. See compass rose. Such maps would necessarily have been in the Mercator projection therefore not all old maps would have been capable of showing rhumb line markings.

The radial lines on a compass rose are also called rhumbs. The expression "sailing on a rhumb" was used in the 16th-19th centuries to indicate a particular compass heading.[1]

Early navigators in the time before the invention of the marine chronometer used rhumb line courses on long ocean passages, because the ship's latitude could be established accurately by sightings of the Sun or stars but there was no accurate way to determine the longitude. The ship would sail north or south until the latitude of the destination was reached, and the ship would then sail east or west along the rhumb line (actually a parallel, which is a special case of the rhumb line), maintaining a constant latitude and recording regular estimates of the distance sailed until evidence of land was sighted.[6] Generalizations On the Riemann sphere Main article: Möbius transformation

The surface of the Earth can be understood mathematically as a Riemann sphere, that is, as a projection of the sphere to the complex plane. In this case, loxodromes can be understood as certain classes of Möbius transformations. Spheroid The formulation above can be easily extended to a spheroid.[7][8][9][10][11] The course of the rhumb line is found merely by using the ellipsoidal isometric latitude. Similarly distances are found by multiplying the ellipsoidal meridian arc length by the secant of the azimuth. Source: https://en.wikipedia.org/wiki/Rhumb-line

Pag. 138(159) -6.1 What Is a Polyhedron? Polyhedra are mathematically sophisticated and appear in more than three dimensions. In solid geometry, a polyhedron is a 3D solid whose faces join at their edges. The word derives from the Greek poly (many) plus the Indo-European hedron (seat). There are many distinct families of polyhedra, the result of differences in their geometry and various mathematical properties. We focus on two types, the Platonic and Archimedean, because they are the most common polyhedral frameworks used in spherical subdivision. The five Platonic solids are regular polyhedra, which means their faces are the same regular type-equilateral triangles, squares, or pentagons. The 13 Archimedean solids are closely related to the Platonic solids, but have two or more regular faces and some have hexagons, octagons, and decagons. We can define Platonic and Archimedean solids as 3D convex forms with no holes, depressions, protrusions, or penetrations. They are totally defined by their vertices, edges, and faces. All vertices lie on the surface of a surrounding sphere called the circumsphere, whose origin is the same as the center of the polyhedron. The edges of Platonic and Archimedean solids are equal-length straight edges between two neighboring vertices. On spherical versions, edges are equal-length geodesic arcs. The faces of planar polyhedra are regular polygons, and the plane of any one of them, if extended, does not pass through the interior volume of the polyhedron. An individual Platonic or Archimedean solid will have the same number and types of faces sequenced in the same way around every one of its vertices. Faces do not penetrate one another and every face joins another at an edge, leaving no gaps and causing no overlaps. For spherical polyhedra, the sum of the face angles surrounding any vertex is always 360^o. Figure 6.1 shows the planar and spherical version of a dodecahedron, a Platonic solid with 20 vertices, 30 edges, and 12 pentagonal faces. The planar face angles shown in (a) are all 72^o, and the dihedral angle, the angle between faces measured perpendicular to their shared edge, is approximately 116.56^o. The spherical version shown in (b) has face angles= 120^o.The arc angles of the spherical edges are each approximately 41.81^o Spherical Platonic and Archimedean solids can be derived from their planar versions very easily. All vertices of these solids are the same distance from the center of the polyhedron, thus they are all on the surface of a circumscribing sphere. The vertices on either end of a chord, a platonic edge, and the center of the solid define the plane of the arc, a geodesic arc, between neighboring points. In Figure 6.1(a), one such plane is shown as a small

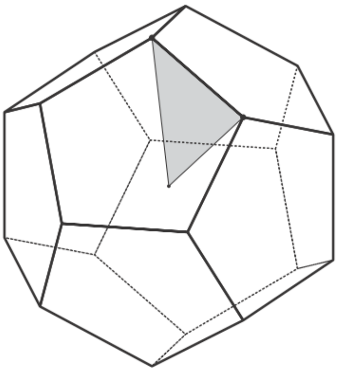


Figure 1.9: ds09a.png - Planar and spherical polyhedra.

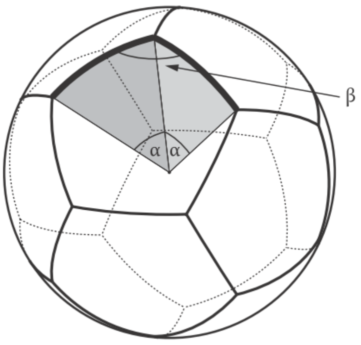

Figure 1.10: ds09b.png - Planar and spherical polyhedra.

gray triangle defined by three points: the origin and two vertices. 1 Figure 6.1(b) shows the spherical version of the dodecahedron from the same viewpoint and scale as (a), and every edge in (a) has been transformed into a geodesic arc in (b). The planes of two arcs are emphasized in (b). You can think of these geodesic arcs as central projections of a planar polyhedron's edges. The projection is on the polyhedron's circumsphere, which acts like a curved projection screen. An imaginary point light source located at the origin produces a shadow of the chord, its arc, on the circumsphere screen. In Figure 6.1(b), the two emphasized arcs demonstrate another fact about angles on a sphere. The surface anglebetween the two arcs is the dihedral angle, between the great circle planes that define them (see Section 4.16.6). The arcs themselves are the sides of the spherical face and are measured by their central angles from the center or origin of the sphere. They are each labeled . In any given Platonic or Archimedean polyhedron (planar or spherical version), all chords or arcs are the same length. With this general introduction, let us take a closer look at the properties of these two families of polyhedra.

Pag. 174(195) - 6.4.8 Waterman Polyhedra We have discussed Platonic and Archimedean solids in detail because we will use them in the next chapter to jump-start the spherical subdivision process. For completeness, however, we want to mention the Waterman polyhedra because some are nearly spherical and already highly subdivided. Unlike spherical Platonic and Archimedean solids, Waterman polyhedra do not evenly distribute points on a sphere or even distribute points on the same radius sphere. Waterman polyhedra are important additions to a spherist's tool kit because they exhibit many of the properties we have been discussing, such as symmetry, great circles, antipodal points, and so forth, and they demonstrate a rich way to develop spherical geometry that can solve certain application problems. In 1988, Steve Waterman began a series of investigations into gridded maps. We saw an example of his butterfly map projection alongside Cahill's map when we discussed Fuller's Dymaxion maps in Chapter 2. Waterman's projection studies led to the development of entirely new families of polyhedra and some resemble highly subdivided spheres. The way they are constructed is unique. Waterman polyhedra begin with a 3D lattice of points. The points are the centers of stacked spheres arranged similarly to the way oranges are stacked in a grocery store. There are several ways to pack (stack) equal spheres to maximize the number in any given volume. In cubic close packing (CCP), also called face-centered cubic (FCC) packing, an infinite number of tangent spheres are packed in layers or square grids and stacked,one layer on top of another. Each layer of spheres occupies the intergrid spaces of their adjacent layers. If all spheres have a diameter of 2 , their centers will fall only on integer coordinate values, if one of the sphere's center occupies the origin of the Cartesian space at coordinates (0, 0, 0). Figure 6.30(a) shows how CCP spheres are arranged on alternating layers. The grid spacing is one unit in the x, y, and z (perpendicular to the page) direction. The solid spheres are on even z-planes, including the z = 0 plane. The spheres shown dashed are on odd z-planes. The centers of all the spheres, the lattice points in Waterman clusters of spheres, are marked with small dots on the grid. Figure 6.30(b) shows the section of the CCP stack indicated by (a). Both the grid in (a) and the stack in (b) are examples of a theoretical grid and stacking that extends infinitely in the x,y, and z directions. Footnote - It is interesting to note that Johann Carl Friedrich Gauss(1777-1855) proved that the densest possible packing of equal spheres is $d = \frac{\pi}{3\sqrt{2}} = 0.74048$, or 74 percent and that the space between spheres (not occupied) is 0.25951, or 25.9 percent. Coincidentally, this is the same density packing ratio of an inscribed sphere to a rhombic dodecahedron polyhedron. The rhombic dodecahedron also stacks as a polyhedron with coincident lattice points to the FCC. In CCP, 12 spheres surround every sphere in the pack, and their centers are equidistant from the center of the sphere they surround. If the centers of these 12 spheres are connected, they define the vertices of a cuboctahedron, Fuller's vector equilibrium (see Section 2.1). Footnote - In synergetic geometry, Buckminster Fuller makes extensive use of CCP spheres and refers to some of their configurations as the isotropic vector matrix (IVM). See (Edmondson 1987, 127) for a good explanation of how IVM extends Fuller's concept of vector equilibrium (VE) and how it relates to his octet truss design. Steven Waterman believes that Fuller was not aware that FCC (he called it CCP) had square root integer distance between any two-sphere centers.

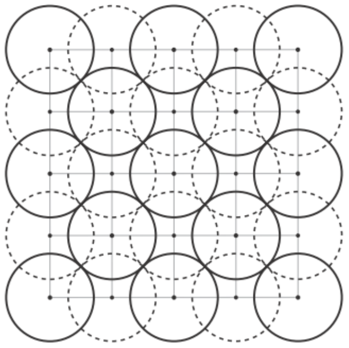

Figure 1.11: ds10a.png - Cubic closest packing.

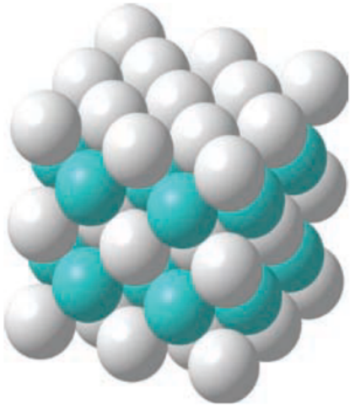

Figure 1.12: ds10b.png - Cubic closest packing.

A Waterman polyhedron is defined by the convex hull of all the lattice points (the centers of stacked spheres) that are within a defined radius from the lattice's origin. Points outside this radius are ignored. A convex hull is the minimum convex polyhedra (faces, points, and edges) that completely surround the points. In a sense, the convex hull is like a shrink-wrap surrounding the most extended set of points. The Waterman Polyhedra, called W1, are defined by a radius of $\sqrt{2}$X 1. This radius selects only the 12 points surrounding the origin, and their convex hull is the same as the cuboctahedron or Fuller's VE. As the defined radius increases, more lattice points are selected and their convex hull, the Waterman polyhedron, becomes more and more complex and is made up of many more faces, points, and edges. When the defined radius has a root greater than 300, Waterman polyhedra resemble spherical subdivisions. Figure 6.31 shows two examples with selected lattice points (with spheres around them) and the resulting convex hull Waterman polyhedron. Footnote - Images courtesy of Rene K. Mueller, SimplyDifferently.org. These Waterman polyhedra are referred to by their square root numbers. Notice that a higher root number results in more points, edges, and faces on the sphere. Waterman polyhedra exhibit high degrees of edge, face, and vertex symmetry. For some cases, it is possible to pass planes through the Waterman sphere stack and define a lattice of points that create a hemispherical or copula polyhedra that resemble a geodesic dome. Footnote - See Paul Bourke, \Waterman polyhedra data generator," http://local.wasp.uwa.edu.au/ pbourke/geometry/waterman/gen/, 2004. The FCC packing and positioning (one sphere at the origin of the Cartesian space) produces one family of Waterman polyhedra; however, other families result when the origin of the sphere cluster is repositioning to other symmetrical positions within the lattice. There are seven possible origins for FCC packings, Footnote - Seven possible point lattice origins: (1) sphere center, (2) spheres touch point, (3) spheres triangle center (there are two variations), (4) spheres forming tetrahedron, (5) spheres forming square-based pyramid, and (6) spheres. and corresponding Waterman Polyhedra can be created with sphere stacks having a 2 diameter, or any other consistent diameter. If their diameter is not 2, their centers will not necessarily fall on integer xyz-coordinates.

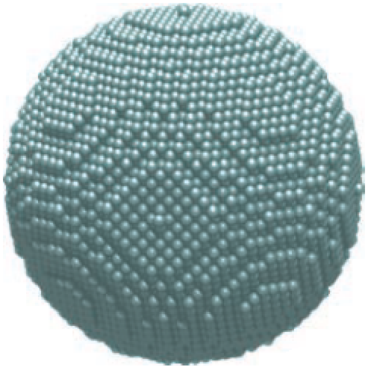

Figure 1.13: ds11a.png - $\sqrt{200}$

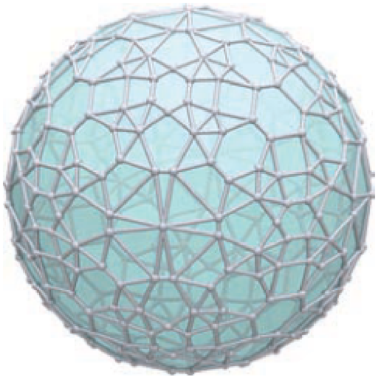

Figure 1.14: ds11b.png - $\sqrt{200}$

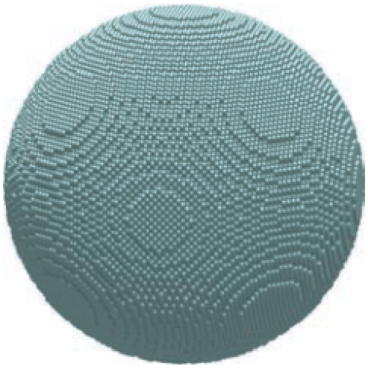

Figure 1.15: ds11c.png - $\sqrt{2000}$

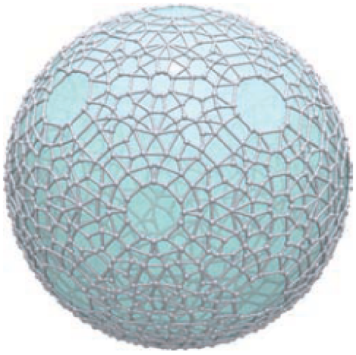

Figure 1.16: ds11d.png - $\sqrt{2000}$

Waterman polyhedra names are simple. They are labeled Wn, with n being the defined radius integer parameter. The concept of Waterman polyhedra has been generalized to include point lattices created by packed (stacked) polyhedra in addition to spheres. Packs of polyhedra, restricted to certain integer x,y,z grids, will produce more than 60 new families of polyhedra. In these cases, the Waterman polyhedra naming convention is necessarily more complex because their names must account for the type of polyhedron in the stack, the origin location for the stack lattice, and the defined radius parameter. For more information on Waterman polyhedra, see Mark Newbold's website. Footnote - http://dogfeathers.com/java/ccppoly.html. To summarize, basic Waterman polyhedra are developed from Waterman spheres with diameters of $\sqrt{2}$ and packed in a CCP or FCC manner. Their centers are located at integer x-, y-, and z-coordinates, and one sphere in the pack is centered at the Cartesian origin, at coordinates (0, 0, 0). A defined radius from the origin, a multiple of 2n, selects a set of lattice points, the centers of spheres. A Waterman polyhedron is the convex hull of the selected set of lattice points. The number of points, edges, and faces in a Waterman polyhedron (the convex hull of the selected points) obey Euler's law, which states the number of vertices + faces = edges + 2. The number of vertices in a Waterman polyhedron is a fixed set. In other words, if one Waterman polyhedron has 2,000 points, another will not have an arbitrary 2,001 points. Chords between points define polygons, most of which are not regular (equilateral triangles, pentagons, hexagons, etc.). A general definition of Waterman polyhedra include FCC lattices created by both polyhedral and spherical packs. Different Cartesian origins for these lattices in combination with defined radii producing different families of Waterman polyhedra. Not all points of a Waterman polyhedron are on a circumscribing sphere, such as the Platonic and Archimedean solids already described; Waterman polyhedra exhibit high degrees of point, edge, and face symmetry. As the defined radius increases, the number of different face types, edge lengths, angles, and areas also increase. These may be limiting factors in some spherical applications.

Pag. 202(223) - 8.5.2 Edge Reference Points Class I subdivision begins at the PPT's edges. A series of reference points is located along the edges, dividing the edges into segments equal in number to the subdivision frequency. Reference points have a regular pattern. Their spacing may be equal or unequal, but all three PPT edges will have the same pattern regardless of the spacing used. There are two approaches to defining reference points: Equal-chords and Equal-arcs. Each approach can produce several different grids. For Equal-chords, the PPT's apex-to-apex chords (all three are the same length) are subdivided with equally spaced reference points. These reference points are on the PPT's edge chord; thus, they are inside the sphere. They must be projected to the surface of the sphere before they can be used as subdivision

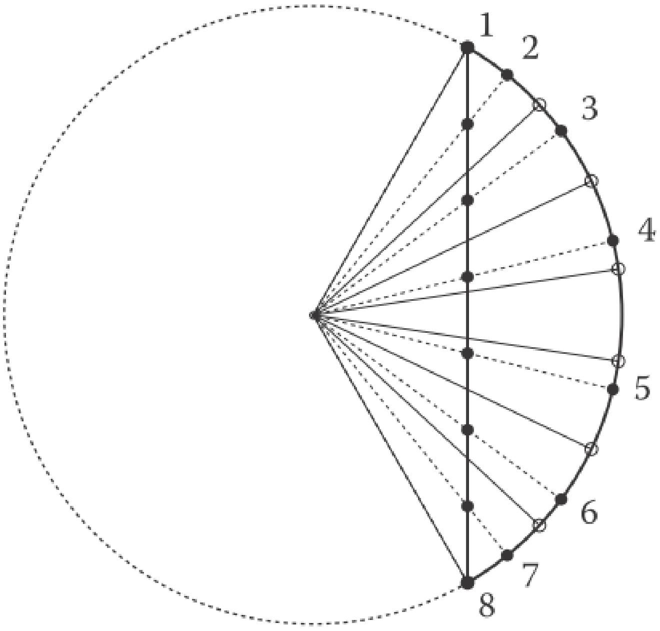

Figure 1.17: ds05-01.png - 7v Equal-chords, Equal-arcs subdivision.

references. For Equal-arcs, the PPT's arc edge (not its chords) is evenly subdivided with points, which are used as references, as is. No projection is needed because these points are already on the surface of the sphere. Figure 8.8 illustrates the difference between these two approaches with a 7v subdivision of a tetrahedron's chord. We use an odd frequency so that reference points from the two approaches will not be superimposed on one another. This makes the figure easier to read. We also use the chord of a tetrahedron, the longest of any Platonic with a unit circumsphere, to make comparisons between Equal-chords and Equal-arcs more vivid. Referring to the figure, points 1 and 8 are the chord's end points on the surface of the circumscribing sphere represented in the cross section by the circumscribing circle. For grids based on equal chord reference points, the chord between points 1 and 8 is divided into seven equal segments (7v) with points located between them. The dashed lines show chord points projected from the center of the sphere to its surface. They are numbered 2 through 7 (1 and 8 are vertices of the tetrahedron's PPT edge and are already on the sphere's surface). By inspecting the figure, you can easily see the arc spacing between projected chord points is not equal. The difference between the largest and smallest arc length is more than 2:1 in this example. To put some numbers to this, the tetrahedron's overall edge arc is approximately 109.5°, and the seven arcs resulting from Equal-chords subdivision are 9.4°, 14.1°, 19.8°, 22.8°, 19.8°, 14.1°, and 9.4°, in that order. It is also evident that the arc lengths are symmetrical; that is, arc 1-2 equals 7-8, arc 2-3 equals 6-7, and so on. The equal-arc points in Figure 8.8 are marked with small hollow circles on the surface of the sphere. They do not have to be projected. Each is spaced at 15.6o.Note that lines between them and the center of the sphere divide the chord into unequal segments. Appendix C lists simple formulas for dividing chords and arcs between any two points on the sphere into equal segments and projecting points to the surface of the sphere.

Radian Measure Another commonly used angle measurement is the radian. To define a radian, first consider a circle of radius r and two radii OA and OB. The angle formed by the two radii is a central angle. The portion of the circle between and is an arc of the circle and is written $\overline{AB}$. We say that $\overline{AB}$ subtends the angle . The length of $\overline{AB}$ is s (see Figure 5.19).

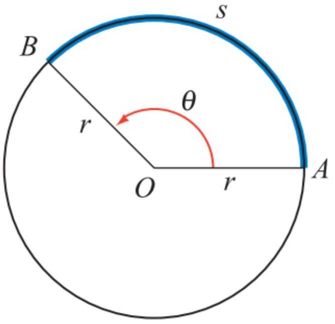

Figure 1.18: ds05-02a.png

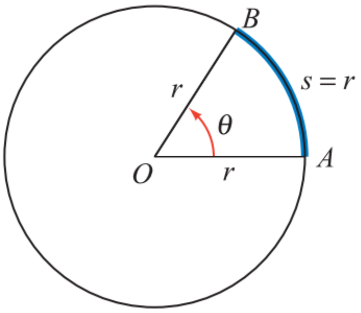

Figure 1.19: ds05-02b.png

One radian is the measure of the central angle subtended by an arc of length r on a circle of radius r.

Definition of Radian Measure

Given an arc of length s on a circle of radius r, the measure of the central angle subtended by the arc is $= \frac{s}{r}$ radians.

Pag. 236(257) - Class III grid development and PPT projection sequence.

8.7.5 Developing Grids Class III lacks the convenient 3D equal-chord and equal-arc references that were the starting points for Class I and II subdivisions. For Class III, we use a different approach and create a 2D grid, which we will eventually project onto the PPT's surface. Although we will develop a triangular grid in our example, it is possible to use this same technique to project any 2D geometry or pattern onto a sphere. Figure 8.42 graphically summarizes the entire sequence we will use; the remainder of this chapter details these steps. The PPT's tessellation is first defined as a 2D trigrid with the required frequency and orientation relative to the PPT's edges. Figure 8.42(a) shows the grid and the triangular faces that are completely within the PPT. Trigrid point coordinates are converted to Cartesian values and positioned so that one of the grid's directions is perpendicular to the xz-plane and centered over the origin, where it is scaled to correspond to the final PPT's chord length, as shown in (b). The scaled grid is then translated up the +z-axis, a distance equal to the polyhedron's insphere radius. The center of the grid is tangent to the insphere and its apices are tangent to its circumsphere (c). Trigrid points are projected from the origin to the surface of the sphere by normalizing each grid point's coordinates. An arrow from the origin through one grid point shows its projection to the sphere (d). The result is a single face-zenith tessellated PPT. Copies are then replicated to cover the rest of the sphere.

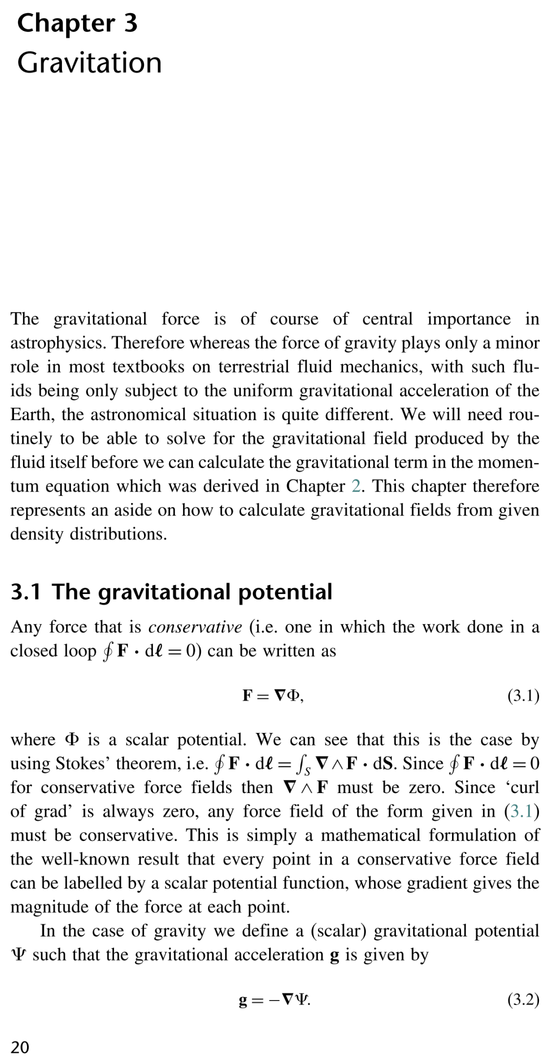
2) C:/DATA-NovoVivo-127-2020/Books-127-2020/Advances In Geometric Modeling/Advances In Geometric Modeling.pdf Pag. 01(13) - Polygonal Subdivision Curves for Computer Graphics and Geometric Modeling.

A polygonal subdivision curve is the limit of subdivision of a polygonal complex. Such a complex, whose shape depends on the scheme involved, is simply a control mesh that converges to a curve rather than a surface. The use of polygonal complexes has been motivated by the curve interpolation problem in subdivision surfaces. This is one of the major interpolation constraints that is partially addressed in the literature. The definition of curves by polygonal complexes carries with it cross derivative information which can be naturally embodied in the mesh of a subdivision surface. This chapter gives an overview of such complexes, their polygonal subdivision curves and their applications for computer graphics and geometric modeling.

3) C:/DATA-NovoVivo-127-2020/Books-127-2020/Principles of Astrophysical Fluid Dynamics 2007/Principles of Astrophysical Fluid Dynamics 2007.pdf Pag. 20 (32) - Chapter 3 - Gravitation.

The gravitational force is of course of central importance in astrophysics. Therefore whereas the force of gravity plays only a minor role in most textbooks on terrestrial fluid mechanics, with such flu- ids being only subject to the uniform gravitational acceleration of the Earth, the astronomical situation is quite different. We will need rou- tinely to be able to solve for the gravitational field produced by the fluid itself before we can calculate the gravitational term in the momen- tum equation which was derived in Chapter 2. This chapter therefore represents an aside on how to calculate gravitational fields from given density distributions.



Chapter 3

Gravitation

The gravitational force is of course of central importance in astrophysics. Therefore whereas the force of gravity plays only a minor role in most textbooks on terrestrial fluid mechanics, with such fluids being only subject to the uniform gravitational acceleration of the Earth, the astronomical situation is quite different. We will need routinely to be able to solve for the gravitational field produced by the fluid itself before we can calculate the gravitational term in the momentum equation which was derived in Chapter 2. This chapter therefore represents an aside on how to calculate gravitational fields from given density distributions.

3.1 The gravitational potential

Any force that is *conservative* (i.e. one in which the work done in a closed loop $\oint \mathbf{F} \cdot \mathrm{d}\boldsymbol{\ell} = 0$) can be written as

$$\mathbf{F} = \boldsymbol{\nabla}\Phi, \tag{3.1}$$

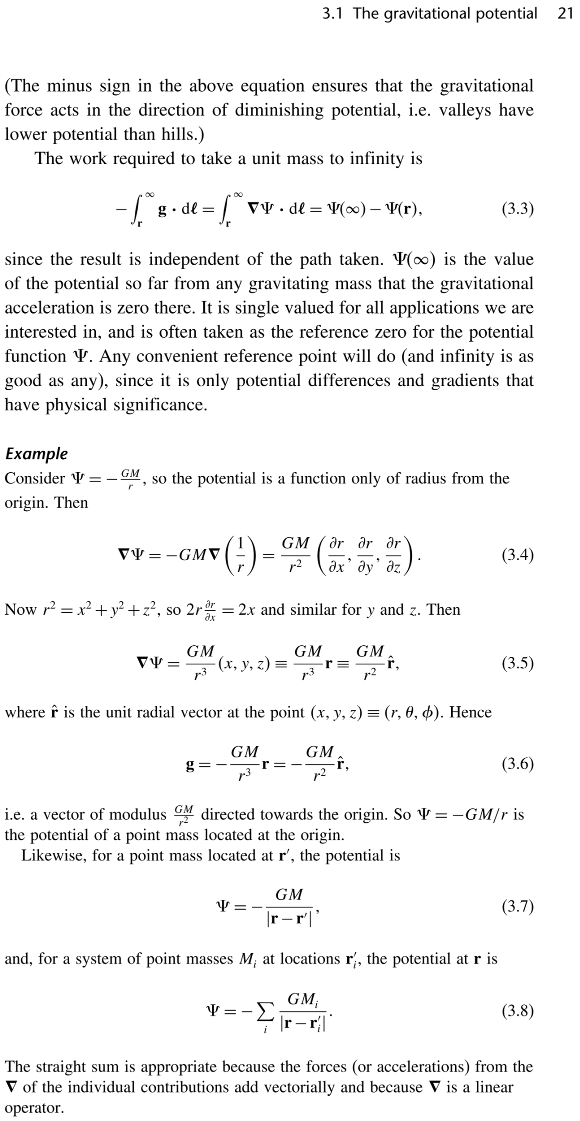
where Φ is a scalar potential. We can see that this is the case by using Stokes' theorem, i.e. $\oint \mathbf{F} \cdot \mathrm{d}\boldsymbol{\ell} = \int_S \boldsymbol{\nabla} \wedge \mathbf{F} \cdot \mathrm{d}\mathbf{S}$. Since $\oint \mathbf{F} \cdot \mathrm{d}\boldsymbol{\ell} = 0$ for conservative force fields then $\boldsymbol{\nabla} \wedge \mathbf{F}$ must be zero. Since 'curl of grad' is always zero, any force field of the form given in (3.1) must be conservative. This is simply a mathematical formulation of the well-known result that every point in a conservative force field can be labelled by a scalar potential function, whose gradient gives the magnitude of the force at each point.

In the case of gravity we define a (scalar) gravitational potential Ψ such that the gravitational acceleration $\mathbf{g}$ is given by

$$\mathbf{g} = -\boldsymbol{\nabla}\Psi. \tag{3.2}$$

20

Figure 1.36: pafd01.png



(The minus sign in the above equation ensures that the gravitational force acts in the direction of diminishing potential, i.e. valleys have lower potential than hills.)

The work required to take a unit mass to infinity is

$$-\int_{\mathbf{r}}^{\infty} \mathbf{g} \cdot \mathrm{d}\boldsymbol{\ell} = \int_{\mathbf{r}}^{\infty} \boldsymbol{\nabla}\Psi \cdot \mathrm{d}\boldsymbol{\ell} = \Psi(\infty) - \Psi(\mathbf{r}), \tag{3.3}$$

since the result is independent of the path taken. $\Psi(\infty)$ is the value of the potential so far from any gravitating mass that the gravitational acceleration is zero there. It is single valued for all applications we are interested in, and is often taken as the reference zero for the potential function Ψ. Any convenient reference point will do (and infinity is as good as any), since it is only potential differences and gradients that have physical significance.

Example

Consider $\Psi = -\frac{GM}{r}$, so the potential is a function only of radius from the origin. Then

$$\boldsymbol{\nabla}\Psi = -GM\boldsymbol{\nabla}\left(\frac{1}{r}\right) = \frac{GM}{r^2}\left(\frac{\partial r}{\partial x}, \frac{\partial r}{\partial y}, \frac{\partial r}{\partial z}\right). \tag{3.4}$$

Now $r^2 = x^2 + y^2 + z^2$, so $2r\frac{\partial r}{\partial x} = 2x$ and similar for y and z. Then

$$\boldsymbol{\nabla}\Psi = \frac{GM}{r^3}(x, y, z) \equiv \frac{GM}{r^3}\mathbf{r} \equiv \frac{GM}{r^2}\hat{\mathbf{r}}, \tag{3.5}$$

where $\hat{\mathbf{r}}$ is the unit radial vector at the point $(x, y, z) \equiv (r, \theta, \phi)$. Hence

$$\mathbf{g} = -\frac{GM}{r^3}\mathbf{r} = -\frac{GM}{r^2}\hat{\mathbf{r}}, \tag{3.6}$$

i.e. a vector of modulus $\frac{GM}{r^2}$ directed towards the origin. So $\Psi = -GM/r$ is the potential of a point mass located at the origin.

Likewise, for a point mass located at $\mathbf{r}'$, the potential is

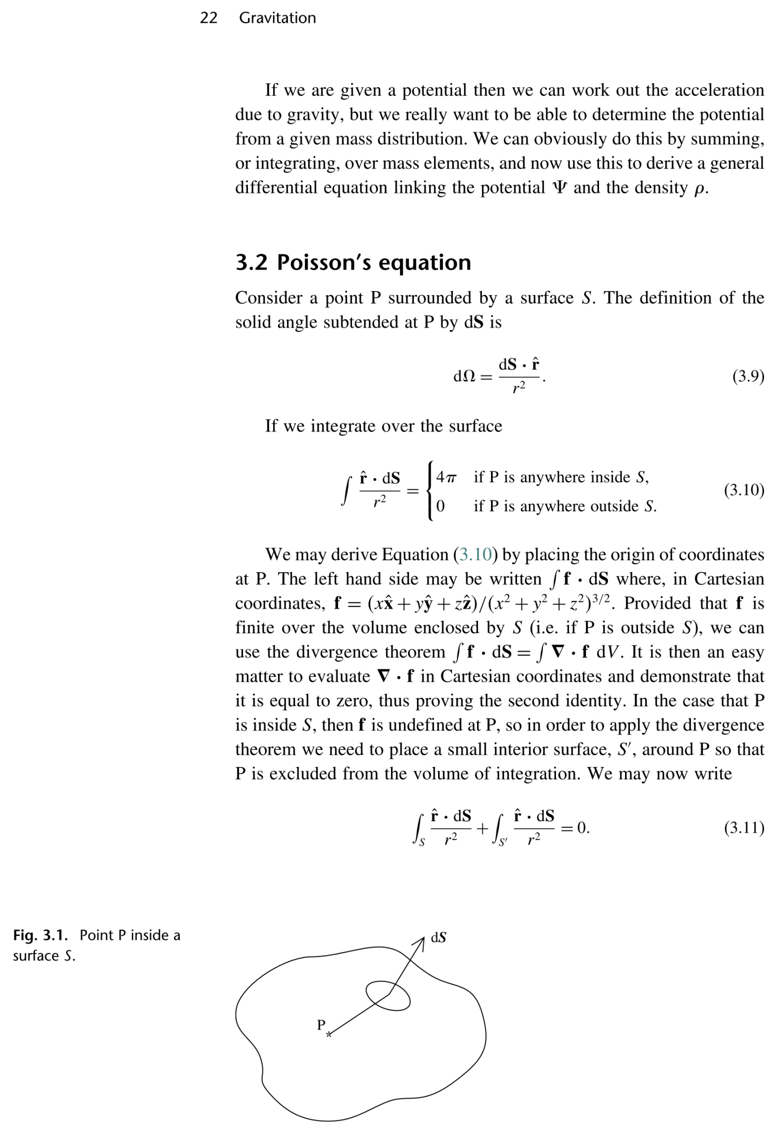
$$\Psi = -\frac{GM}{|\mathbf{r} - \mathbf{r}'|}, \tag{3.7}$$

and, for a system of point masses M_i at locations $\mathbf{r}_i'$, the potential at $\mathbf{r}$ is

$$\Psi = -\sum_i \frac{GM_i}{|\mathbf{r} - \mathbf{r}_i'|}. \tag{3.8}$$

The straight sum is appropriate because the forces (or accelerations) from the $\boldsymbol{\nabla}$ of the individual contributions add vectorially and because $\boldsymbol{\nabla}$ is a linear operator.

Figure 1.37: pafd02.png



If we are given a potential then we can work out the acceleration due to gravity, but we really want to be able to determine the potential from a given mass distribution. We can obviously do this by summing, or integrating, over mass elements, and now use this to derive a general differential equation linking the potential Ψ and the density ρ.

3.2 Poisson's equation

Consider a point P surrounded by a surface S. The definition of the solid angle subtended at P by d$\mathbf{S}$ is

$$d\Omega = \frac{d\mathbf{S} \cdot \hat{\mathbf{r}}}{r^2}. \tag{3.9}$$

If we integrate over the surface

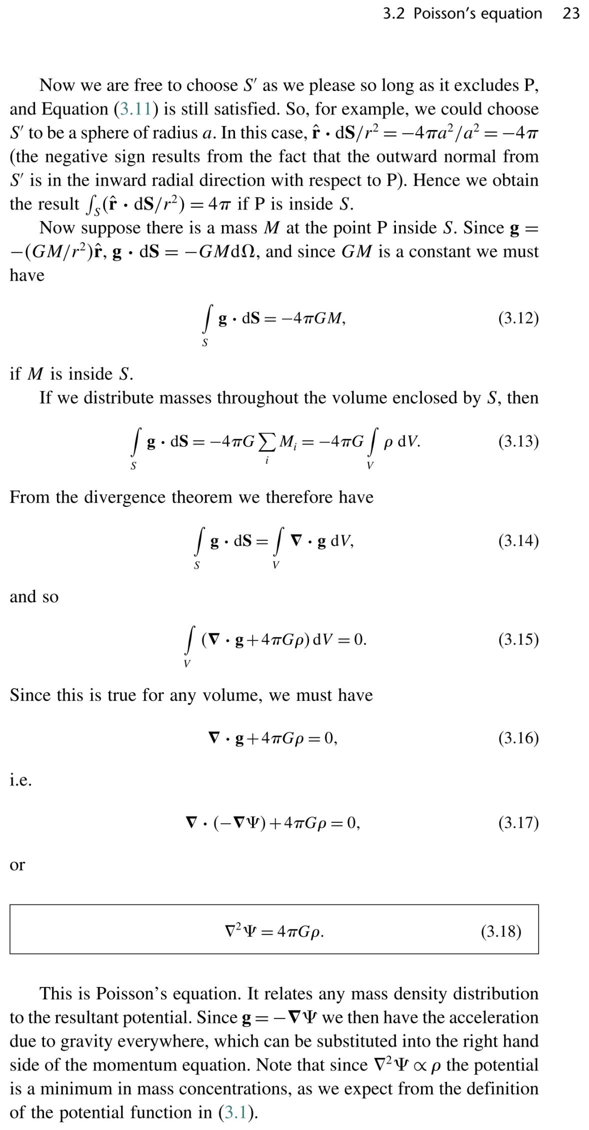
$$\int \frac{\hat{\mathbf{r}} \cdot d\mathbf{S}}{r^2} = \begin{cases} 4\pi & \text{if P is anywhere inside } S, \\ 0 & \text{if P is anywhere outside } S. \end{cases} \tag{3.10}$$

We may derive Equation (3.10) by placing the origin of coordinates at P. The left hand side may be written $\int \mathbf{f} \cdot d\mathbf{S}$ where, in Cartesian coordinates, $\mathbf{f} = (x\hat{\mathbf{x}} + y\hat{\mathbf{y}} + z\hat{\mathbf{z}})/(x^2 + y^2 + z^2)^{3/2}$. Provided that $\mathbf{f}$ is finite over the volume enclosed by S (i.e. if P is outside S), we can use the divergence theorem $\int \mathbf{f} \cdot d\mathbf{S} = \int \nabla \cdot \mathbf{f}\, dV$. It is then an easy matter to evaluate $\nabla \cdot \mathbf{f}$ in Cartesian coordinates and demonstrate that it is equal to zero, thus proving the second identity. In the case that P is inside S, then $\mathbf{f}$ is undefined at P, so in order to apply the divergence theorem we need to place a small interior surface, S', around P so that P is excluded from the volume of integration. We may now write

$$\int_S \frac{\hat{\mathbf{r}} \cdot d\mathbf{S}}{r^2} + \int_{S'} \frac{\hat{\mathbf{r}} \cdot d\mathbf{S}}{r^2} = 0. \tag{3.11}$$

Fig. 3.1. Point P inside a surface S.

Figure 1.38: pafd03.png



Now we are free to choose S' as we please so long as it excludes P, and Equation (3.11) is still satisfied. So, for example, we could choose S' to be a sphere of radius a. In this case, $\hat{\mathbf{r}}\cdot \mathrm{d}\mathbf{S}/r^2 = -4\pi a^2/a^2 = -4\pi$ (the negative sign results from the fact that the outward normal from S' is in the inward radial direction with respect to P). Hence we obtain the result $\int_S(\hat{\mathbf{r}}\cdot \mathrm{d}\mathbf{S}/r^2) = 4\pi$ if P is inside S.

Now suppose there is a mass M at the point P inside S. Since $\mathbf{g} = -(GM/r^2)\hat{\mathbf{r}}$, $\mathbf{g}\cdot \mathrm{d}\mathbf{S} = -GM\mathrm{d}\Omega$, and since GM is a constant we must have

$$\int_S \mathbf{g}\cdot \mathrm{d}\mathbf{S} = -4\pi GM, \tag{3.12}$$

if M is inside S.

If we distribute masses throughout the volume enclosed by S, then

$$\int_S \mathbf{g}\cdot \mathrm{d}\mathbf{S} = -4\pi G\sum_i M_i = -4\pi G\int_V \rho\ \mathrm{d}V. \tag{3.13}$$

From the divergence theorem we therefore have

$$\int_S \mathbf{g}\cdot \mathrm{d}\mathbf{S} = \int_V \boldsymbol{\nabla}\cdot \mathbf{g}\ \mathrm{d}V, \tag{3.14}$$

and so

$$\int_V (\boldsymbol{\nabla}\cdot \mathbf{g} + 4\pi G\rho)\,\mathrm{d}V = 0. \tag{3.15}$$

Since this is true for any volume, we must have

$$\boldsymbol{\nabla}\cdot \mathbf{g} + 4\pi G\rho = 0, \tag{3.16}$$

i.e.

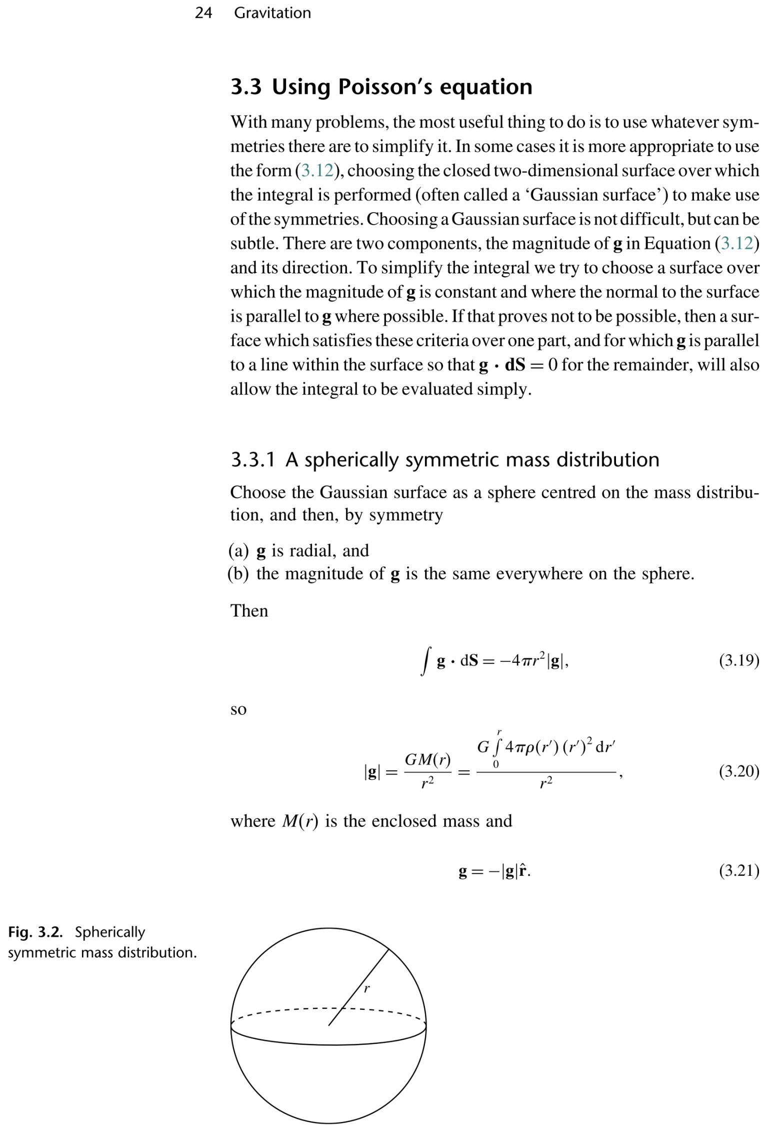
$$\boldsymbol{\nabla}\cdot(-\boldsymbol{\nabla}\Psi) + 4\pi G\rho = 0, \tag{3.17}$$

or

$$\boxed{\nabla^2\Psi = 4\pi G\rho.} \tag{3.18}$$

This is Poisson's equation. It relates any mass density distribution to the resultant potential. Since $\mathbf{g} = -\boldsymbol{\nabla}\Psi$ we then have the acceleration due to gravity everywhere, which can be substituted into the right hand side of the momentum equation. Note that since $\nabla^2\Psi \propto \rho$ the potential is a minimum in mass concentrations, as we expect from the definition of the potential function in (3.1).

Figure 1.39: pafd04.png



3.3 Using Poisson's equation

With many problems, the most useful thing to do is to use whatever symmetries there are to simplify it. In some cases it is more appropriate to use the form (3.12), choosing the closed two-dimensional surface over which the integral is performed (often called a 'Gaussian surface') to make use of the symmetries. Choosing a Gaussian surface is not difficult, but can be subtle. There are two components, the magnitude of **g** in Equation (3.12) and its direction. To simplify the integral we try to choose a surface over which the magnitude of **g** is constant and where the normal to the surface is parallel to **g** where possible. If that proves not to be possible, then a surface which satisfies these criteria over one part, and for which **g** is parallel to a line within the surface so that $\mathbf{g} \cdot \mathbf{dS} = 0$ for the remainder, will also allow the integral to be evaluated simply.

3.3.1 A spherically symmetric mass distribution

Choose the Gaussian surface as a sphere centred on the mass distribution, and then, by symmetry

(a) **g** is radial, and
(b) the magnitude of **g** is the same everywhere on the sphere.

Then

$$\int \mathbf{g} \cdot \mathrm{d}\mathbf{S} = -4\pi r^2 |\mathbf{g}|, \tag{3.19}$$

so

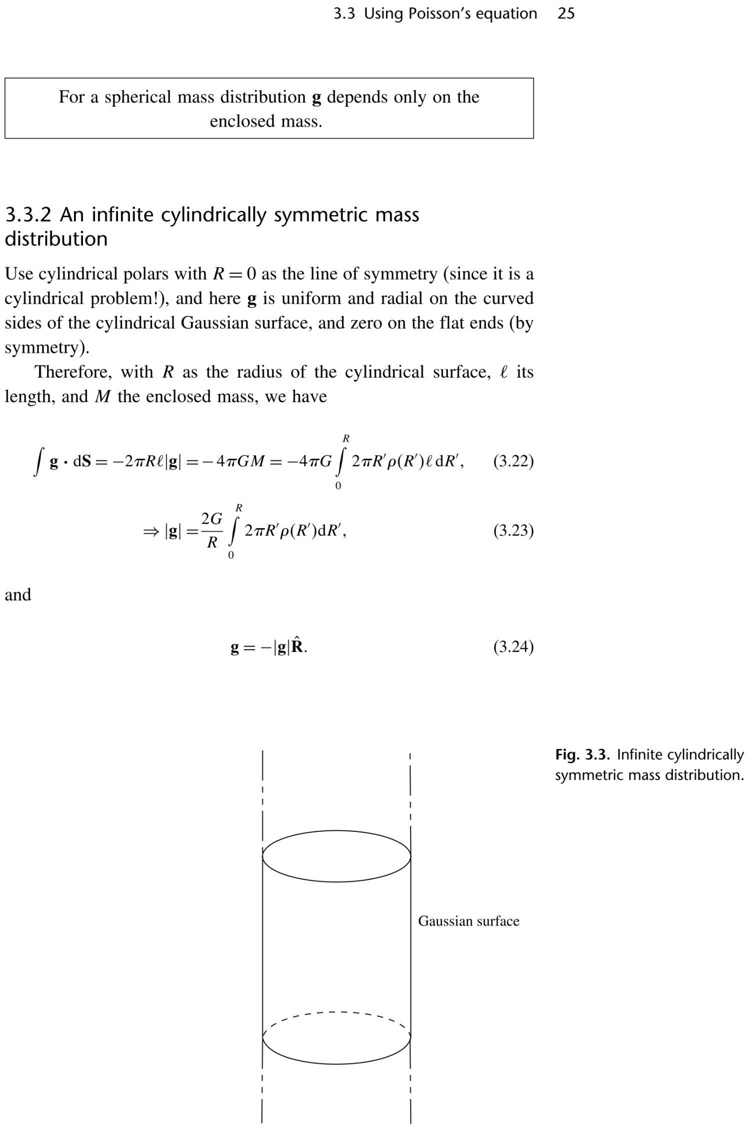
$$|\mathbf{g}| = \frac{GM(r)}{r^2} = \frac{G\int\limits_0^r 4\pi\rho(r')\,(r')^2\,\mathrm{d}r'}{r^2}, \tag{3.20}$$

where $M(r)$ is the enclosed mass and

$$\mathbf{g} = -|\mathbf{g}|\hat{\mathbf{r}}. \tag{3.21}$$

Fig. 3.2. Spherically symmetric mass distribution.

Figure 1.40: pafd05.png



For a spherical mass distribution **g** depends only on the enclosed mass.

3.3.2 An infinite cylindrically symmetric mass distribution

Use cylindrical polars with $R = 0$ as the line of symmetry (since it is a cylindrical problem!), and here **g** is uniform and radial on the curved sides of the cylindrical Gaussian surface, and zero on the flat ends (by symmetry).

Therefore, with R as the radius of the cylindrical surface, ℓ its length, and M the enclosed mass, we have

$$\int \mathbf{g}\cdot \mathrm{d}\mathbf{S} = -2\pi R\ell|\mathbf{g}| = -4\pi GM = -4\pi G\int_0^R 2\pi R'\rho(R')\ell\,\mathrm{d}R', \tag{3.22}$$

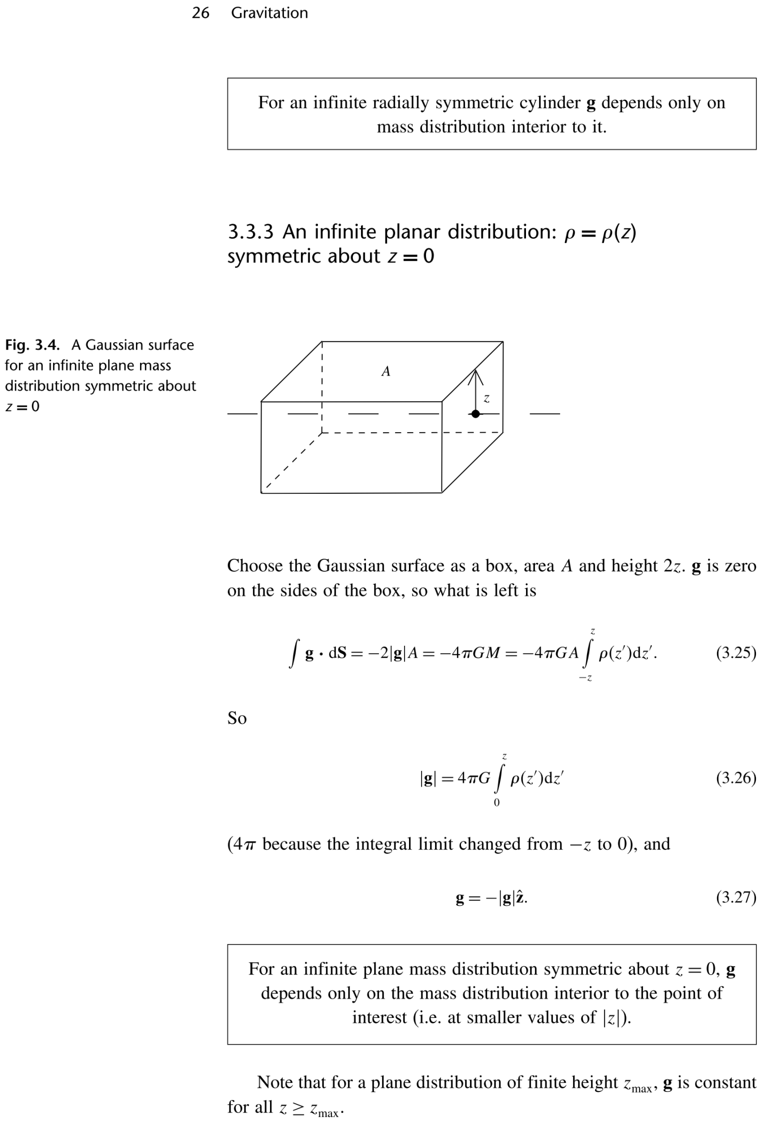
$$\Rightarrow |\mathbf{g}| = \frac{2G}{R}\int_0^R 2\pi R'\rho(R')\mathrm{d}R', \tag{3.23}$$

and

$$\mathbf{g} = -|\mathbf{g}|\hat{\mathbf{R}}. \tag{3.24}$$

Fig. 3.3. Infinite cylindrically symmetric mass distribution.

Figure 1.41: pafd06.png



For an infinite radially symmetric cylinder **g** depends only on mass distribution interior to it.

3.3.3 An infinite planar distribution: $\rho = \rho(z)$ symmetric about $z = 0$

Fig. 3.4. A Gaussian surface for an infinite plane mass distribution symmetric about $z = 0$

Choose the Gaussian surface as a box, area A and height $2z$. **g** is zero on the sides of the box, so what is left is

$$\int \mathbf{g} \cdot \mathrm{d}\mathbf{S} = -2|\mathbf{g}|A = -4\pi GM = -4\pi GA \int_{-z}^{z} \rho(z')\mathrm{d}z'. \tag{3.25}$$

So

$$|\mathbf{g}| = 4\pi G \int_{0}^{z} \rho(z')\mathrm{d}z' \tag{3.26}$$

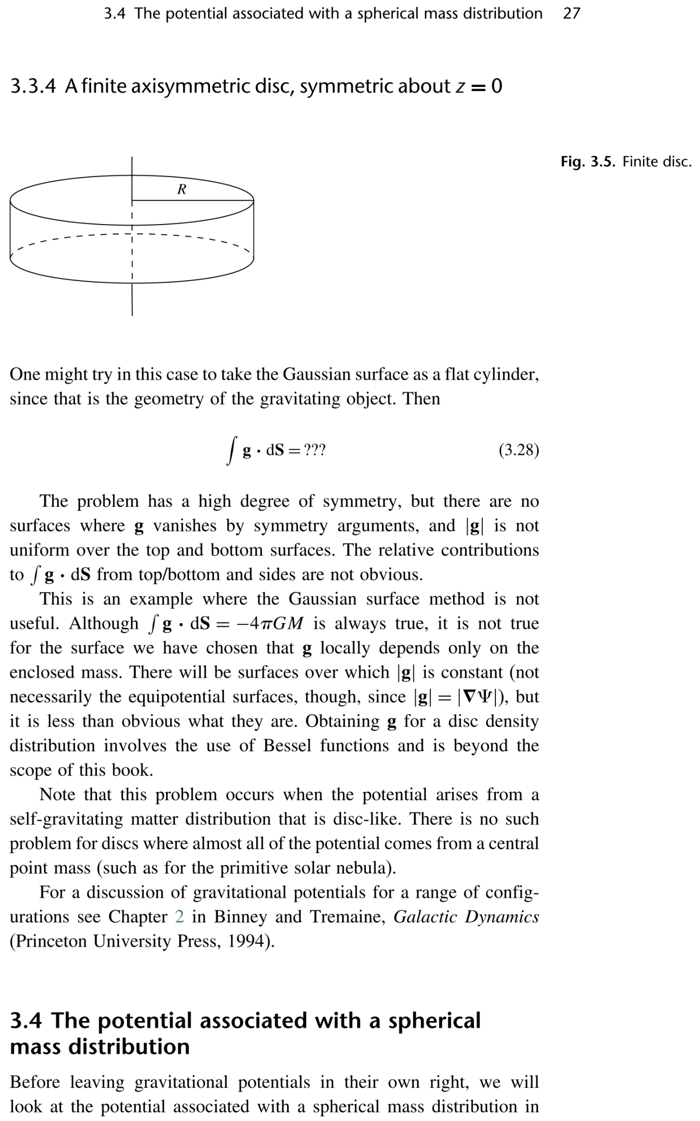
(4π because the integral limit changed from $-z$ to 0), and

$$\mathbf{g} = -|\mathbf{g}|\hat{\mathbf{z}}. \tag{3.27}$$

For an infinite plane mass distribution symmetric about $z = 0$, **g** depends only on the mass distribution interior to the point of interest (i.e. at smaller values of $|z|$).

Note that for a plane distribution of finite height z_{max}, **g** is constant for all $z \geq z_{\mathrm{max}}$.

Figure 1.42: pafd07.png



3.3.4 A finite axisymmetric disc, symmetric about $z = 0$

Fig. 3.5. Finite disc.

One might try in this case to take the Gaussian surface as a flat cylinder, since that is the geometry of the gravitating object. Then

$$\int \mathbf{g} \cdot \mathrm{d}\mathbf{S} = ??? \tag{3.28}$$

The problem has a high degree of symmetry, but there are no surfaces where $\mathbf{g}$ vanishes by symmetry arguments, and $|\mathbf{g}|$ is not uniform over the top and bottom surfaces. The relative contributions to $\int \mathbf{g} \cdot \mathrm{d}\mathbf{S}$ from top/bottom and sides are not obvious.

This is an example where the Gaussian surface method is not useful. Although $\int \mathbf{g} \cdot \mathrm{d}\mathbf{S} = -4\pi GM$ is always true, it is not true for the surface we have chosen that $\mathbf{g}$ locally depends only on the enclosed mass. There will be surfaces over which $|\mathbf{g}|$ is constant (not necessarily the equipotential surfaces, though, since $|\mathbf{g}| = |\boldsymbol{\nabla}\Psi|$), but it is less than obvious what they are. Obtaining $\mathbf{g}$ for a disc density distribution involves the use of Bessel functions and is beyond the scope of this book.

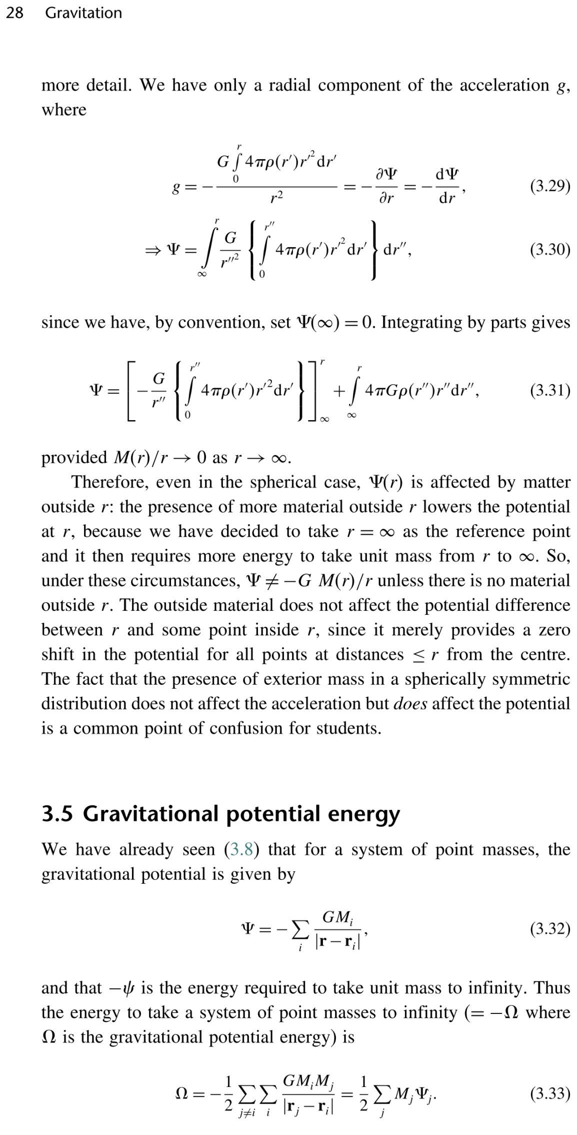
Note that this problem occurs when the potential arises from a self-gravitating matter distribution that is disc-like. There is no such problem for discs where almost all of the potential comes from a central point mass (such as for the primitive solar nebula).

For a discussion of gravitational potentials for a range of configurations see Chapter 2 in Binney and Tremaine, *Galactic Dynamics* (Princeton University Press, 1994).

3.4 The potential associated with a spherical mass distribution

Before leaving gravitational potentials in their own right, we will look at the potential associated with a spherical mass distribution in

Figure 1.43: pafd08.png



more detail. We have only a radial component of the acceleration g, where

$$g = -\frac{G\int_0^r 4\pi\rho(r')r'^2\,\mathrm{d}r'}{r^2} = -\frac{\partial\Psi}{\partial r} = -\frac{\mathrm{d}\Psi}{\mathrm{d}r}, \tag{3.29}$$

$$\Rightarrow \Psi = \int_\infty^r \frac{G}{r''^2}\left\{\int_0^{r''} 4\pi\rho(r')r'^2\,\mathrm{d}r'\right\}\mathrm{d}r'', \tag{3.30}$$

since we have, by convention, set $\Psi(\infty) = 0$. Integrating by parts gives

$$\Psi = \left[-\frac{G}{r''}\left\{\int_0^{r''} 4\pi\rho(r')r'^2\,\mathrm{d}r'\right\}\right]_\infty^r + \int_\infty^r 4\pi G\rho(r'')r''\,\mathrm{d}r'', \tag{3.31}$$

provided $M(r)/r \to 0$ as $r \to \infty$.

Therefore, even in the spherical case, $\Psi(r)$ is affected by matter outside r: the presence of more material outside r lowers the potential at r, because we have decided to take $r = \infty$ as the reference point and it then requires more energy to take unit mass from r to ∞. So, under these circumstances, $\Psi \neq -G\ M(r)/r$ unless there is no material outside r. The outside material does not affect the potential difference between r and some point inside r, since it merely provides a zero shift in the potential for all points at distances $\leq r$ from the centre. The fact that the presence of exterior mass in a spherically symmetric distribution does not affect the acceleration but *does* affect the potential is a common point of confusion for students.

3.5 Gravitational potential energy

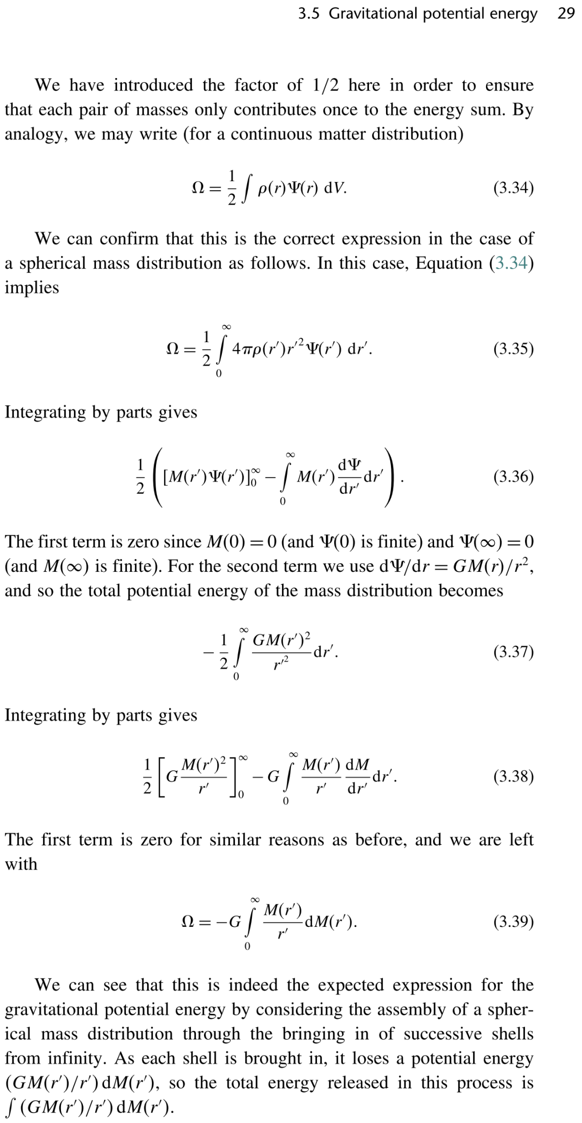
We have already seen (3.8) that for a system of point masses, the gravitational potential is given by

$$\Psi = -\sum_i \frac{GM_i}{|\mathbf{r} - \mathbf{r}_i|}, \tag{3.32}$$

and that $-\psi$ is the energy required to take unit mass to infinity. Thus the energy to take a system of point masses to infinity ($= -\Omega$ where Ω is the gravitational potential energy) is

$$\Omega = -\frac{1}{2}\sum_{j\neq i}\sum_i \frac{GM_iM_j}{|\mathbf{r}_j - \mathbf{r}_i|} = \frac{1}{2}\sum_j M_j\Psi_j. \tag{3.33}$$

Figure 1.44: pafd09.png



We have introduced the factor of 1/2 here in order to ensure that each pair of masses only contributes once to the energy sum. By analogy, we may write (for a continuous matter distribution)

$$\Omega = \frac{1}{2}\int \rho(r)\Psi(r)\ \mathrm{d}V. \tag{3.34}$$

We can confirm that this is the correct expression in the case of a spherical mass distribution as follows. In this case, Equation (3.34) implies

$$\Omega = \frac{1}{2}\int_0^\infty 4\pi\rho(r')r'^2\Psi(r')\ \mathrm{d}r'. \tag{3.35}$$

Integrating by parts gives

$$\frac{1}{2}\left([M(r')\Psi(r')]_0^\infty - \int_0^\infty M(r')\frac{\mathrm{d}\Psi}{\mathrm{d}r'}\mathrm{d}r' \right). \tag{3.36}$$

The first term is zero since $M(0) = 0$ (and $\Psi(0)$ is finite) and $\Psi(\infty) = 0$ (and $M(\infty)$ is finite). For the second term we use $\mathrm{d}\Psi/\mathrm{d}r = GM(r)/r^2$, and so the total potential energy of the mass distribution becomes

$$-\frac{1}{2}\int_0^\infty \frac{GM(r')^2}{r'^2}\mathrm{d}r'. \tag{3.37}$$

Integrating by parts gives

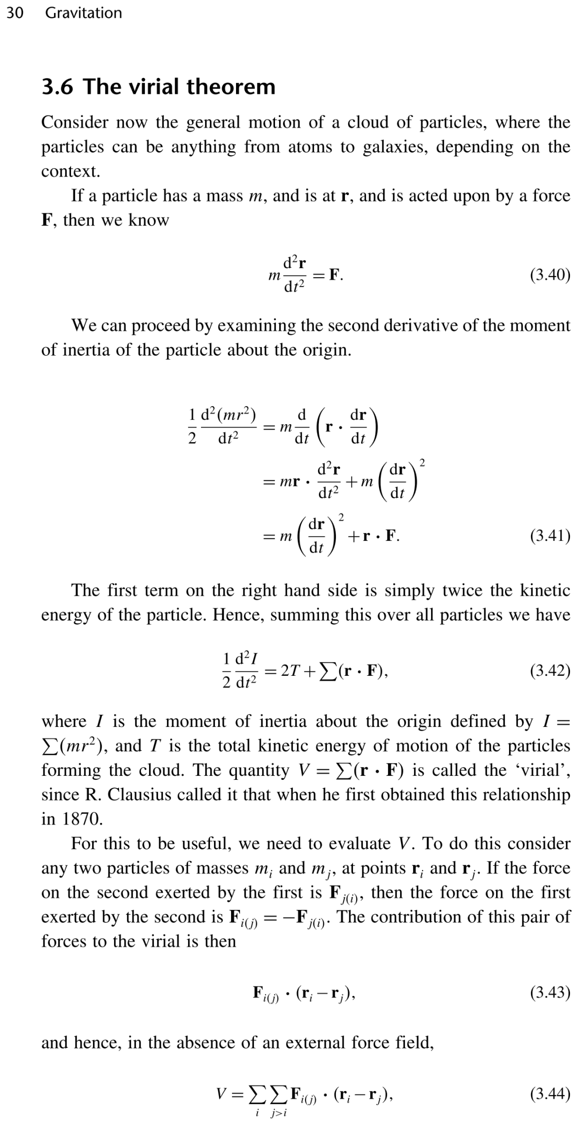
$$\frac{1}{2}\left[G\frac{M(r')^2}{r'}\right]_0^\infty - G\int_0^\infty \frac{M(r')}{r'}\frac{\mathrm{d}M}{\mathrm{d}r'}\mathrm{d}r'. \tag{3.38}$$

The first term is zero for similar reasons as before, and we are left with

$$\Omega = -G\int_0^\infty \frac{M(r')}{r'}\mathrm{d}M(r'). \tag{3.39}$$

We can see that this is indeed the expected expression for the gravitational potential energy by considering the assembly of a spherical mass distribution through the bringing in of successive shells from infinity. As each shell is brought in, it loses a potential energy $(GM(r')/r')\,\mathrm{d}M(r')$, so the total energy released in this process is $\int (GM(r')/r')\,\mathrm{d}M(r')$.

Figure 1.45: pafd10.png



3.6 The virial theorem

Consider now the general motion of a cloud of particles, where the particles can be anything from atoms to galaxies, depending on the context.

If a particle has a mass m, and is at $\mathbf{r}$, and is acted upon by a force $\mathbf{F}$, then we know

$$m\frac{\mathrm{d}^2\mathbf{r}}{\mathrm{d}t^2} = \mathbf{F}. \tag{3.40}$$

We can proceed by examining the second derivative of the moment of inertia of the particle about the origin.

$$\begin{aligned}\frac{1}{2}\frac{\mathrm{d}^2(mr^2)}{\mathrm{d}t^2} &= m\frac{\mathrm{d}}{\mathrm{d}t}\left(\mathbf{r}\cdot\frac{\mathrm{d}\mathbf{r}}{\mathrm{d}t}\right)\\ &= m\mathbf{r}\cdot\frac{\mathrm{d}^2\mathbf{r}}{\mathrm{d}t^2} + m\left(\frac{\mathrm{d}\mathbf{r}}{\mathrm{d}t}\right)^2\\ &= m\left(\frac{\mathrm{d}\mathbf{r}}{\mathrm{d}t}\right)^2 + \mathbf{r}\cdot\mathbf{F}.\end{aligned} \tag{3.41}$$

The first term on the right hand side is simply twice the kinetic energy of the particle. Hence, summing this over all particles we have

$$\frac{1}{2}\frac{\mathrm{d}^2 I}{\mathrm{d}t^2} = 2T + \sum(\mathbf{r}\cdot\mathbf{F}), \tag{3.42}$$

where I is the moment of inertia about the origin defined by $I = \sum(mr^2)$, and T is the total kinetic energy of motion of the particles forming the cloud. The quantity $V = \sum(\mathbf{r}\cdot\mathbf{F})$ is called the 'virial', since R. Clausius called it that when he first obtained this relationship in 1870.

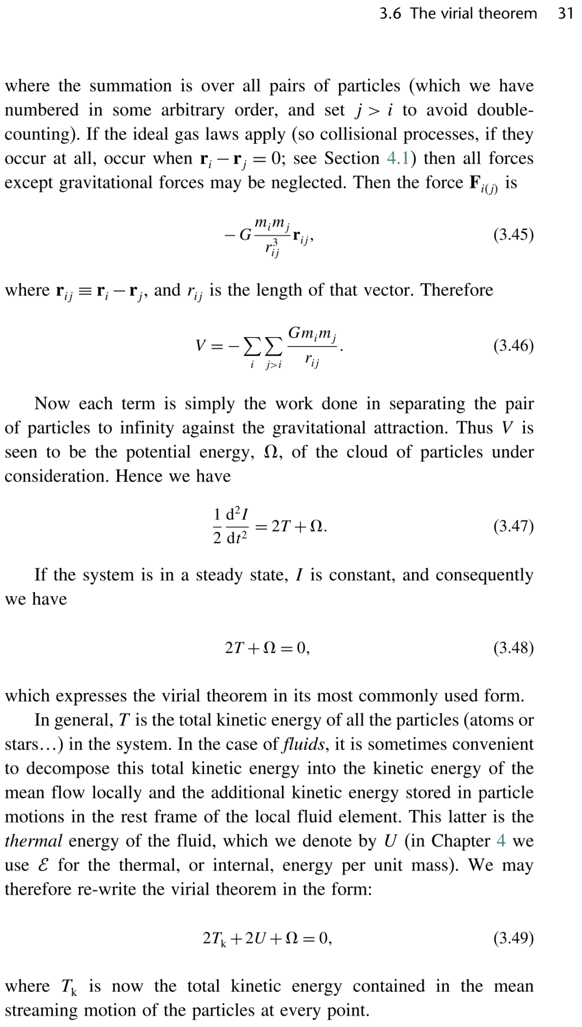
For this to be useful, we need to evaluate V. To do this consider any two particles of masses m_i and m_j, at points $\mathbf{r}_i$ and $\mathbf{r}_j$. If the force on the second exerted by the first is $\mathbf{F}_{j(i)}$, then the force on the first exerted by the second is $\mathbf{F}_{i(j)} = -\mathbf{F}_{j(i)}$. The contribution of this pair of forces to the virial is then

$$\mathbf{F}_{i(j)}\cdot(\mathbf{r}_i - \mathbf{r}_j), \tag{3.43}$$

and hence, in the absence of an external force field,

$$V = \sum_i\sum_{j>i}\mathbf{F}_{i(j)}\cdot(\mathbf{r}_i - \mathbf{r}_j), \tag{3.44}$$

Figure 1.46: pafd11.png



where the summation is over all pairs of particles (which we have numbered in some arbitrary order, and set $j > i$ to avoid double-counting). If the ideal gas laws apply (so collisional processes, if they occur at all, occur when $\mathbf{r}_i - \mathbf{r}_j = 0$; see Section 4.1) then all forces except gravitational forces may be neglected. Then the force $\mathbf{F}_{i(j)}$ is

$$-G\frac{m_i m_j}{r_{ij}^3}\mathbf{r}_{ij}, \qquad (3.45)$$

where $\mathbf{r}_{ij} \equiv \mathbf{r}_i - \mathbf{r}_j$, and r_{ij} is the length of that vector. Therefore

$$V = -\sum_i \sum_{j>i} \frac{Gm_i m_j}{r_{ij}}. \qquad (3.46)$$

Now each term is simply the work done in separating the pair of particles to infinity against the gravitational attraction. Thus V is seen to be the potential energy, Ω, of the cloud of particles under consideration. Hence we have

$$\frac{1}{2}\frac{\mathrm{d}^2 I}{\mathrm{d}t^2} = 2T + \Omega. \qquad (3.47)$$

If the system is in a steady state, I is constant, and consequently we have

$$2T + \Omega = 0, \qquad (3.48)$$

which expresses the virial theorem in its most commonly used form.

In general, T is the total kinetic energy of all the particles (atoms or stars…) in the system. In the case of *fluids*, it is sometimes convenient to decompose this total kinetic energy into the kinetic energy of the mean flow locally and the additional kinetic energy stored in particle motions in the rest frame of the local fluid element. This latter is the *thermal* energy of the fluid, which we denote by U (in Chapter 4 we use $\mathcal{E}$ for the thermal, or internal, energy per unit mass). We may therefore re-write the virial theorem in the form:

$$2T_{\mathrm{k}} + 2U + \Omega = 0, \qquad (3.49)$$

where T_{k} is now the total kinetic energy contained in the mean streaming motion of the particles at every point.

5) C:/DATA-NovoVivo-127-2020/Books-127-2020/Multi-Variable Calculus A First Step/Multi-Variable Calculus A First Step.pdf

Pag. 27(40) - Figure 1.16: Distance from a point P to a plane ax + by + cz + d = 0.

Find a formula for the perpendicular distance D from the point P $(x_0; y_0; z_0))$ to the plane ax + by + cz + d = 0.

Solution. Let $P_1 (x_1; y_1; z_1)$ be any point in the given plane. Then

$$\overline{P_1P} = hx_0 \quad x_1; y_0 \quad y_1; z_0 \quad z_1 i$$

.

The vector $\overline{n} = ha; b; ci$ is a normal vector of the plane. Then, as shown in Figure 1.16, the distance D from P to the plane is

$$D = \; j \overline{P_1P} j \cos \quad :$$

$$D = k \overline{P_1P} \; j \cos \quad j = k \overline{P_1P} \; j \cos \quad j \frac{j \overline{n} j}{j \overline{n} j} = \frac{j P_1P \; j : \overline{n} j}{j \overline{n} j}$$

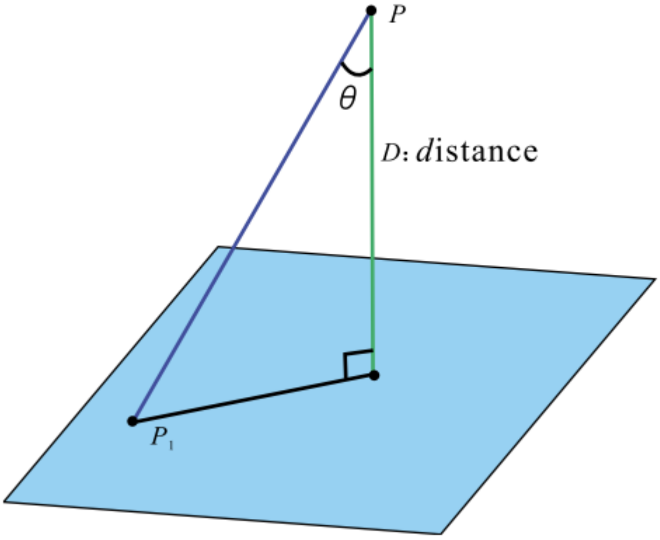

Figure 1.48: mv01.png

Thus,

$$D = \; j \overline{P_1P} j \cos \quad = \; j \overline{P_1P} j : \cos : \frac{j \overline{n} j}{j \overline{n} j} \tag{1.1}$$

$$= \frac{1}{|\overline{n}|}\,|\overline{P_1P}:\cos:|\overline{n}| = \frac{|\overline{P_1P}:\overline{n}|}{|\overline{n}|} \tag{1.2}$$

$$= \frac{|a(x_0 \quad x_1)+b(y_0 \quad y_1)+c(z_0 \quad z_1)|}{\sqrt{a^2+b^2+c^2}} \tag{1.3}$$

$$= \frac{|ax_0+by_0+cz_0 \quad (ax_1+by_1+cz_1)|}{\sqrt{a^2+b^2+c^2}} \tag{1.4}$$

$$= \frac{|ax_0+by_0+cz_0+d)|}{\sqrt{a^2+b^2+c^2}} \tag{1.5}$$

$$= d: \tag{1.6}$$

since $(ax_1+by_1+cz_1) = d:$

Versão diferente de apresentar as mesmas equações de cima.

$$D = |\overline{P_1P}|\cos = |\overline{P_1P}|:\cos:\frac{|\overline{n}|}{|\overline{n}|} \tag{1.7}$$

$$= \frac{1}{|\overline{n}|}\,|\overline{P_1P}:\cos:|\overline{n}| = \frac{|\overline{P_1P}:\overline{n}|}{|\overline{n}|} \tag{1.8}$$

$$= \frac{|a(x_0 \quad x_1)+b(y_0 \quad y_1)+c(z_0 \quad z_1)|}{\sqrt{a^2+b^2+c^2}} \tag{1.9}$$

$$= \frac{|ax_0+by_0+cz_0 \quad (ax_1+by_1+cz_1)|}{\sqrt{a^2+b^2+c^2}} \tag{1.10}$$

$$= \frac{|ax_0+by_0+cz_0+d)|}{\sqrt{a^2+b^2+c^2}} \tag{1.11}$$

$$= d: \tag{1.12}$$

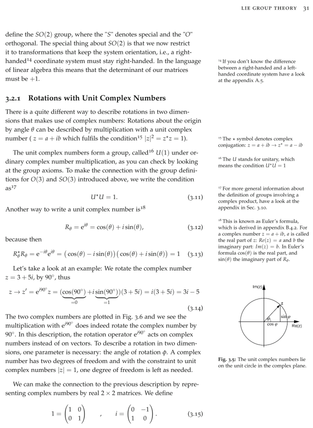
1.2 Rotations with Unit Complex Numbers

1) C:/DATA-NovoVivo-129-2020/Books-129-2020/Physics from Symmetry/book-47331.pdf Pag. 31 (44) - 3.2.1 Rotations with Unit Complex Numbers



LIE GROUP THEORY 31

define the $SO(2)$ group, where the "S" denotes special and the "O" orthogonal. The special thing about $SO(2)$ is that we now restrict it to transformations that keep the system orientation, i.e., a right-handed[14] coordinate system must stay right-handed. In the language of linear algebra this means that the determinant of our matrices must be $+1$.

3.2.1 Rotations with Unit Complex Numbers

There is a quite different way to describe rotations in two dimensions that makes use of complex numbers: Rotations about the origin by angle θ can be described by multiplication with a unit complex number ($z = a + ib$ which fulfils the condition[15] $|z|^2 = z^\star z = 1$).

The unit complex numbers form a group, called[16] $U(1)$ under ordinary complex number multiplication, as you can check by looking at the group axioms. To make the connection with the group definitions for $O(3)$ and $SO(3)$ introduced above, we write the condition as[17]

$$U^\star U = 1. \tag{3.11}$$

Another way to write a unit complex number is[18]

$$R_\theta = e^{i\theta} = \cos(\theta) + i\sin(\theta), \tag{3.12}$$

because then

$$R_\theta^\star R_\theta = e^{-i\theta}e^{i\theta} = \big(\cos(\theta) - i\sin(\theta)\big)\big(\cos(\theta) + i\sin(\theta)\big) = 1 \tag{3.13}$$

Let's take a look at an example: We rotate the complex number $z = 3 + 5i$, by 90°, thus

$$z \to z' = e^{i90^\circ} z = (\underbrace{\cos(90^\circ)}_{=0} + i\underbrace{\sin(90^\circ)}_{=1})(3+5i) = i(3+5i) = 3i - 5 \tag{3.14}$$

The two complex numbers are plotted in Fig. 3.6 and we see the multiplication with e^{i90° does indeed rotate the complex number by 90°. In this description, the rotation operator e^{i90° acts on complex numbers instead of on vectors. To describe a rotation in two dimensions, one parameter is necessary: the angle of rotation ϕ. A complex number has two degrees of freedom and with the constraint to unit complex numbers $|z| = 1$, one degree of freedom is left as needed.

We can make the connection to the previous description by representing complex numbers by real 2×2 matrices. We define

$$1 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \quad , \quad i = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}. \tag{3.15}$$

Fig. 3.5: The unit complex numbers lie on the unit circle in the complex plane.

[14] If you don't know the difference between a right-handed and a left-handed coordinate system have a look at the appendix A.5.

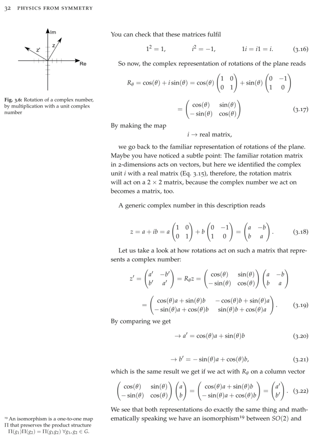
[15] The $\star$ symbol denotes complex conjugation: $z = a + ib \to z^\star = a - ib$

[16] The U stands for unitary, which means the condition $U^\star U = 1$

[17] For more general information about the definition of groups involving a complex product, have a look at the appendix in Sec. 3.10.

[18] This is known as Euler's formula, which is derived in appendix B.4.2. For a complex number $z = a + ib$, a is called the real part of z: $Re(z) = a$ and b the imaginary part: $Im(z) = b$. In Euler's formula $\cos(\theta)$ is the real part, and $\sin(\theta)$ the imaginary part of R_θ.

Figure 1.49: ps01.png



32 PHYSICS FROM SYMMETRY

You can check that these matrices fulfil

$$1^2 = 1, \qquad i^2 = -1, \qquad 1i = i1 = i. \tag{3.16}$$

So now, the complex representation of rotations of the plane reads

$$R_\theta = \cos(\theta) + i\sin(\theta) = \cos(\theta)\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} + \sin(\theta)\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$$

$$= \begin{pmatrix} \cos(\theta) & \sin(\theta) \\ -\sin(\theta) & \cos(\theta) \end{pmatrix} \tag{3.17}$$

By making the map

$$i \to \text{real matrix},$$

we go back to the familiar representation of rotations of the plane. Maybe you have noticed a subtle point: The familiar rotation matrix in 2-dimensions acts on vectors, but here we identified the complex unit i with a real matrix (Eq. 3.15), therefore, the rotation matrix will act on a 2×2 matrix, because the complex number we act on becomes a matrix, too.

A generic complex number in this description reads

$$z = a + ib = a\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} + b\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} = \begin{pmatrix} a & -b \\ b & a \end{pmatrix}. \tag{3.18}$$

Let us take a look at how rotations act on such a matrix that represents a complex number:

$$z' = \begin{pmatrix} a' & -b' \\ b' & a' \end{pmatrix} = R_\theta z = \begin{pmatrix} \cos(\theta) & \sin(\theta) \\ -\sin(\theta) & \cos(\theta) \end{pmatrix}\begin{pmatrix} a & -b \\ b & a \end{pmatrix}$$

$$= \begin{pmatrix} \cos(\theta)a + \sin(\theta)b & -\cos(\theta)b + \sin(\theta)a \\ -\sin(\theta)a + \cos(\theta)b & \sin(\theta)b + \cos(\theta)a \end{pmatrix}. \tag{3.19}$$

By comparing we get

$$\to a' = \cos(\theta)a + \sin(\theta)b \tag{3.20}$$

$$\to b' = -\sin(\theta)a + \cos(\theta)b, \tag{3.21}$$

which is the same result we get if we act with R_θ on a column vector

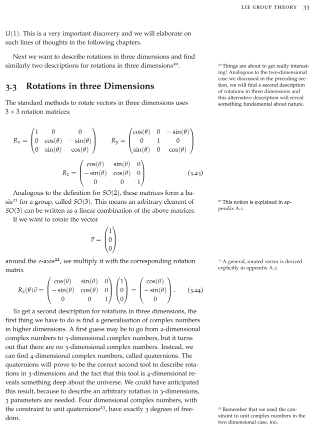
$$\begin{pmatrix} \cos(\theta) & \sin(\theta) \\ -\sin(\theta) & \cos(\theta) \end{pmatrix}\begin{pmatrix} a \\ b \end{pmatrix} = \begin{pmatrix} \cos(\theta)a + \sin(\theta)b \\ -\sin(\theta)a + \cos(\theta)b \end{pmatrix} = \begin{pmatrix} a' \\ b' \end{pmatrix}. \tag{3.22}$$

We see that both representations do exactly the same thing and mathematically speaking we have an isomorphism[19] between $SO(2)$ and

Fig. 3.6: Rotation of a complex number, by multiplication with a unit complex number

[19] An isomorphism is a one-to-one map Π that preserves the product structure $\Pi(g_1)\Pi(g_2) = \Pi(g_1 g_2)\ \forall g_1, g_2 \in G$.

Figure 1.50: ps02.png



LIE GROUP THEORY 33

$U(1)$. This is a very important discovery and we will elaborate on such lines of thoughts in the following chapters.

Next we want to describe rotations in three dimensions and find similarly two descriptions for rotations in three dimensions[20].

3.3 Rotations in three Dimensions

The standard methods to rotate vectors in three dimensions uses 3×3 rotation matrices:

$$R_x = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos(\theta) & -\sin(\theta) \\ 0 & \sin(\theta) & \cos(\theta) \end{pmatrix} \qquad R_y = \begin{pmatrix} \cos(\theta) & 0 & -\sin(\theta) \\ 0 & 1 & 0 \\ \sin(\theta) & 0 & \cos(\theta) \end{pmatrix}$$

$$R_z = \begin{pmatrix} \cos(\theta) & \sin(\theta) & 0 \\ -\sin(\theta) & \cos(\theta) & 0 \\ 0 & 0 & 1 \end{pmatrix} \tag{3.23}$$

Analogous to the definition for $SO(2)$, these matrices form a basis[21] for a group, called $SO(3)$. This means an arbitrary element of $SO(3)$ can be written as a linear combination of the above matrices.

If we want to rotate the vector

$$\vec{v} = \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix}$$

around the z-axis[22], we multiply it with the corresponding rotation matrix

$$R_z(\theta)\vec{v} = \begin{pmatrix} \cos(\theta) & \sin(\theta) & 0 \\ -\sin(\theta) & \cos(\theta) & 0 \\ 0 & 0 & 1 \end{pmatrix}\begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix} = \begin{pmatrix} \cos(\theta) \\ -\sin(\theta) \\ 0 \end{pmatrix}. \tag{3.24}$$

To get a second description for rotations in three dimensions, the first thing we have to do is find a generalisation of complex numbers in higher dimensions. A first guess may be to go from 2-dimensional complex numbers to 3-dimensional complex numbers, but it turns out that there are no 3-dimensional complex numbers. Instead, we can find 4-dimensional complex numbers, called quaternions. The quaternions will prove to be the correct second tool to describe rotations in 3-dimensions and the fact that this tool is 4-dimensional reveals something deep about the universe. We could have anticipated this result, because to describe an arbitrary rotation in 3-dimensions, 3 parameters are needed. Four dimensional complex numbers, with the constraint to unit quaternions[23], have exactly 3 degrees of freedom.

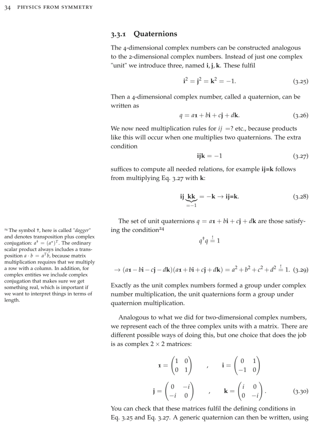
[20] Things are about to get really interesting! Analogous to the two-dimensional case we discussed in the preceding section, we will find a second description of rotations in three dimensions and this alternative description will reveal something fundamental about nature.

[21] This notion is explained in appendix A.1.

[22] A general, rotated vector is derived explicitly in appendix A.2.

[23] Remember that we used the constraint to unit complex numbers in the two dimensional case, too.

Figure 1.51: ps03.png



34 PHYSICS FROM SYMMETRY

3.3.1 Quaternions

The 4-dimensional complex numbers can be constructed analogous to the 2-dimensional complex numbers. Instead of just one complex "unit" we introduce three, named $\mathbf{i}, \mathbf{j}, \mathbf{k}$. These fulfil

$$\mathbf{i}^2 = \mathbf{j}^2 = \mathbf{k}^2 = -1. \tag{3.25}$$

Then a 4-dimensional complex number, called a quaternion, can be written as

$$q = a\mathbf{1} + b\mathbf{i} + c\mathbf{j} + d\mathbf{k}. \tag{3.26}$$

We now need multiplication rules for ij =? etc., because products like this will occur when one multiplies two quaternions. The extra condition

$$\mathbf{ijk} = -1 \tag{3.27}$$

suffices to compute all needed relations, for example **ij=k** follows from multiplying Eq. 3.27 with **k**:

$$\mathbf{ij}\underbrace{\mathbf{kk}}_{=-1} = -\mathbf{k} \to \mathbf{ij} = \mathbf{k}. \tag{3.28}$$

The set of unit quaternions $q = a\mathbf{1} + b\mathbf{i} + c\mathbf{j} + d\mathbf{k}$ are those satisfying the condition[24]

$$q^\dagger q \overset{!}{=} 1$$

$$\to (a\mathbf{1} - b\mathbf{i} - c\mathbf{j} - d\mathbf{k})(a\mathbf{1} + b\mathbf{i} + c\mathbf{j} + d\mathbf{k}) = a^2 + b^2 + c^2 + d^2 \overset{!}{=} 1. \tag{3.29}$$

Exactly as the unit complex numbers formed a group under complex number multiplication, the unit quaternions form a group under quaternion multiplication.

Analogous to what we did for two-dimensional complex numbers, we represent each of the three complex units with a matrix. There are different possible ways of doing this, but one choice that does the job is as complex 2×2 matrices:

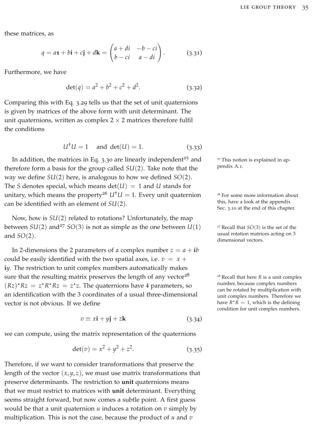
$$\mathbf{1} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \quad , \quad \mathbf{i} = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$$

$$\mathbf{j} = \begin{pmatrix} 0 & -i \\ -i & 0 \end{pmatrix} \quad , \quad \mathbf{k} = \begin{pmatrix} i & 0 \\ 0 & -i \end{pmatrix}. \tag{3.30}$$

You can check that these matrices fulfil the defining conditions in Eq. 3.25 and Eq. 3.27. A generic quaternion can then be written, using

[24] The symbol †, here is called "*dagger*" and denotes transposition plus complex conjugation: $a^\dagger = (a^\star)^T$. The ordinary scalar product always includes a transposition $a \cdot b = a^T b$, because matrix multiplication requires that we multiply a row with a column. In addition, for complex entities we include complex conjugation that makes sure we get something real, which is important if we want to interpret things in terms of length.

Figure 1.52: ps04.png



LIE GROUP THEORY 35

these matrices, as

$$q = a\mathbf{1} + b\mathbf{i} + c\mathbf{j} + d\mathbf{k} = \begin{pmatrix} a+di & -b-ci \\ b-ci & a-di \end{pmatrix}. \tag{3.31}$$

Furthermore, we have

$$\det(q) = a^2 + b^2 + c^2 + d^2. \tag{3.32}$$

Comparing this with Eq. 3.29 tells us that the set of unit quaternions is given by matrices of the above form with unit determinant. The unit quaternions, written as complex 2×2 matrices therefore fulfil the conditions

$$U^\dagger U = 1 \quad \text{and } \det(U) = 1. \tag{3.33}$$

In addition, the matrices in Eq. 3.30 are linearly independent[25] and therefore form a basis for the group called $SU(2)$. Take note that the way we define $SU(2)$ here, is analogous to how we defined $SO(2)$. The S denotes special, which means $\det(U) = 1$ and U stands for unitary, which means the property[26] $U^\dagger U = 1$. Every unit quaternion can be identified with an element of $SU(2)$.

Now, how is $SU(2)$ related to rotations? Unfortunately, the map between $SU(2)$ and[27] $SO(3)$ is not as simple as the one between $U(1)$ and $SO(2)$.

In 2-dimensions the 2 parameters of a complex number $z = a + \mathbf{i}b$ could be easily identified with the two spatial axes, i.e. $v = x + \mathbf{i}y$. The restriction to unit complex numbers automatically makes sure that the resulting matrix preserves the length of any vector[28] $(Rz)^\star Rz = z^\star R^\star Rz = z^\star z$. The quaternions have 4 parameters, so an identification with the 3 coordinates of a usual three-dimensional vector is not obvious. If we define

$$v \equiv x\mathbf{i} + y\mathbf{j} + z\mathbf{k} \tag{3.34}$$

we can compute, using the matrix representation of the quaternions

$$\det(v) = x^2 + y^2 + z^2. \tag{3.35}$$

Therefore, if we want to consider transformations that preserve the length of the vector (x, y, z), we must use matrix transformations that preserve determinants. The restriction to **unit** quaternions means that we must restrict to matrices with **unit** determinant. Everything seems straight forward, but now comes a subtle point. A first guess would be that a unit quaternion u induces a rotation on v simply by multiplication. This is not the case, because the product of u and v

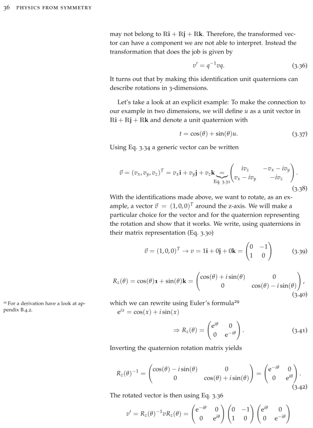
[25] This notion is explained in appendix A.1.

[26] For some more information about this, have a look at the appendix Sec. 3.10 at the end of this chapter.

[27] Recall that $SO(3)$ is the set of the usual rotation matrices acting on 3 dimensional vectors.

[28] Recall that here R is a unit complex number, because complex numbers can be rotated by multiplication with unit complex numbers. Therefore we have $R^\star R = 1$, which is the defining condition for unit complex numbers.

Figure 1.53: ps05.png



36 PHYSICS FROM SYMMETRY

may not belong to $\mathbb{R}\mathbf{i} + \mathbb{R}\mathbf{j} + \mathbb{R}\mathbf{k}$. Therefore, the transformed vector can have a component we are not able to interpret. Instead the transformation that does the job is given by

$$v' = q^{-1}vq. \tag{3.36}$$

It turns out that by making this identification unit quaternions can describe rotations in 3-dimensions.

Let's take a look at an explicit example: To make the connection to our example in two dimensions, we will define u as a unit vector in $\mathbb{R}\mathbf{i} + \mathbb{R}\mathbf{j} + \mathbb{R}\mathbf{k}$ and denote a unit quaternion with

$$t = \cos(\theta) + \sin(\theta)u. \tag{3.37}$$

Using Eq. 3.34 a generic vector can be written

$$\vec{v} = (v_x, v_y, v_z)^T = v_x\mathbf{i} + v_y\mathbf{j} + v_z\mathbf{k} \underbrace{=}_{\text{Eq. 3.31}} \begin{pmatrix} iv_z & -v_x - iv_y \\ v_x - iv_y & -iv_z \end{pmatrix}. \tag{3.38}$$

With the identifications made above, we want to rotate, as an example, a vector $\vec{v} = (1,0,0)^T$ around the z-axis. We will make a particular choice for the vector and for the quaternion representing the rotation and show that it works. We write, using quaternions in their matrix representation (Eq. 3.30)

$$\vec{v} = (1,0,0)^T \to v = 1\mathbf{i} + 0\mathbf{j} + 0\mathbf{k} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \tag{3.39}$$

$$R_z(\theta) = \cos(\theta)\mathbf{1} + \sin(\theta)\mathbf{k} = \begin{pmatrix} \cos(\theta) + i\sin(\theta) & 0 \\ 0 & \cos(\theta) - i\sin(\theta) \end{pmatrix}, \tag{3.40}$$

which we can rewrite using Euler's formula[29]
$e^{ix} = \cos(x) + i\sin(x)$

$$\Rightarrow R_z(\theta) = \begin{pmatrix} e^{i\theta} & 0 \\ 0 & e^{-i\theta} \end{pmatrix}. \tag{3.41}$$

Inverting the quaternion rotation matrix yields

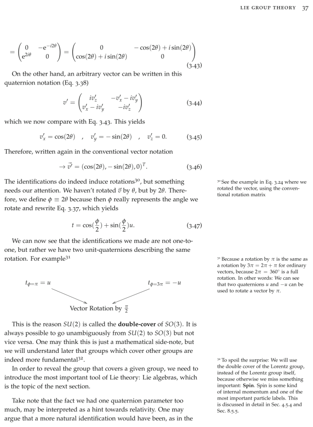
$$R_z(\theta)^{-1} = \begin{pmatrix} \cos(\theta) - i\sin(\theta) & 0 \\ 0 & \cos(\theta) + i\sin(\theta) \end{pmatrix} = \begin{pmatrix} e^{-i\theta} & 0 \\ 0 & e^{i\theta} \end{pmatrix}. \tag{3.42}$$

The rotated vector is then using Eq. 3.36

$$v' = R_z(\theta)^{-1}vR_z(\theta) = \begin{pmatrix} e^{-i\theta} & 0 \\ 0 & e^{i\theta} \end{pmatrix}\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} e^{i\theta} & 0 \\ 0 & e^{-i\theta} \end{pmatrix}$$

[29] For a derivation have a look at appendix B.4.2.

Figure 1.54: ps06.png



LIE GROUP THEORY 37

$$= \begin{pmatrix} 0 & -e^{-i2\theta} \\ e^{2i\theta} & 0 \end{pmatrix} = \begin{pmatrix} 0 & -\cos(2\theta) + i\sin(2\theta) \\ \cos(2\theta) + i\sin(2\theta) & 0 \end{pmatrix} \tag{3.43}$$

On the other hand, an arbitrary vector can be written in this quaternion notation (Eq. 3.38)

$$v' = \begin{pmatrix} iv'_z & -v'_x - iv'_y \\ v'_x - iv'_y & -iv'_z \end{pmatrix} \tag{3.44}$$

which we now compare with Eq. 3.43. This yields

$$v'_x = \cos(2\theta) \quad , \quad v'_y = -\sin(2\theta) \quad , \quad v'_z = 0. \tag{3.45}$$

Therefore, written again in the conventional vector notation

$$\to \vec{v'} = (\cos(2\theta), -\sin(2\theta), 0)^T. \tag{3.46}$$

The identifications do indeed induce rotations[30], but something needs our attention. We haven't rotated $\vec{v}$ by θ, but by 2θ. Therefore, we define $\phi \equiv 2\theta$ because then ϕ really represents the angle we rotate and rewrite Eq. 3.37, which yields

$$t = \cos(\frac{\phi}{2}) + \sin(\frac{\phi}{2})u. \tag{3.47}$$

We can now see that the identifications we made are not one-to-one, but rather we have two unit-quaternions describing the same rotation. For example[31]

$$\begin{tikzcd}
t_{\phi=\pi} = u \arrow[dr] & & t_{\phi=3\pi} = -u \arrow[dl] \\
& \text{Vector Rotation by } \frac{\pi}{2} &
\end{tikzcd}$$

This is the reason $SU(2)$ is called the **double-cover** of $SO(3)$. It is always possible to go unambiguously from $SU(2)$ to $SO(3)$ but not vice versa. One may think this is just a mathematical side-note, but we will understand later that groups which cover other groups are indeed more fundamental[32].

In order to reveal the group that covers a given group, we need to introduce the most important tool of Lie theory: Lie algebras, which is the topic of the next section.

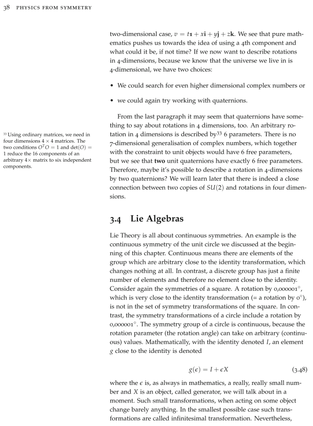
Take note that the fact we had one quaternion parameter too much, may be interpreted as a hint towards relativity. One may argue that a more natural identification would have been, as in the

[30] See the example in Eq. 3.24 where we rotated the vector, using the conventional rotation matrix

[31] Because a rotation by π is the same as a rotation by $3\pi = 2\pi + \pi$ for ordinary vectors, because $2\pi = 360°$ is a full rotation. In other words: We can see that two quaternions u and $-u$ can be used to rotate a vector by π.

[32] To spoil the surprise: We will use the double cover of the Lorentz group, instead of the Lorentz group itself, because otherwise we miss something important: **Spin**. Spin is some kind of internal momentum and one of the most important particle labels. This is discussed in detail in Sec. 4.5.4 and Sec. 8.5.5.

Figure 1.55: ps07.png



38 PHYSICS FROM SYMMETRY

two-dimensional case, $v = t\mathbf{1} + x\mathbf{i} + y\mathbf{j} + z\mathbf{k}$. We see that pure mathematics pushes us towards the idea of using a 4th component and what could it be, if not time? If we now want to describe rotations in 4-dimensions, because we know that the universe we live in is 4-dimensional, we have two choices:

- We could search for even higher dimensional complex numbers or
- we could again try working with quaternions.

From the last paragraph it may seem that quaternions have something to say about rotations in 4 dimensions, too. An arbitrary rotation in 4 dimensions is described by[33] 6 parameters. There is no 7-dimensional generalisation of complex numbers, which together with the constraint to unit objects would have 6 free parameters, but we see that **two** unit quaternions have exactly 6 free parameters. Therefore, maybe it's possible to describe a rotation in 4-dimensions by two quaternions? We will learn later that there is indeed a close connection between two copies of $SU(2)$ and rotations in four dimensions.

3.4 Lie Algebras

Lie Theory is all about continuous symmetries. An example is the continuous symmetry of the unit circle we discussed at the beginning of this chapter. Continuous means there are elements of the group which are arbitrary close to the identity transformation, which changes nothing at all. In contrast, a discrete group has just a finite number of elements and therefore no element close to the identity. Consider again the symmetries of a square. A rotation by 0,000001°, which is very close to the identity transformation (= a rotation by 0°), is not in the set of symmetry transformations of the square. In contrast, the symmetry transformations of a circle include a rotation by 0,000001°. The symmetry group of a circle is continuous, because the rotation parameter (the rotation angle) can take on arbitrary (continuous) values. Mathematically, with the identity denoted I, an element g close to the identity is denoted

$$g(\epsilon) = I + \epsilon X \tag{3.48}$$

where the ϵ is, as always in mathematics, a really, really small number and X is an object, called generator, we will talk about in a moment. Such small transformations, when acting on some object change barely anything. In the smallest possible case such transformations are called infinitesimal transformation. Nevertheless,

[33] Using ordinary matrices, we need in four dimensions 4×4 matrices. The two conditions $O^TO = 1$ and $\det(O) = 1$ reduce the 16 components of an arbitrary $4\times$ matrix to six independent components.

Figure 1.56: ps08.png

2) C:/DATA-NovoVivo-128-2020/Books-128-2020/Electromechanical Energy Conversion/Electromechanical-Energy-Conversion.pdf Pag. 148 (167) - 4.4 CYLINDRICAL MACHINES

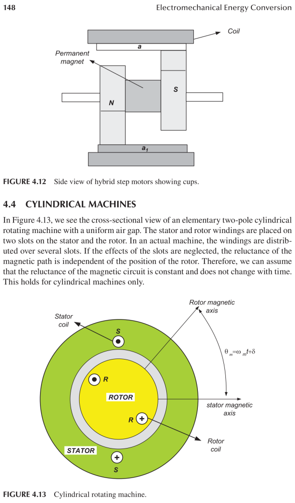


FIGURE 4.12 Side view of hybrid step motors showing cups.

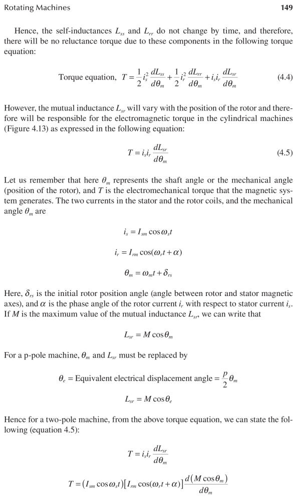
4.4 CYLINDRICAL MACHINES

In Figure 4.13, we see the cross-sectional view of an elementary two-pole cylindrical rotating machine with a uniform air gap. The stator and rotor windings are placed on two slots on the stator and the rotor. In an actual machine, the windings are distributed over several slots. If the effects of the slots are neglected, the reluctance of the magnetic path is independent of the position of the rotor. Therefore, we can assume that the reluctance of the magnetic circuit is constant and does not change with time. This holds for cylindrical machines only.

FIGURE 4.13 Cylindrical rotating machine.

Figure 1.57: eec01.png



Hence, the self-inductances L_{ss} and L_{rr} do not change by time, and therefore, there will be no reluctance torque due to these components in the following torque equation:

$$\text{Torque equation,}\quad T=\frac{1}{2}i_s^2\frac{dL_{ss}}{d\theta_m}+\frac{1}{2}i_r^2\frac{dL_{rr}}{d\theta_m}+i_si_r\frac{dL_{sr}}{d\theta_m} \tag{4.4}$$

However, the mutual inductance L_{sr} will vary with the position of the rotor and therefore will be responsible for the electromagnetic torque in the cylindrical machines (Figure 4.13) as expressed in the following equation:

$$T=i_si_r\frac{dL_{sr}}{d\theta_m} \tag{4.5}$$

Let us remember that here θ_m represents the shaft angle or the mechanical angle (position of the rotor), and T is the electromechanical torque that the magnetic system generates. The two currents in the stator and the rotor coils, and the mechanical angle θ_m are

$$i_s=I_{sm}\cos\omega_st$$

$$i_r=I_{rm}\cos(\omega_rt+\alpha)$$

$$\theta_m=\omega_mt+\delta_{rs}$$

Here, δ_{rs} is the initial rotor position angle (angle between rotor and stator magnetic axes), and α is the phase angle of the rotor current i_r with respect to stator current i_s. If M is the maximum value of the mutual inductance L_{sr}, we can write that

$$L_{sr}=M\cos\theta_m$$

For a p-pole machine, θ_m and L_{sr} must be replaced by

$$\theta_e=\text{Equivalent electrical displacement angle}=\frac{p}{2}\theta_m$$

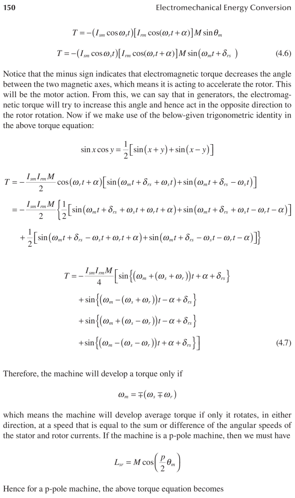
$$L_{sr}=M\cos\theta_e$$

Hence for a two-pole machine, from the above torque equation, we can state the following (equation 4.5):

$$T=i_si_r\frac{dL_{sr}}{d\theta_m}$$

$$T=(I_{sm}\cos\omega_st)[I_{rm}\cos(\omega_rt+\alpha)]\frac{d(M\cos\theta_m)}{d\theta_m}$$

Figure 1.58: eec02.png



$$T=-(I_{sm}\cos\omega_st)[I_{rm}\cos(\omega_rt+\alpha)]M\sin\theta_m$$

$$T=-(I_{sm}\cos\omega_st)[I_{rm}\cos(\omega_rt+\alpha)]M\sin(\omega_mt+\delta_{rs}\ ) \tag{4.6}$$

Notice that the minus sign indicates that electromagnetic torque decreases the angle between the two magnetic axes, which means it is acting to accelerate the rotor. This will be the motor action. From this, we can say that in generators, the electromagnetic torque will try to increase this angle and hence act in the opposite direction to the rotor rotation. Now if we make use of the below-given trigonometric identity in the above torque equation:

$$\sin x\cos y=\frac{1}{2}\left[\sin(x+y)+\sin(x-y)\right]$$

$$\begin{aligned}T&=-\frac{I_{sm}I_{rm}M}{2}\cos(\omega_rt+\alpha)\left[\sin(\omega_mt+\delta_{rs}+\omega_st)+\sin(\omega_mt+\delta_{rs}-\omega_st)\right]\\&=-\frac{I_{sm}I_{rm}M}{2}\left\{\frac{1}{2}\left[\sin(\omega_mt+\delta_{rs}+\omega_st+\omega_rt+\alpha)+\sin(\omega_mt+\delta_{rs}+\omega_st-\omega_rt-\alpha)\right]\right.\\&\quad\left.+\frac{1}{2}\left[\sin(\omega_mt+\delta_{rs}-\omega_st+\omega_rt+\alpha)+\sin(\omega_mt+\delta_{rs}-\omega_st-\omega_rt-\alpha)\right]\right\}\end{aligned}$$

$$\begin{aligned}T=-\frac{I_{sm}I_{rm}M}{4}\Big[&\sin\{(\omega_m+(\omega_s+\omega_r))t+\alpha+\delta_{rs}\}\\&+\sin\{(\omega_m-(\omega_s+\omega_r))t-\alpha+\delta_{rs}\}\\&+\sin\{(\omega_m+(\omega_s-\omega_r))t-\alpha+\delta_{rs}\}\\&+\sin\{(\omega_m-(\omega_s-\omega_r))t+\alpha+\delta_{rs}\}\Big]\end{aligned} \tag{4.7}$$

Therefore, the machine will develop a torque only if

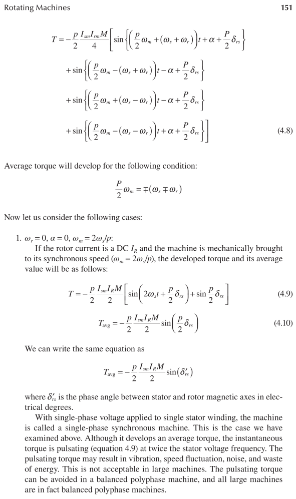
$$\omega_m=\mp(\omega_s\mp\omega_r)$$

which means the machine will develop average torque if only it rotates, in either direction, at a speed that is equal to the sum or difference of the angular speeds of the stator and rotor currents. If the machine is a p-pole machine, then we must have

$$L_{sr}=M\cos\left(\frac{p}{2}\theta_m\right)$$

Hence for a p-pole machine, the above torque equation becomes

Figure 1.59: eec03.png



$$\begin{aligned}T=-\frac{p}{2}\frac{I_{sm}I_{rm}M}{4}\Bigg[&\sin\left\{\left(\frac{p}{2}\omega_m+(\omega_s+\omega_r)\right)t+\alpha+\frac{P}{2}\delta_{rs}\right\}\\&+\sin\left\{\left(\frac{p}{2}\omega_m-(\omega_s+\omega_r)\right)t-\alpha+\frac{P}{2}\delta_{rs}\right\}\\&+\sin\left\{\left(\frac{p}{2}\omega_m+(\omega_s-\omega_r)\right)t-\alpha+\frac{P}{2}\delta_{rs}\right\}\\&+\sin\left\{\left(\frac{p}{2}\omega_m-(\omega_s-\omega_r)\right)t+\alpha+\frac{P}{2}\delta_{rs}\right\}\Bigg]\end{aligned} \tag{4.8}$$

Average torque will develop for the following condition:

$$\frac{P}{2}\omega_m=\mp(\omega_s\mp\omega_r)$$

Now let us consider the following cases:

1. $\omega_r=0$, $\alpha=0$, $\omega_m=2\omega_s/p$:
   If the rotor current is a DC I_R and the machine is mechanically brought to its synchronous speed ($\omega_m=2\omega_s/p$), the developed torque and its average value will be as follows:

   $$T=-\frac{p}{2}\frac{I_{sm}I_RM}{2}\left[\sin\left(2\omega_st+\frac{p}{2}\delta_{rs}\right)+\sin\frac{p}{2}\delta_{rs}\right] \tag{4.9}$$

   $$T_{\text{avg}}=-\frac{p}{2}\frac{I_{sm}I_RM}{2}\sin\left(\frac{p}{2}\delta_{rs}\right) \tag{4.10}$$

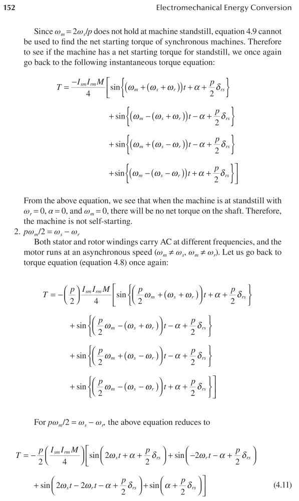
   We can write the same equation as

   $$T_{\text{avg}}=-\frac{p}{2}\frac{I_{sm}I_RM}{2}\sin(\delta'_{rs})$$

   where δ'_{rs} is the phase angle between stator and rotor magnetic axes in electrical degrees.

   With single-phase voltage applied to single stator winding, the machine is called a single-phase synchronous machine. This is the case we have examined above. Although it develops an average torque, the instantaneous torque is pulsating (equation 4.9) at twice the stator voltage frequency. The pulsating torque may result in vibration, speed fluctuation, noise, and waste of energy. This is not acceptable in large machines. The pulsating torque can be avoided in a balanced polyphase machine, and all large machines are in fact balanced polyphase machines.

Figure 1.60: eec04.png



152 Electromechanical Energy Conversion

Since $\omega_m = 2\omega_s/p$ does not hold at machine standstill, equation 4.9 cannot be used to find the net starting torque of synchronous machines. Therefore to see if the machine has a net starting torque for standstill, we once again go back to the following instantaneous torque equation:

$$T = \frac{-I_{sm}I_{rm}M}{4}\left[\sin\left\{(\omega_m + (\omega_s + \omega_r))t + \alpha + \frac{p}{2}\delta_{rs}\right\}\right.$$
$$+ \sin\left\{(\omega_m - (\omega_s + \omega_r))t - \alpha + \frac{p}{2}\delta_{rs}\right\}$$
$$+ \sin\left\{(\omega_m + (\omega_s - \omega_r))t - \alpha + \frac{p}{2}\delta_{rs}\right\}$$
$$\left.+ \sin\left\{(\omega_m - (\omega_s - \omega_r))t + \alpha + \frac{p}{2}\delta_{rs}\right\}\right]$$

From the above equation, we see that when the machine is at standstill with $\omega_r = 0$, $\alpha = 0$, and $\omega_m = 0$, there will be no net torque on the shaft. Therefore, the machine is not self-starting.

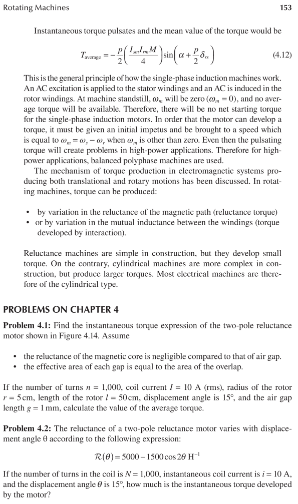
2. $p\omega_m/2 = \omega_s - \omega_r$

Both stator and rotor windings carry AC at different frequencies, and the motor runs at an asynchronous speed ($\omega_m \neq \omega_s$, $\omega_m \neq \omega_r$). Let us go back to torque equation (equation 4.8) once again:

$$T = -\left(\frac{p}{2}\right)\frac{I_{sm}I_{rm}M}{4}\left[\sin\left\{\left(\frac{p}{2}\omega_m + (\omega_s + \omega_r)\right)t + \alpha + \frac{p}{2}\delta_{rs}\right\}\right.$$
$$+ \sin\left\{\left(\frac{p}{2}\omega_m - (\omega_s + \omega_r)\right)t - \alpha + \frac{p}{2}\delta_{rs}\right\}$$
$$+ \sin\left\{\left(\frac{p}{2}\omega_m + (\omega_s - \omega_r)\right)t - \alpha + \frac{p}{2}\delta_{rs}\right\}$$
$$\left.+ \sin\left\{\left(\frac{p}{2}\omega_m - (\omega_s - \omega_r)\right)t + \alpha + \frac{p}{2}\delta_{rs}\right\}\right]$$

For $p\omega_m/2 = \omega_s - \omega_r$, the above equation reduces to

$$T = -\frac{p}{2}\left(\frac{I_{sm}I_{rm}M}{4}\right)\left[\sin\left(2\omega_s t + \alpha + \frac{p}{2}\delta_{rs}\right) + \sin\left(-2\omega_r t - \alpha + \frac{p}{2}\delta_{rs}\right)\right.$$
$$\left.+ \sin\left(2\omega_s t - 2\omega_r t - \alpha + \frac{p}{2}\delta_{rs}\right) + \sin\left(\alpha + \frac{p}{2}\delta_{rs}\right)\right] \tag{4.11}$$



Rotating Machines 153

Instantaneous torque pulsates and the mean value of the torque would be

$$T_{\text{average}} = -\frac{p}{2}\left(\frac{I_{sm}I_{rm}M}{4}\right)\sin\left(\alpha + \frac{p}{2}\delta_{rs}\right) \tag{4.12}$$

This is the general principle of how the single-phase induction machines work. An AC excitation is applied to the stator windings and an AC is induced in the rotor windings. At machine standstill, ω_m will be zero ($\omega_m = 0$), and no average torque will be available. Therefore, there will be no net starting torque for the single-phase induction motors. In order that the motor can develop a torque, it must be given an initial impetus and be brought to a speed which is equal to $\omega_m = \omega_s - \omega_r$ when ω_m is other than zero. Even then the pulsating torque will create problems in high-power applications. Therefore for high-power applications, balanced polyphase machines are used.

The mechanism of torque production in electromagnetic systems producing both translational and rotary motions has been discussed. In rotating machines, torque can be produced:

- by variation in the reluctance of the magnetic path (reluctance torque)
- or by variation in the mutual inductance between the windings (torque developed by interaction).

Reluctance machines are simple in construction, but they develop small torque. On the contrary, cylindrical machines are more complex in construction, but produce larger torques. Most electrical machines are therefore of the cylindrical type.

PROBLEMS ON CHAPTER 4

Problem 4.1: Find the instantaneous torque expression of the two-pole reluctance motor shown in Figure 4.14. Assume

- the reluctance of the magnetic core is negligible compared to that of air gap.
- the effective area of each gap is equal to the area of the overlap.

If the number of turns $n = 1{,}000$, coil current $I = 10$ A (rms), radius of the rotor $r = 5$ cm, length of the rotor $l = 50$ cm, displacement angle is 15°, and the air gap length $g = 1$ mm, calculate the value of the average torque.

Problem 4.2: The reluctance of a two-pole reluctance motor varies with displacement angle θ according to the following expression:

$$\mathcal{R}(\theta) = 5000 - 1500\cos 2\theta \ \mathrm{H}^{-1}$$

If the number of turns in the coil is $N = 1{,}000$, instantaneous coil current is $i = 10$ A, and the displacement angle θ is 15°, how much is the instantaneous torque developed by the motor?

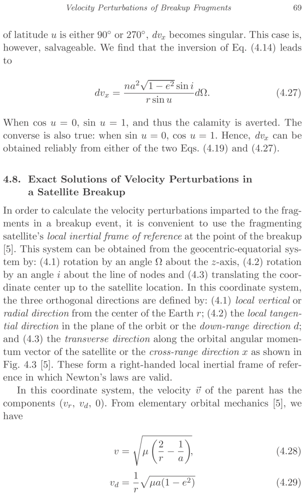
3) C:/DATA-NovoVivo-128-2020/Books-128-2020/Theory of Satellite Fragmentation in Orbit/9811208557.pdf Pag. 72 (83) - Fig. 4.4. Plane change angle from the breakup spherical triangles of parent and fragment satellites.



Velocity Perturbations of Breakup Fragments 69

of latitude u is either 90° or 270°, dv_x becomes singular. This case is, however, salvageable. We find that the inversion of Eq. (4.14) leads to

$$dv_x = \frac{na^2\sqrt{1-e^2}\sin i}{r\sin u}d\Omega. \tag{4.27}$$

When $\cos u = 0$, $\sin u = 1$, and thus the calamity is averted. The converse is also true: when $\sin u = 0$, $\cos u = 1$. Hence, dv_x can be obtained reliably from either of the two Eqs. (4.19) and (4.27).

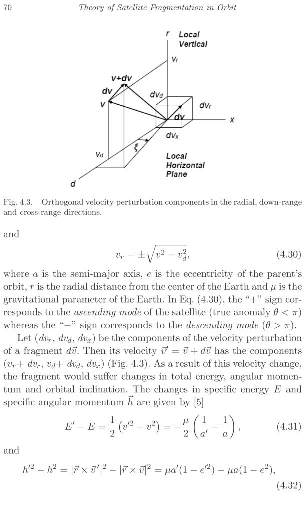
4.8. Exact Solutions of Velocity Perturbations in a Satellite Breakup

In order to calculate the velocity perturbations imparted to the fragments in a breakup event, it is convenient to use the fragmenting satellite's *local inertial frame of reference* at the point of the breakup [5]. This system can be obtained from the geocentric-equatorial system by: (4.1) rotation by an angle Ω about the z-axis, (4.2) rotation by an angle i about the line of nodes and (4.3) translating the coordinate center up to the satellite location. In this coordinate system, the three orthogonal directions are defined by: (4.1) *local vertical* or *radial direction* from the center of the Earth r; (4.2) the *local tangential direction* in the plane of the orbit or the *down-range direction* d; and (4.3) the *transverse direction* along the orbital angular momentum vector of the satellite or the *cross-range direction* x as shown in Fig. 4.3 [5]. These form a right-handed local inertial frame of reference in which Newton's laws are valid.

In this coordinate system, the velocity $\vec{v}$ of the parent has the components (v_r, v_d, 0). From elementary orbital mechanics [5], we have

$$v = \sqrt{\mu\left(\frac{2}{r} - \frac{1}{a}\right)}, \tag{4.28}$$

$$v_d = \frac{1}{r}\sqrt{\mu a(1-e^2)} \tag{4.29}$$



70 Theory of Satellite Fragmentation in Orbit

Fig. 4.3. Orthogonal velocity perturbation components in the radial, down-range and cross-range directions.

and

$$v_r = \pm\sqrt{v^2 - v_d^2}, \tag{4.30}$$

where a is the semi-major axis, e is the eccentricity of the parent's orbit, r is the radial distance from the center of the Earth and μ is the gravitational parameter of the Earth. In Eq. (4.30), the "+" sign corresponds to the *ascending mode* of the satellite (true anomaly $\theta < \pi$) whereas the "−" sign corresponds to the *descending mode* ($\theta > \pi$).

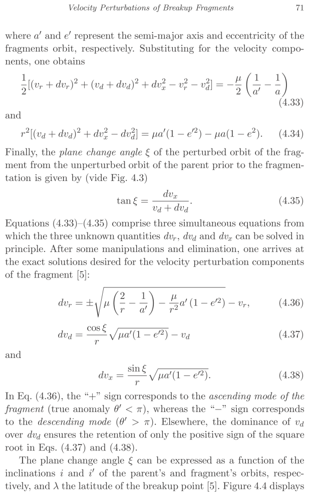
Let (dv_r, dv_d, dv_x) be the components of the velocity perturbation of a fragment $d\vec{v}$. Then its velocity $\vec{v}' = \vec{v} + d\vec{v}$ has the components (v_r+ dv_r, v_d+ dv_d, dv_x) (Fig. 4.3). As a result of this velocity change, the fragment would suffer changes in total energy, angular momentum and orbital inclination. The changes in specific energy E and specific angular momentum $\vec{h}$ are given by [5]

$$E' - E = \frac{1}{2}\left(v'^2 - v^2\right) = -\frac{\mu}{2}\left(\frac{1}{a'} - \frac{1}{a}\right), \tag{4.31}$$

and

$$h'^2 - h^2 = |\vec{r}\times\vec{v}'|^2 - |\vec{r}\times\vec{v}|^2 = \mu a'(1-e'^2) - \mu a(1-e^2), \tag{4.32}$$

Figure 1.63: tsfo01.png   Figure 1.64: tsfo02.png



where a' and e' represent the semi-major axis and eccentricity of the fragments orbit, respectively. Substituting for the velocity components, one obtains

$$\frac{1}{2}[(v_r + dv_r)^2 + (v_d + dv_d)^2 + dv_x^2 - v_r^2 - v_d^2] = -\frac{\mu}{2}\left(\frac{1}{a'} - \frac{1}{a}\right) \tag{4.33}$$

and

$$r^2[(v_d + dv_d)^2 + dv_x^2 - dv_d^2] = \mu a'(1 - e'^2) - \mu a(1 - e^2). \tag{4.34}$$

Finally, the *plane change angle* ξ of the perturbed orbit of the fragment from the unperturbed orbit of the parent prior to the fragmentation is given by (vide Fig. 4.3)

$$\tan\xi = \frac{dv_x}{v_d + dv_d}. \tag{4.35}$$

Equations (4.33)–(4.35) comprise three simultaneous equations from which the three unknown quantities dv_r, dv_d and dv_x can be solved in principle. After some manipulations and elimination, one arrives at the exact solutions desired for the velocity perturbation components of the fragment [5]:

$$dv_r = \pm\sqrt{\mu\left(\frac{2}{r} - \frac{1}{a'}\right) - \frac{\mu}{r^2}a'\,(1 - e'^2)} - v_r, \tag{4.36}$$

$$dv_d = \frac{\cos\xi}{r}\sqrt{\mu a'(1 - e'^2)} - v_d \tag{4.37}$$

and

$$dv_x = \frac{\sin\xi}{r}\sqrt{\mu a'(1 - e'^2)}. \tag{4.38}$$

In Eq. (4.36), the "+" sign corresponds to the *ascending mode of the fragment* (true anomaly $\theta' < \pi$), whereas the "−" sign corresponds to the *descending mode* ($\theta' > \pi$). Elsewhere, the dominance of v_d over dv_d ensures the retention of only the positive sign of the square root in Eqs. (4.37) and (4.38).

The plane change angle ξ can be expressed as a function of the inclinations i and i' of the parent's and fragment's orbits, respectively, and λ the latitude of the breakup point [5]. Figure 4.4 displays

Figure 1.65: tsfo03.png

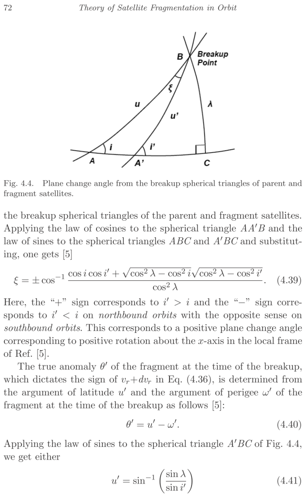


Fig. 4.4. Plane change angle from the breakup spherical triangles of parent and fragment satellites.

the breakup spherical triangles of the parent and fragment satellites. Applying the law of cosines to the spherical triangle $AA'B$ and the law of sines to the spherical triangles ABC and $A'BC$ and substituting, one gets [5]

$$\xi = \pm\cos^{-1}\frac{\cos i\cos i' + \sqrt{\cos^2\lambda - \cos^2 i}\sqrt{\cos^2\lambda - \cos^2 i'}}{\cos^2\lambda}. \tag{4.39}$$

Here, the "+" sign corresponds to $i' > i$ and the "−" sign corresponds to $i' < i$ on *northbound orbits* with the opposite sense on *southbound orbits*. This corresponds to a positive plane change angle corresponding to positive rotation about the x-axis in the local frame of Ref. [5].

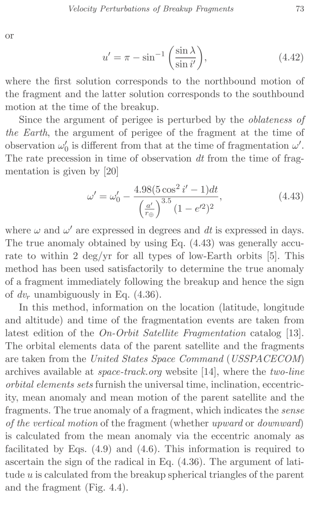
The true anomaly θ' of the fragment at the time of the breakup, which dictates the sign of $v_r + dv_r$ in Eq. (4.36), is determined from the argument of latitude u' and the argument of perigee ω' of the fragment at the time of the breakup as follows [5]:

$$\theta' = u' - \omega'. \tag{4.40}$$

Applying the law of sines to the spherical triangle $A'BC$ of Fig. 4.4, we get either

$$u' = \sin^{-1}\left(\frac{\sin\lambda}{\sin i'}\right) \tag{4.41}$$

Figure 1.66: tsfo04.png



or

$$u' = \pi - \sin^{-1}\left(\frac{\sin\lambda}{\sin i'}\right), \tag{4.42}$$

where the first solution corresponds to the northbound motion of the fragment and the latter solution corresponds to the southbound motion at the time of the breakup.

Since the argument of perigee is perturbed by the *oblateness of the Earth*, the argument of perigee of the fragment at the time of observation ω'_0 is different from that at the time of fragmentation ω'. The rate precession in time of observation dt from the time of fragmentation is given by [20]

$$\omega' = \omega'_0 - \frac{4.98(5\cos^2 i' - 1)dt}{\left(\frac{a'}{r_\oplus}\right)^{3.5}(1 - e'^2)^2}, \tag{4.43}$$

where ω and ω' are expressed in degrees and dt is expressed in days. The true anomaly obtained by using Eq. (4.43) was generally accurate to within 2 deg/yr for all types of low-Earth orbits [5]. This method has been used satisfactorily to determine the true anomaly of a fragment immediately following the breakup and hence the sign of dv_r unambiguously in Eq. (4.36).

In this method, information on the location (latitude, longitude and altitude) and time of the fragmentation events are taken from latest edition of the *On-Orbit Satellite Fragmentation* catalog [13]. The orbital elements data of the parent satellite and the fragments are taken from the *United States Space Command* (*USSPACECOM*) archives available at *space-track.org* website [14], where the *two-line orbital elements sets* furnish the universal time, inclination, eccentricity, mean anomaly and mean motion of the parent satellite and the fragments. The true anomaly of a fragment, which indicates the *sense of the vertical motion* of the fragment (whether *upward* or *downward*) is calculated from the mean anomaly via the eccentric anomaly as facilitated by Eqs. (4.9) and (4.6). This information is required to ascertain the sign of the radical in Eq. (4.36). The argument of latitude u is calculated from the breakup spherical triangles of the parent and the fragment (Fig. 4.4).

Figure 1.67: tsfo05.png

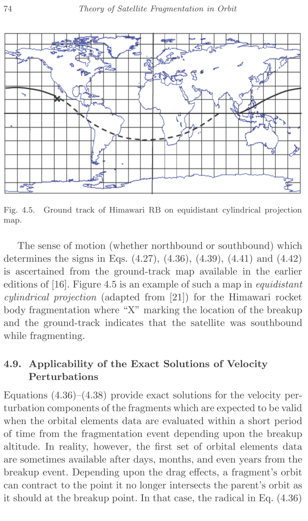


Fig. 4.5. Ground track of Himawari RB on equidistant cylindrical projection map.

The sense of motion (whether northbound or southbound) which determines the signs in Eqs. (4.27), (4.36), (4.39), (4.41) and (4.42) is ascertained from the ground-track map available in the earlier editions of [16]. Figure 4.5 is an example of such a map in *equidistant cylindrical projection* (adapted from [21]) for the Himawari rocket body fragmentation where "X" marking the location of the breakup and the ground-track indicates that the satellite was southbound while fragmenting.

4.9. Applicability of the Exact Solutions of Velocity Perturbations

Equations (4.36)–(4.38) provide exact solutions for the velocity perturbation components of the fragments which are expected to be valid when the orbital elements data are evaluated within a short period of time from the fragmentation event depending upon the breakup altitude. In reality, however, the first set of orbital elements data are sometimes available after days, months, and even years from the breakup event. Depending upon the drag effects, a fragment's orbit can contract to the point it no longer intersects the parent's orbit as it should at the breakup point. In that case, the radical in Eq. (4.36)

IMPORTANT

Pag. 07 (09) - Definition 2.2. The Gaussian curvature at a point x on a surface is

$$\kappa(x) = \lim_{r \to 0+} 12 \frac{\pi r^2 - A(r,x)}{\pi r^4}$$

Figure 1.71: cg03.png

The above formula is known as the Bertrand{Diquet{Puiseux theorem[7] We chose it for its simplicity and since it compares neatly to the definition of the curvature at a point of a curve: the deviation from its tangent. A foundamental theorem by Gauss, Theorema Egregium, published in 1827, says that Gaussian curvature is intrinsic which means that it does not depend on how the surface is embedded into Euclidean 3-space[8]

---

[7] First described in 1848 by its eponymous authors in the French journal Journal de mathematiques pures et appliquees (which can be found online). Gaussian curvature is generally defined as the product of principal curvatures, the formula chosen is an alternate definition.

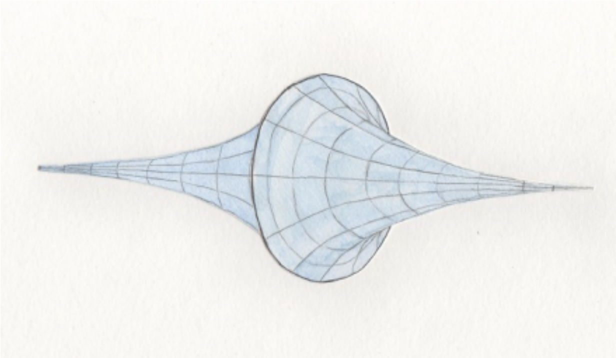

Figure 1.72: cg04.png - Pseudosphere - tractricoid

A tractricoid, which is an example of a pseudosphere. Note that as pseudosphere will necessarily contain singularities; no complete and regular surface of constant negative curvature exists in Euclidean 3-space by Hilbert's theorem (1901).

1.4 Hyperbolische Geometrie

1) https://www.spektrum.de/lexikon/mathematik/hyperbolische-geometrie/4090 Hyperbolische Geometrie Anzeige I.

Als hyperbolische Geometrie oder Lobatschewski-Geometrie wird eine nichteuklidische Geometrie bezeichnet, in der alle Axiome der absoluten Geometrie, also die Axiome der Inzidenz, der Anordnung, der Kongruenz und der Stetigkeit (siehe Axiome der Geometrie), sowie die Verneinung des Parallelenaxioms des Euklid gelten:

Es existiert eine Gerade g und ein nicht auf g liegender Punkt P, durch den mindestens zwei Geraden verlaufen, die mit g in einer Ebene liegen und g nicht schneiden.

Aus diesem Axiom, das auch als Lobatschewskisches Parallelenaxiom bezeichnet wird, und den Axiomen der absoluten Geometrie läßt sich ableiten, daß sogar zu jeder Geraden g und jedem nicht auf g liegenden Punkt P unendlich viele Geraden verlaufen, die mit g in einer Ebene liegen und g nicht schneiden. Allerdings werden nicht alle dieser Geraden als zu g parallel bezeichnet (siehe III.).

Zu der Erkenntnis, daß es eine nichteuklidische Geometrie, basierend auf den Axiomen der absoluten Geometrie und der Negation des euklidischen Parallelenaxioms gibt, gelangten zwischen 1816 und 1832 weitgehend unabhängig voneinander die drei Mathematiker Janos Bolyai, Carl Friedrich Gauss und Nikolai Iwanowitsch Lobatschewski (nichteuklidische Geometrie). Sie lösten damit das seit mehr als zweitausend Jahren bestehende Parallelenproblem auf eine unerwartete Weise, indem sie zeigten, daß das euklidische Parallelenaxiom nicht aus den Axiomen der absoluten Geometrie ableitbar ist. II. Eigenschaften der hyperbolischen Geometrie

Obwohl sich die euklidische und die hyperbolische Geometrie in ihrer Axiomatik nur um ein einziges Axiom, das Parallelenaxiom, unterscheiden, ergeben sich daraus gravierende Unterschiede beider Geometrien in wichtigen Eigenschaften. Zu den interessantesten Eigenschaften der hyperbolischen

Geometrie, die von denen der euklidischen Geometrie abweichen, gehören die folgenden:

Die Innenwinkelsumme eines jeden Dreiecks ist kleiner als 180°. Es existiert kein spitzer Winkel, für den alle in beliebigen Punken eines seiner Schenkel errichteten Senkrechten den anderen Schenkel treffen. Abstandslinien sind keine Geraden, d. h. die Menge aller Punkte, die von einer gegebenen Geraden g denselben positiven Abstand haben und in einer durch g begrenzten Halbebene liegen, ist in keinem Fall eine Gerade. Zwei Dreiecke, die paarweise in allen drei Winkeln übereinstimmen, sind kongruent. Es existieren also keine ähnlichen und dabei nicht kongruenten Dreiecke. Drei Punkte, die nicht auf einer Geraden liegen, gehören nicht in jedem Falle einem Kreis an; im Raum wird durch vier nicht auf einer Ebene liegende Punkte nicht notwendigerweise eine Kugel bestimmt.

III. Parallele und divergierende Geraden

Um in der hyperbolischen Geometrie die Parallelität von Geraden zu definieren, wird der Parallelwinkel ' betrachtet. Es handelt sich dabei für eine gegebene Gerade a und einen nicht auf a liegenden Punkt P um den kleinsten Winkel zwischen einer Geraden b durch P, die mit a in einer Ebene liegt und a nicht schneidet, und dem Lot von P auf a. Dieser Parallelwinkel (oder Grenzwinkel) ist auf beiden Seiten des Lotes gleich groß.

Die Halbgeraden

$$b_1^+$$

und

$$b_2^+$$

mit dem Anfangspunkt P, für die

$$< \; PA^+ ; b_1^+ \; = < \; Pa^+ ; b_2^+ \; =$$

gilt (wobei ' Parallelwinkel in P in Bezug auf a und A Fußpunkt des Lotes von P auf a ist), haben mit der Geraden a keinen Punkt gemeinsam.

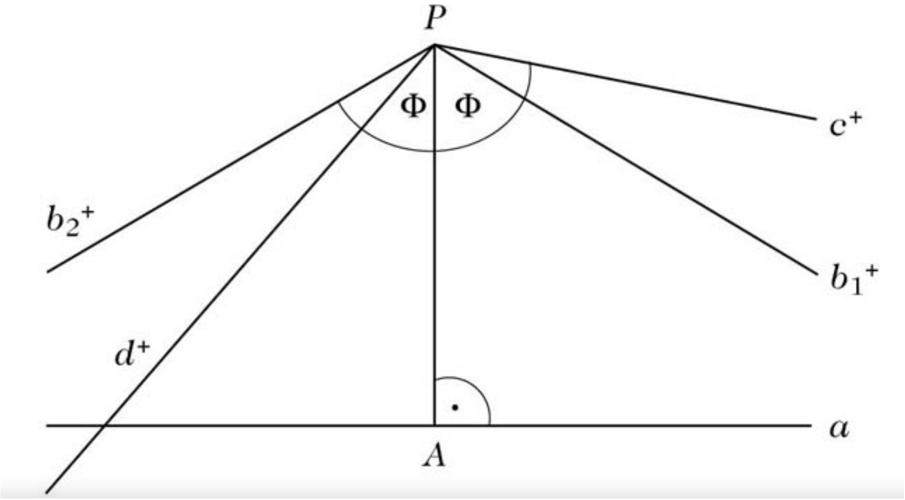

Figure 1.75: hg01.png

Parallelwinkel

Gleiches gilt für jede Halbgerade c^+ mit dem Anfangspunkt P und $<(PA^+ ; c^+) > '$. Ist dagegen d^+ eine Halbgerade mit $< (PA^+ ; d^+) < '$, so schneidet d^+ die Gerade a. Die Geraden b1 und b2, denen die Halbgeraden

$$b_1^+$$

und

$$b_2^+$$

angehören. sind Grenzgeraden in der Gesamtheit aller Geraden, die durch P verlaufen und a nicht schneiden und werden als zu a parallele Geraden bezeichnet. Die so definierte Parallelität ist symmetrisch und transitiv.

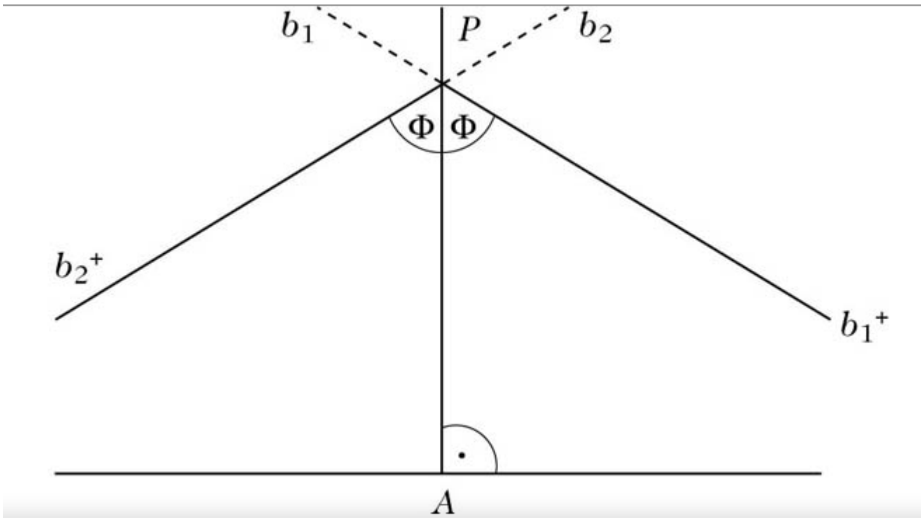

Figure 1.76: hg02.png

Zwei Geraden einer Ebene, die keinen gemeinsamen Punkt besitzen und nicht parallel sind, heißen divergierend. Zwei divergierende Geraden besitzen stets eine gemeinsame Senkrechte, dagegen gibt es zu zwei parallelen Geraden in keinem Falle eine Gerade, die auf den beiden Parallelen senkrecht steht. Es gilt sogar, daß es keine Gerade gibt, die mit zwei parallelen Geraden gleiche Stufen- oder Wechselwinkel bildet.

IV. Die Lobatschewskische Funktion

Eine fundamentale Eigenschaft der hyperbolischen Geometrie besteht darin, daß der Parallelwinkel in einem Punkt P in Bezug auf eine Gerade g nur vom Abstand x des Punktes P von der Geraden g abhängt. Der Parallelwinkel läßt sich somit als Funktion des Abstandes x auffassen:

$$= (\ x); \tag{1.14}$$

wobei ; als Lobatschewskische Funktion bezeichnet wird. Der Definitionsbereich dieser Funktion ist $(0;1)$. ihr Weterbereich

$$(0;\frac{}{2}) \tag{1.15}$$

. ist auf ihrem gesamten Definitionsbereich stetig sowie streng monoton fallend und besitzt folgende uneigentliche Grenzwerte:

$$\lim_{x!1}(x)=0;\quad \lim_{x!\ 0^{+}}(x)=\frac{}{2}: \tag{1.16}$$

Aus dem zweiten dieser Grenzwerte ergibt sich, daß für sehr gering ausgedehnte Bereiche der Parallelwinkel nahezu gleich

$$\frac{}{2} \tag{1.17}$$

ist, damit sind die beiden Parallelen zu einer Geraden durch einen Punkt kaum voneinander zu unterscheiden. Alle Eigenschaften der hyperbolischen Geometrie nähern sich deshalb in sehr kleinen Bereichen denen der euklidischen Geometrie an, da die Unterschiede beider Geometrien nur auf den verschiedenen Parallelenaxiomen beruhen. Das bedeutet, daß sich aus der Kenntnis "sehr kleiner Teile" eines Raumes nicht genau bestimmen läßt, ob es sich um einen euklidischen oder einen nichteuklidischen Raum handelt.

Analytisch läßt sich die Lobatschewskische Funktion durch die Gleichung

$$(x)=2\quad\arctan\exp\frac{x}{R} \tag{1.18}$$

darstellen, die u. a. benötigt wird, um die Formeln der hyperbolischen Trigonometrie herzuleiten.

Eine sehr wichtige Schlußfolgerung aus der Existenz der Lobatschewskischen Funktion besteht darin, daß es in der hyperbolischen Geometrie eine absolute Länge gibt. Durch einen gestreckten Winkel (bzw. Teile eines solchen, die beispielsweise durch Halbierung gewonnen werden können) sind in der euklidischen Geometrie absolute Winkelgrößen gegeben, die sich durch eine abstrakte Vorschrift beschreiben lassen. So ist die Größe eines rechten Winkels durch die Konstruktionsbeschreibung "Errichtung der Senkrechten" gegeben und bedarf keiner willkürlich festgelegten Eichhilfen, wie des Einheitsmeters. Im Gegensatz dazu gibt es in der euklidischen Geometrie keine absoluten

Streckengrößen. In der hyperbolischen Geometrie existieren derartige absolute Längen. Sie lassen sich aus absoluten Winkeln mittels der Umkehrfunktion der Funktion ermitteln. Beispielsweise wird durch

$$l := {}^{1}\ \frac{}{4} \tag{1.19}$$

eine Länge l ausgezeichnet, die keinerlei Willkür unterliegt.

Die Existenz einer absoluten Länge ist mit der Nichtexistenz ähnlicher Figuren verbunden. Das (PageNum - 460) Vorhandensein ähnlicher Figuren (die nur in der euklidischen Geometrie existieren) schließt die Möglichkeit der Bestimmung absoluter Längen aus. V. Modelle der hyperbolischen Geometrie

Um die Widerspruchsfreiheit der hyperbolischen Geometrie (und gleichbedeutend damit die Unabhängigkeit des Parallelenaxioms des Euklid von den Axiomen der absoluten Geometrie) nachzuweisen sowie eine anschauliche Interpretation der hyperbolischen Geometrie zu geben, werden die Grundbegriffe der hyperbolischen Geometrie durch bekannte Objekte der euklidischen (oder projektiven) Geometrie interpretiert. Dabei sind sehr unterschiedliche Interpretationen (Modelle) möglich. Zu den bekanntesten zählen die Poincaré-Halbebene, die Poincaré-Kreisscheibe sowie das Kleinsche Modell, bei denen die zweidimensionale hyperbolische Geometrie innerhalb einer offenen Halbebene bzw. einer offenen Kreisscheibe der euklidischen Ebene aufgebaut wird.

Eines der interessantesten Modelle der hyperbolischen Geometrie ist das pseudoeuklidische Modell, bei dem die Analogie zur sphärischen Geometrie (die ihrerseits ein Modell der elliptischen Geometrie ist) gut sichtbar wird. Die hyperbolische Ebene wird hierbei als Sphäre H mit imaginärem Radius innerhalb eines dreidimensionalen pseudoeuklidischen Raumes modelliert. (Aus euklidischer Sicht ist diese Sphäre ein zweischaliges Rotationshyperboloid, aus der Sicht der hyperbolischen Geometrie eine Ebene.) Hyperbolische Punkte sind bei diesem Modell alle diametralen Punktepaare auf H, also Paare von Punkten, die auf einer Geraden durch den Koordinatenursprung liegen (siehe Abbildung { die euklidischen Punkte P1 und P2 werden als ein H-Punkt identifiziert).

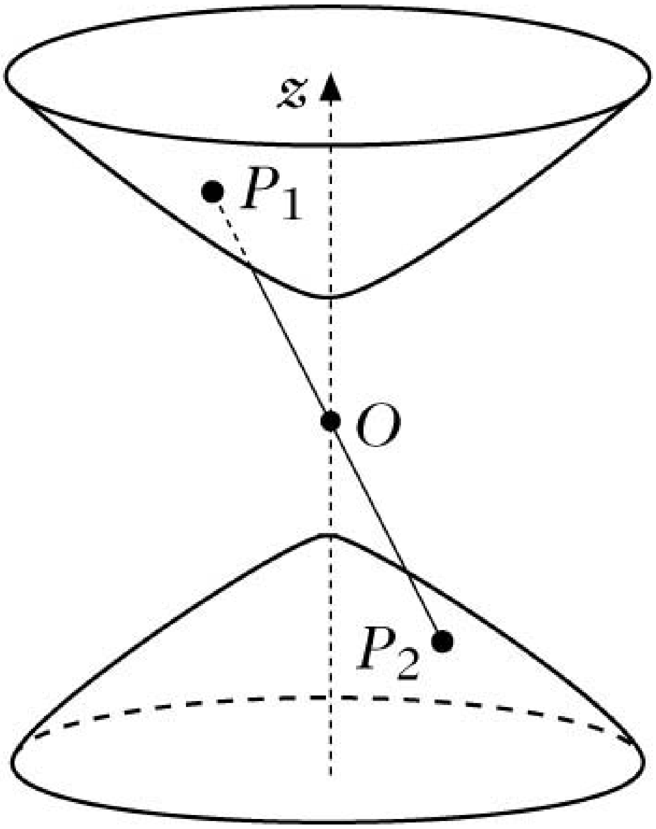

Figure 1.77: hg03.png

Hyperbolische Geraden sind alle Schnittkurven der hyperbolischen Ebene H mit (euklidischen) Ebenen, die durch den Mittelpunkt bzw. Koordinatenursprung verlaufen. Pseudoeuklidisch gesehen handelt es sich bei diesen Geraden also um Gro kreise und euklidisch um Hyperbeln.

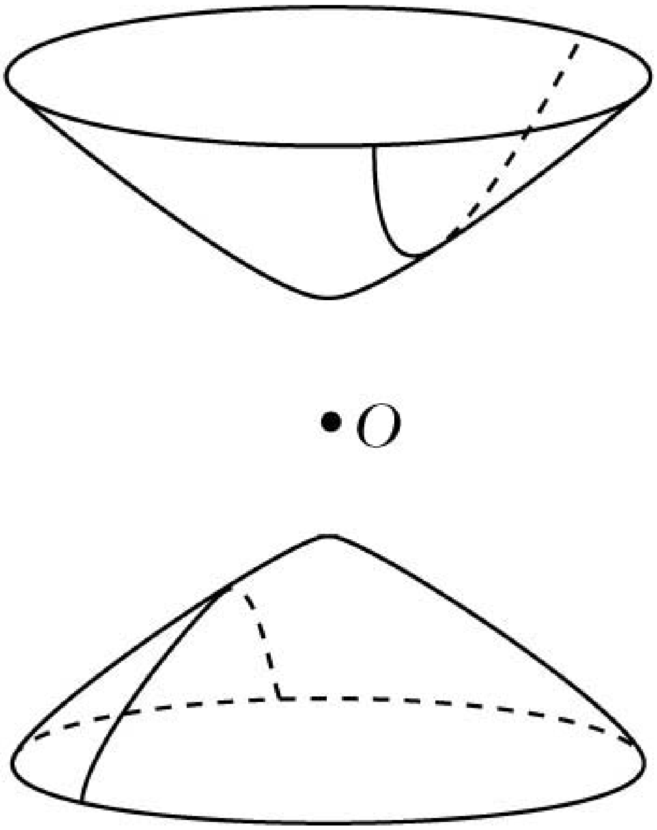

Figure 1.78: hg04.png

Geraden im pseudoeuklidischen Modell

Hyperbolische Abstände von Punkten werden im pseudoeuklidischen Modell als Längen von Großkreisbögen, welche die entsprechenden Punkte miteinander verbinden, definiert (wobei es sich bei diesen Großkreisbögen euklidisch gesehen um Hyperbelbögen handelt). Wie in der sphärischen Geometrie besteht ein Zusammenhang zwischen der Länge des Großkreisbogens zwischen zwei Punkten und dem Winkel ihrer Radiusvektoren, wobei hier die Winkel pseudoeuklidisch zu messen sind (pseudoeuklidischer Raum).

Durch Projektion der oberen Schale des Hyperboloids (mit dem Radius i) vom Koordinatenursprung aus auf die Ebene z = 1 entsteht aus dem pseudoeuklidischen Modell der hyperbolischen Geometrie das Kleinsche Modell. VI. Hyperbolische Geometrie als Geometrie auf einer Fläche konstanter negativer Krümmung

So wie die Elliptische Geometrie als Geometrie auf einer (Hyper-)Fläche konstanter positiver Krümmung und die euklidische Geometrie als Geometrie auf einer Fläche der Krümmung Null aufgefaßt werden können, läßt sich die hyperbolische Geometrie als Geometrie auf einer Fläche konstanter negativer Krümmung interpretieren. Innerhalb des pseudoeuklidischen Raumes besitzt eine Sphäre mit imaginärem Radius (siehe V.) eine konstante negative Krümmung, für r = i ist z. B.

$$k = \frac{1}{r^2} = \quad 1: \qquad (1.20)$$

Innerhalb des euklidischen Raumes ist die Pseudosphäre eine Fläche konstanter negativer Krümmung (der Name weist auf die Verwandtschaft mit der Sphäre als Fläche konstanter positiver Krümmung hin). Es handelt sich dabei um die Rotationsfläche der Traktrix (auch als Schleppkurve bekannt). Diese Pseudosphäre wird durch folgende Parameterdarstellung (mit den Parametern %und sowie (PageNum - 461 einer Konstante R) beschrieben:

$$\begin{aligned} x &= \% \cos ; \\ y &= \% \sin ; \\ z &= R \ln \frac{R + \sqrt{R^2 \quad \%^2}}{\%} \quad \sqrt{R^2 \quad \%^2}: \end{aligned} \qquad (1.21)$$

Die Kruuml;mmung der Pseudosphare ist in jedem ihrer Punkte

$$k = \quad \frac{1}{R^2} \qquad (1.22)$$

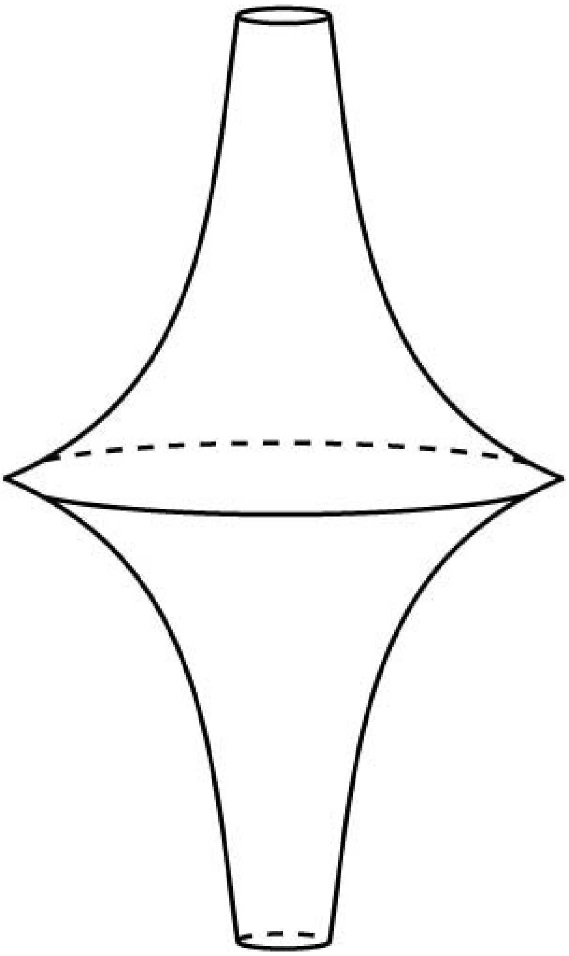

Figure 1.79: hg05.png

Pseudosphäre

Die Geometrie auf der Pseudosphäre wurde um 1840 durch Minding eingehend untersucht. ohne daß dieser jedoch einen Bezug zu den Erkenntnissen von Bolyai. Gauss und Lobatschewski hergestellte.

Beltrami schuf 1868 auf Grundlage der Untersuchungen Mindings das erste Modell der hyperbolischen Geometrie und trug damit maßgeblich zu deren Akzeptanz bei. Literatur

1.5 Testing the Limit of Einstein's Theories

1) https://www.discovermagazine.com/the-sciences/testing-the-limit-of-einsteins-theories

Scientists finally have the technology to construct mind-boggling experiments that can tell us just how far relativity can be stretched. By Robert Kunzig September 30, 2004 2:00 AM

Einstein didn't care much about experiments. Of the three tests he proposed for general relativity, the first|that clocks should tick slower in a gravitational field|wasn't satisfied until after his death. Early experiments tended to contradict the prediction. His second prediction, that light from distant stars would be deflected by the warped space-time around the sun, catapulted him to world fame in 1919, when observations of a solar eclipse seemed to confirm his prediction. But as historians have since shown, the 1919 measurements were equivocal at best.

The one unequivocal verification of Einstein's theory during his lifetime was his explanation of a tiny anomaly in the orbit of Mercury. When he finally got that calculation to work, that was the only evidence he needed that space and time really were warped. \Nature had spoken to him," wrote biographer Abraham Pais. \He had to be right."

We now know he was. Just last year, for instance, radio signals transmitted from the Cassini spacecraft on its way to Saturn proved to be deflected by the sun by just the amount predicted by general relativity. Einstein would have been unimpressed. He believed his theory was correct because it was consistent, simple, and beautiful. \It is my conviction that pure mathematical construction enables us to discover the concepts and the laws connecting them, which give us the key to the understanding of the phenomena of Nature," he declared in 1933.

For better and worse, this aspect of Einstein's approach to physics is very much alive today: \Pure mathematical construction" is an industry that employs hundreds of workers. What they have been trying to construct is a unified theory of the four forces|gravity, electromagnetism, and the strong and weak nuclear forces. To build that, they first have to find a way of describing gravity, not in Einsteinian terms as a curvature of space-time but like the other three forces, as an exchange of force-bearing quanta. This quantum gravity theory would take over from general relativity in the extraordinarily tight quarters|the very core of a black hole, the very instant of the Big Bang|where relativity now predicts, absurdly, that space-time is infinitely curved. The final unified theory, in turn, would gratify most physicists' deep belief that the four forces really were equivalent once, in the first nanosecond after the Big Bang. That idea "is so beautiful that it has to be that way," explains physicist Clifford Will of Washington University. "That's an Einsteinian point of view."

Sure enough, there is as yet no experimental evidence to support this view—indeed, the improbability of ever reproducing black holes or big bangs in the laboratory has caused some researchers to wonder whether there will ever be any evidence. "Since the middle 1970s we've been in a situation in fundamental physics in which theory has run on, largely unchecked by experiments," says Lee Smolin, a theoretical physicist at the Perimeter Institute near Toronto. (Smolin's article on Einstein and his scientific legacy begins on page 36.) "And most of us think this has been very bad."

But lately Smolin and others have been finding grounds for optimism: The reign of the theorists seems to be coming to an end. The several schools of quantum gravity, physicists have realized, are slowly reaching consensus that incremental violations of relativity might be detectable even outside a black hole, and without building a particle accelerator the size of the universe. For that reason, and also because experimenters like to poke at the marble facades of grand theories, Einstein's ideas are being tested with increasing frequency these days and to extraordinary precision. What follows is a sampling of these experiments—just a few of the many now under way or on the drawing boards.

"I do not consider the main significance of the general theory of relativity to be the prediction of some tiny observable effects," wrote Einstein in 1930. Nonetheless, it was tiny observable effects that eventually proved that in certain situations Newton's physics needed to be replaced by Einstein's. In the same way it will be tiny observable effects that will one day prove where the limits of Einstein's genius lie. "People sometimes ask, 'Why have you felt you should persist in this way to perform a test of Einstein?' " says Stanford University physicist Francis Everitt, one of the leaders of a satellite experiment called Gravity Probe B, which was launched in April. "Aren't Einstein's theories all established and confirmed? After all, it's a hundred years ago that he developed his first theory of relativity. Don't we already know it all? And the answer is no." Some of the most important experiments under way may answer the questions that follow.

IS THE SPEED OF LIGHT CONSTANT?

Late in life Einstein couldn't even remember whether he'd been aware, in 1905, of the Michelson-Morley experiment, which showed that the speed of light is constant in all directions. Although we now think of the experiment as having shattered absolute space and time, that result was not at all what

Albert Michelson and Edward Morley expected when they did their experiment in 1887, in a basement of the Western Reserve University in Cleveland. They were trying to detect variations in the speed of light to prove the existence of the "luminiferous aether," a perfectly immobile, transparent, and mysterious substance that was thought to pervade the universe. Physicists had conceived of the ether as a medium that could transmit light waves, the way air or water transmits sound. The ether had to exist, but no one had seen it—it was a bit like dark matter today.

Because Earth orbits the sun at 18 miles per second, Michelson and Morley reasoned that they should be able to detect an ether wind blowing through their Cleveland basement with the help of an experimental setup called an interferometer. They split a light beam in two with a half-silvered mirror, sent the two halves of light off at right angles, and then bounced them off mirrors about five feet away. The two men expected that light waves traveling against the ether wind, in the same direction as Earth's motion, would be slowed and would arrive back at the starting point slightly later than the light waves traveling across the wind. When the two beams were recombined, the offset waves would interfere with each other to produce a distinctive pattern of light and dark bands. Michelson and Morley made their measurements with extraordinary care but saw no disruption in the pattern—the light beams traveled the same speed in all directions, impervious to any ether wind.

One null result, of course, did not rid the universe of the ether. Michelson went to his grave in 1931 convinced that it had to exist. But by then Einstein had changed most people's minds and persuaded them to accept the simple, beautiful truth: The velocity of light, c, really is different from any other velocity. Anyone who measures the speed of any light beam—or any other type of electromagnetic radiation—will get the same value for c: 299,792,458 meters per second. There is no absolute space, Einstein decided, ether-filled or otherwise. Seen in that light, the Michelson-Morley result made perfect sense.

And yet today theorists are questioning the absoluteness of c. Some versions of string theory, the most popular candidate for a unified theory, say there could be extremely feeble force fields left over from the Big Bang that point in different directions in different parts of space. An experiment to measure c might produce variations depending on how the setup was oriented with respect to one of those fields, variations far smaller than Michelson and Morley could have detected.

Several groups are looking for such variations with modern versions of the Michelson-Morley experiment. Peter Wolf, Sebastien Bize, and their colleagues at the Paris Observatory measure c with microwaves oscillating at 12 gigahertz inside a small sapphire crystal. Microwaves reflecting back and forth within the crystal line up and reinforce each other, or resonate|as long as they are moving precisely at c. If c were to change because the orientation of the crystal had changed with respect to some \preferred" direction of space, then the resonant frequency of the sapphire oscillator would change as well. The apparatus containing the crystal is bathed in liquid helium, chilling it to a few degrees above absolute zero to make sure that the crystal doesn't expand or contract by even a femtometer.

Over a period of months, as Earth spins on its axis and revolves around the sun, the Paris researchers monitor their oscillator, comparing it with the microwaves from a hydrogen maser (microwave laser), which shouldn't be affected by Earth's motion. \What we measure is that small frequency difference," says Bize. \We look for modulations that correlate with the motion of Earth."

Another group, based at Humboldt University in Berlin, uses a slightly different setup, comparing the outputs of a pair of sapphire oscillators. Over the past several years the two groups have achieved broadly comparable null results. \The speed of light in any two directions is the same to about one part in a quadrillion," says Holger Müller, a former member of the Berlin team who now works at Stanford. That's equivalent to knowing the U.S. gross national product to within a penny.

Over vast distances, even such slight variations could become meaningful. If two photons differed that much in velocity, and if they left a galaxy a billion light-years away at the same instant, they would arrive at Earth 30 seconds apart. A few years ago physicist Giovanni Amelino-Camelia at La Sapienza University in Rome had an idea for staging just such a race to test the constancy of c in a new way. Some theories of quantum gravity require space-time itself to be grainy - to be made up of discrete quanta, presumably around 10^{-35} of a meter across because that's the scale at which Einstein's field equations generate their bothersome infinities. (A proton is a hundred million trillion times bigger.) Amelino-Camelia calculated that light photons might navigate this cosmic foam at slightly different speeds, depending not on their direction - the possibility the Michelson-Morley experiments test for - but on their energy.

In 2007 or so, NASA plans to launch GLAST, the Gamma Ray Large Area Space Telescope. Its main purpose is to allow astronomers to study such events as gamma-ray bursts, which are mysteriously powerful explosions in distant galaxies. But it could also serve as Amelino-Camelia's finish line. All the photons in a burst, he reasons, must leave the starting blocks at about the same time. If you compare a lot of high-energy photons with a lot of relatively low-energy ones, you should find that on average, after a billion-year race, the high-energy ones reach GLAST's detector sooner - by about a millisecond. He and other quantum gravity theorists are pretty excited by that possibility, which just goes to show what they're up against.

WAS EINSTEIN RIGHT ABOUT FREE FALL?

In 1907, sitting at his desk in the patent office in Bern, Switzerland, Einstein imagined himself jumping off a house and realized that while falling he wouldn't feel his weight. It would have been more poetic to choose the Tower of Pisa for his thought experiment: Galileo, in his own legendary experiments there—truly legendary, because he probably never actually did them—had shown that objects of different mass and composition are equivalent in that they undergo the same gravitational acceleration. If they are dropped at the same time, they should hit the ground at the same time. Einstein took Galileo's equivalence principle much further. Einstein realized that if a freely falling physicist dropped something, it would stay right next to him. The falling man would have no way of telling (if he closed his eyes) that he was falling, no awareness of gravity at all; that would also go for every instrument in the lab he brought with him. Einstein eventually concluded that gravity was a curvature of space-time, not something that emanated from the masses themselves.

But was Galileo himself right? Newton, among others, tested the equivalence principle. Apparently unbeknownst to Einstein in 1907, a Hungarian baron named Roland von Eötvös had recently completed updated, highly accurate tests using a device called a torsion pendulum. Modern versions of the Eötvös experiment continue to this day in a number of labs. Apollo 15 commander David Scott carried out a less accurate but far more colorful demonstration at the end of his last moonwalk in 1971, when he dropped a geologist's hammer and a falcon feather from shoulder height. A live TV audience watched them hit the airless moon at the same time. After the Apollo missions, physicists on Earth started bouncing laser beams off reflectors that the astronauts had left on the moon, measuring the Earth–moon distance with increasing precision. Although Earth and the moon are made of different stuff—the moon lacks an iron core—the measurements so far reveal that they are “falling” toward the sun with exactly the same acceleration.

Lunar laser ranging and the modern Eötvös experiments have confirmed the equivalence principle to within less than one part in a trillion. Pierre Touboul, a physicist at ONERA, the French aerospace research agency, thinks he can do a hundred to a thousand times better. Touboul is the project scientist for MICROSCOPE, a microsatellite to be launched in 2007 by the European Space Agency. Its purpose is to conduct Galileo's free-fall experiment in space, with test masses of different composition. In space, Touboul explains, you don't need to worry about tiny fluctuations in the gravitational field outside your lab that might throw off your results. Like the moon, orbiting test masses fall for a long time, allowing you to drown out noise with data.

The test masses on MICROSCOPE will be two concentric cylinders of titanium and platinum. (A control experiment will use two platinum cylinders.) The cylinders will be sandwiched between electrodes of gold-plated silicon but also separated from them by thin spaces of vacuum|the test masses will float on the electrodes' electrostatic field. Loose lengths of wire five micrometers wide, which will remove any electric charge delivered by cosmic rays, will be their only physical contact with the rest of the satellite. Thrusters on the satellite will compensate for the small drag exerted by the outer wisps of the atmosphere. The only force the test masses will feel is Earth's gravity. Any differences in the electrostatic field needed to keep them in the same orbit will be supplied by the electrostatic levitation.

Instead of trying to determine whether the two masses fall differently, one dipping toward Earth slightly more, Touboul explains that it is easier and more precise to measure the electrostatic forces required to maintain them at exactly the same orbit. The forces are just a function of the current supplied to the electrodes. \If the forces are identical, there's no violation of the equivalence principle," says Touboul. MICROSCOPE will keep the test mass orbits identical to within 100 billionths of a meter, or a tenth the width of an atom. That should allow it to detect violations of the equivalence principle down to one part in a quadrillion. Some string theorists have predicted bigger violations than that.

\From a scientific point of view, finding no violation is just as interesting as finding one," Touboul says. \But my innermost conviction is that there will certainly be a violation. We just don't know at what level."

DOES EARTH WARP AND TWIST SPACE-TIME?

Eight years before he completed general relativity, Einstein made a weird prediction: Gravity should slow the passage of time and stretch light waves toward the red end of the spectrum. For years people tried and failed to see this gravitational redshift in the spectrum of sunlight. It wasn't precisely confirmed until 1976, when a Scout D rocket carried a hydrogen-maser clock to an altitude of 10,000 kilometers, or about 6,000 miles. In the two hours before it plunged into the Atlantic a thousand miles east of Bermuda, the rocket's timekeeping was compared with that of an identical clock on Earth. A hydrogen maser emits microwaves at 1.42 gigahertz; at the rocket's apogee the clock on board was about one hertz faster than its terrestrial twin. Einstein was vindicated at last, with a precision of a few parts in a hundred thousand: The stronger the gravity, the slower the clock.

That mission was called Gravity Probe A. Since then atomic clocks have progressed tremendously, and a European mission called ACES, for Atomic

Clock Ensemble in Space, may put one on the space station in 2007. Its laser-cooled cesium clock is supposed to measure the gravitational redshift 25 times more precisely than Gravity Probe A; at the altitude of the space station, it should gain about a second in 700 years. And last April NASA finally launched Gravity Probe B, which had been on the drawing boards since 1961. It is designed to measure the curvature of space-time and how the spinning Earth affects it.

The bulk of Gravity Probe B is a thermos filled with 645 gallons of liquid helium. At its heart are four absurdly sensitive gyroscopes. Each one is a quartz sphere the size of a Ping-Pong ball, smooth to within a millionth of an inch and coated with the metal niobium, which is superconducting at liquid helium temperatures. As the sphere floats in an electrostatic field and spins at 10,000 revolutions per minute, a current in the niobium will generate a magnetic field that will be perfectly aligned with the sphere's otherwise invisible spin axis—and be measurable by sensitive detectors.

By early summer the satellite's telescope had locked onto a distant guide star, IM Pegasi; all four spheres are now being aligned with this star. For the next year the Gravity Probe B team, led by Francis Everitt of Stanford, will monitor the spheres to see if the warp or drag of space tilts their spin axes out of alignment. “It's going to be a very dull experiment," Everitt says.

Yet it has been a somewhat controversial one. The mission didn't seem worth its 700 million cost to some physicists, who felt that during its 40-year gestation Gravity Probe B had been overtaken by other research. The measurement of space curvature made with the Cassini spacecraft, for instance, is already several times more accurate than Gravity Probe B's stated goal of 0.01 percent accuracy. (Everitt's team hopes to exceed that.)

But Gravity Probe B will also do something more important. It will quantify how the spinning Earth stirs space-time like molasses—a relativistic effect called frame dragging that has never been measured directly. Around Earth the phenomenon is a curiosity; to see it, Everitt's team will have to detect a deflection of their gyroscope axes of only 42 thousandths of an arc second. (That's an angle, the team's literature explains, the width of a human hair seen at a distance of a quarter mile.) Around spinning black holes, however, frame dragging could be hugely important: By whipping magnetic field lines through the electrically charged gas around the holes, it could convert them into electromagnetic generators, which would explain how they spew jets of energetic particles millions of light-years into space. “What Gravity Probe B will do for us is verify for the first time that this effect exists," says Caltech gravitational theorist Kip Thorne. It will also verify if general relativity can accurately predict the magnitude of the effect.

DO GRAVITATIONAL WAVES ROIL THE UNIVERSE?

If you need any proof of the complete faith modern physicists have in relativity, you can find it in Livingston, Louisiana. Or in Hanford, Washington. Or outside Pisa, Italy. In all those places physicists have built novel observatories costing hundreds of millions of dollars each, with arms extending several miles in perpendicular directions. The observatories are designed to detect a kind of radiation that has never been observed but that general relativity tells the physicists must exist: gravitational waves.

Gravitational waves are ripples in the space-time sea; Einstein predicted that they should exist as early as 1916. They spread out in all directions when something massive in the cosmos makes a big splash. The best sources physicists can think of are two black holes or two neutron stars spiraling toward each other and then colliding. In fact, although no one has seen a gravitational wave, a Nobel Prize has already been awarded for work that demonstrates their reality. Astronomers Joseph Taylor and Russell Hulse showed that two orbiting pulsars|neutron stars that emit beams of radiation as they spin|are slowing down by an amount that corresponds exactly to the energy that relativity predicts they should be emitting as gravitational waves. Still, it would be nice to detect a wave. \It would close the books," says physicist Peter Saulson, who works on the two American observatories, which are called LIGO, for Laser Interferometer Gravitational Wave Observatory. \It's a sanity check."

The observatories now coming online|the two LIGOs are operating but still debugging; the European one, VIRGO, will turn on next year|are all Michelson interferometers. An infrared laser beam is split in two; one half travels down one two-and-a-half-mile vacuum tunnel, and the other half travels down a second tunnel at a right angle to the first. Each beam reflects off a mirror at the end of the tunnel and returns to the starting point, where the two beams interfere. Changes in the interference pattern, which Michelson had hoped would show variations in the speed of light, now serve to indicate changes in the length of the beams. These changes, scientists predict, will be caused by a gravitational wave that stretches and squeezes space-time as it passes through the instruments. The observatories are designed to detect changes as small as a hundred millionth the size of a hydrogen atom. A gravitational wave is so difficult to distinguish from other vibrations that physicists won't believe in a wave's existence unless at least two observatories see the same minuscule shift.

If they do see some waves, they will be able to test general relativity in several ways. Relativity predicts exactly how much stretching and squeezing a gravitational wave should do. It predicts that gravitational waves should travel at the speed of light. It predicts in some detail the space-time turbulence that would result when two black holes collide.

The problem is, no one really knows how often such events occur. The observatories are designed to be sensitive to waves from as far away as the Virgo cluster of galaxies 65 million light-years away. But that may not be enough of a range. Even before LIGO reaches its design sensitivity, its leaders have requested funding to make it 10 times more sensitive still. On the other hand, physicists are confident enough of eventual success that they have persuaded NASA and the European Space Agency to start planning for LISA, for Laser Interferometer Space Antenna, a space-based interferometer consisting of three satellites, now tentatively scheduled for launch in 2012.

The first detection of a gravitational wave, says Clifford Will, \will be an exciting moment. It will legitimize this whole thing."

WILL WE FIND THAT EINSTEIN GOT RELATIVITY JUST A WEE BIT WRONG?

It's just a matter of time, most physicists think, before Einstein fails. Relativity touches so much of physics that a violation could show up almost anywhere. In addition to all the experiments already mentioned, it might come from quasars in the far reaches of the universe. A team of astronomers led by John Webb of the University of New South Wales has been measuring how the light from quasars is absorbed by gas clouds that lie between them and us but are still billions of light-years away, and thus did their absorbing billions of years ago. The frequencies of light absorbed by an atom are governed by a physical property called the fine-structure constant. By comparing their gas cloud data with equivalent measurements made in laboratories on Earth, Webb and his colleagues have hypothesized that the fine-structure constant today is about a thousandth of a percent larger than it was 8 billion years ago. If so, that would clearly violate the equivalence principle|the laws of physics are not supposed to change over time. Recently, though, another team of astronomers failed to confirm Webb's observations. The jury is still out.

A violation of relativity may also show up in observations of cosmic rays, the energetic particles that bombard Earth from all directions. Calculations based on special relativity predict that ultrahigh-energy cosmic rays should reach Earth only rarely, because they lose energy in space. A Japanese observatory has seen more than expected, and theorists such as Amelino-Camelia think this excess might be the first evidence of a space-time graininess that would ease the passage of high-energy particles. A more powerful observatory now beginning work in Argentina may resolve the issue.

Finally, there's that nagging little question of what the universe is made of. The concept of dark matter has been around so long now, and the idea that it makes up much of the universe has been repeated so often that one might almost forget that it has never been detected. One of the main reasons people believe that galaxies have halos of dark matter is that the galaxies rotate faster in their outer reaches than the gravity exerted by their visible matter would seem to permit. But an alternative theory, called modified Newtonian dynamics, or MOND, does an even better job of explaining galaxy rotation by simply tinkering with Newton's law of gravitation|and thus with Einstein's.

It's an ugly fix, and unlike dark matter it's not connected to a larger theory of particle physics, so theorists don't like it. And yet, says Lee Smolin, \a growing number of people from different specialties are telling me they are waking up in the middle of the night worrying about how well MOND does. I hope the dark-matter models in the end do better. If not, we are seeing massive violations of the Einstein equations right in front of us."

Wouldn't that be fun? Wouldn't it be fun, in fact, to see the old clown-haired saint taken down a nano-peg by a few tiny observable effects? Maybe we'd hear a bit less of that \subtle is the Lord" and \God does not play dice" nonsense. \There are two kinds of psychology in physics," says Saulson. \One is people who love order and beauty and hope the theories are right. The other is people who think theorists are full of baloney and who hope we'll find something amazing when we turn on our experiments." With a little luck, the second group is about to have its turn.

2) https://solarsystem.nasa.gov/news/12249/saturn-bound-spacecraft-tests-einsteins-theory/

Saturn-Bound Spacecraft Tests Einstein's Theory

An experiment by Italian scientists using data from NASA's Cassini spacecraft, currently en route to Saturn, confirms Einstein's theory of general relativity with a precision that is 50 times greater than previous measurements.

The findings appear in the Sept. 25 issue of the journal Nature. They are part of a scientific collaboration between NASA and the Italian Space Agency. The experiment took place in the summer of 2002, when the spacecraft and Earth were on opposite sides of the Sun separated by a distance of more than 1 billion kilometers (approximately 621 million miles).

Researchers observed the frequency shift of radio waves to and from the spacecraft as the waves passed near the Sun. They precisely measured the change in the round-trip light time of the radio signal as it traveled close to the Sun. The round-trip light time is the time it takes the signal transmitted from the Deep Space Network station in Goldstone Calif., to the spacecraft on the other side of the Sun and back traveling at the speed of light.

"The scientific significance of these results is the important confirmation of the theory of general relativity and the agreement with Einstein's formulations to an unprecedented experimental accuracy," said Sami Asmar, manager of the Radio Science Group, which acquired the data for this experiment at NASA's Jet Propulsion Laboratory in Pasadena, Calif. "The technological significance of the experiment is the ability to overcome the harsh solar environment on radio links."

The researchers measured how much the Sun's gravity bent an electromagnetic beam, in this case the radio signal transmitted by the spacecraft and received by the ground stations.

According to the theory of general relativity, a massive object like the Sun causes space-time to curve, and a beam of radio waves (or light) that passes by the Sun has to travel further because of the curvature. The extra distance that the radio waves travel from Cassini past the Sun to the Earth delays their arrival; the amount of the delay provides a sensitive test of the predictions of Einstein's theory. Although deviations from general relativity are expected in some cosmological models, none were found in this experiment.

Tests of general relativity have important cosmological implications. The question is not whether general relativity is true or false, but at which level of accuracy it ceases to describe gravity in a realistic way.

Past tests of general relativity confirmed Einstein's prediction to an accuracy of one part per thousand. This accuracy was achieved back in 1979 using the Viking landers on Mars. The Cassini experiment confirmed it to an accuracy of 20 parts per million. The key to this improvement has been the adoption of novel technologies in space telecommunications.

The experiment could not have been conducted to this level of accuracy in the past because of noise on the radio link introduced by the solar corona. With the Cassini experiment, this hindrance was overcome by fitting the spacecraft communication system with multiple links at different frequencies. This new capability on the Cassini spacecraft and on the 34-meter (112 foot) diameter antenna at Goldstone, allowed scientists to remove the effects of the interplanetary and solar plasma from the radio data. In addition, the noise from Earth's atmosphere was strongly reduced by special equipment installed at the Goldstone complex. These technological breakthroughs developed for the Cassini mission have led to unprecedented accuracies in the velocity measurements with benefits for future scientific experiments as well as deep space navigation.

The experiments are part of a series of radio science experiments planned for the cruise phase of the mission, including the search for low frequency gravitational waves.

Cassini will begin orbiting Saturn on July 1, 2004, and release its piggybacked Huygens probe about six months later for descent through the thick atmosphere of the moon Titan.

Cassini-Huygens is a cooperative mission of NASA, the European Space Agency and the Italian Space Agency. JPL, a division of Caltech, manages the mission for NASA's Office of Space Science, Washington, D.C. Authors of the Nature paper, "A New Test of General Relativity With the Cassini Space Mission," are Dr. Bruno Bertotti of the University of Pavia, Italy; Dr Luciano Iess of the University of Rome "La Sapienza", Italy; and Dr. Paolo Tortora of the University of Bologna, Italy. Geometry with an Introduction to Cosmic Topology
Michael P. Hitchman
1.3 Geometry on Surfaces: A First Look

Think for a minute about the space we live in. Think about objects that live in our space. Do the features of objects change when they move around in our space? If I pick up this paper and move it across the room, will it shrink? Will it become a broom?

If you draw a triangle on this page, the angles of the triangle will add to 180o. In fact, any triangle drawn anywhere on the page has this property. Euclidean geometry on this flat page (a portion of the plane) is homogeneous: the local geometry of the plane is the same at all points. Our three-dimensional space appears to be homogeneous as well. This is nice, for it means that if we buy a 5 ft3 freezer at the appliance store, it doesn't shrink to 0.5 ft3

when we get it home. A sphere is another example of a homogenous surface. A two-dimensional bug living on the surface of a sphere could not tell the difference (geometrically) between any two points on the sphere.

The surface of a donut in three-dimensional space is not homogeneous, and a two-dimensional bug living on this surface could tell the difference between various points. One approach to discovering differences in geometry involves triangles.

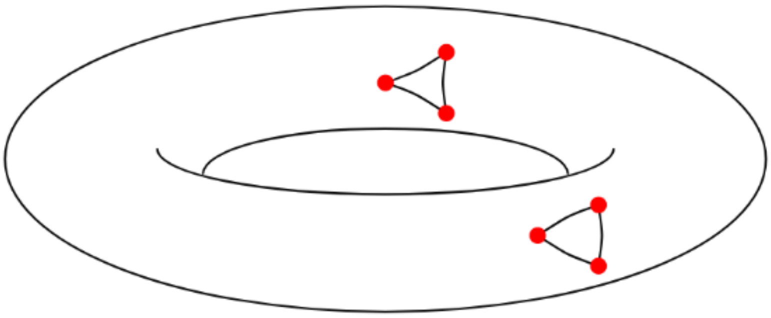

Figure 1.109: edt02.png - This torus surface is not homogeneous.

It is an important matter to decide what we mean, exactly, by a triangle on a surface. A triangle consists of three points and three edges connecting these points. An edge connecting point A to point B is drawn to represent the path of shortest distance between A and B. Such a path is called a geodesic. For the two-dimensional bug, a \straight line" from A to B is simply the shortest path from A to B.

On a sphere, geodesics follow great circles. A great circle is a circle drawn on the surface of the sphere whose center (in three-dimensional space) corresponds to the center of the sphere. Put another way, a great circle is a circle of maximum diameter drawn on the sphere. The circles a and b in are great circles, but circle c is not.

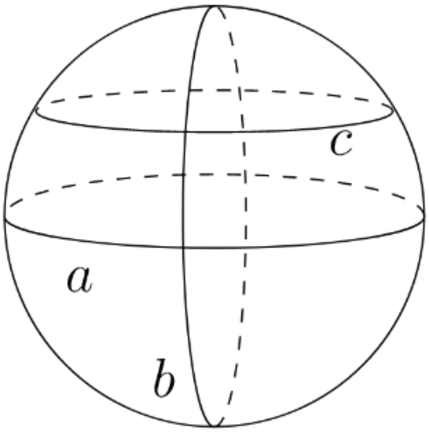

Figure 1.110: edt03.png - Geodesics on the sphere are great circles.

In the Euclidean plane, geodesics are Euclidean lines. One way to determine a geodesic on a surface physically is to pin some string at A and draw the string tight on the surface to a point B. The taut string will follow the geodesic from A to B. In we have drawn geodesic triangles on three different surfaces.

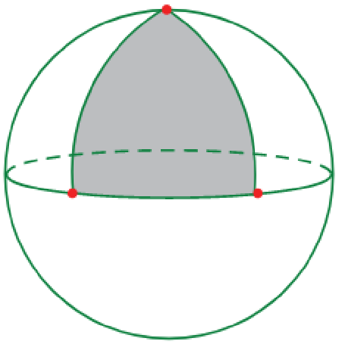

Figure 1.111: et04.png

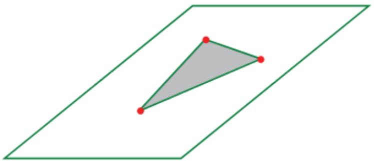

Figure 1.112: et05.png

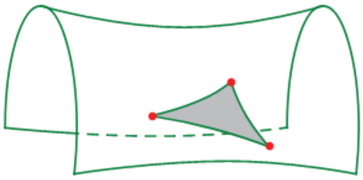

Figure 1.113: et06.png

Figure 1.3.3 Depending on the shape of the surface, geodesic triangles can have angle sum greater than, less than, or equal to 180o.

Getting back to the donut, a two-dimensional bug could use triangles to tell the difference between a \convex" point on an outer wall, and a \saddle-shaped" point on an inner wall. A bug could draw a triangle about the convex point, determine the angle sum, and then move around the surface to a saddle-shaped point, and determine the angle sum of a new triangle (whose legs are the same length as before). The bug would scratch her head at the different angle sums before realizing she'd stumbled upon something big. She'd go home, write up the result, emphasizing the fact that a triangle in the first \convex" region will have angle sum greater than 180o, while a triangle in the \saddle-shaped" region will have angle sum less than 180o.

This happy bug will conclude her donut surface is not homogeneous. She will then sit back and watch the accolades pour in. Perhaps even a Nobel prize. Thus, small triangles and their angles can help a two-dimensional bug distinguish points on a surface.

The donut surface is not homogeneous, so let's build one that is. Example 1.3.4 The Flat Torus

Consider again the world of Figure 1.1.2. This world is called a flat torus. At every spot in this world, the pilot of the ship would report flat surroundings (triangle angles add to 180o). Unlike the donut surface living in three dimensions, the flat torus is homogeneous. Locally, geometry is the same at every point, and thanks to a triangle check, this geometry is Euclidean. But the world as a whole is much different than the Euclidean plane. For instance, if the pilot of the ship has a powerful enough telescope, he'd be able to see the back of his ship. Of course, if the ship had windows just so, he'd be able to see the back of his head. The flat torus is a finite, Euclidean two-dimensional world without any boundary.

Example 1.3.5 Coneland

Here we build cones from flat wedges, and measure angles of some triangles.

a. Begin with a circular disk with a wedge removed, like a pizza missing a slice or two. Joining the two radial edges produces a cone. Try it with a cone of your own to make sure it works. Now, with the cone flat again, pick three points, labeled A, B, and C, such that C is on the radial edge. This means that in this flattened version of the cone, point C actually appears twice: once on each radial edge, as in . These two representatives for C should get identified when you join the radial edges.

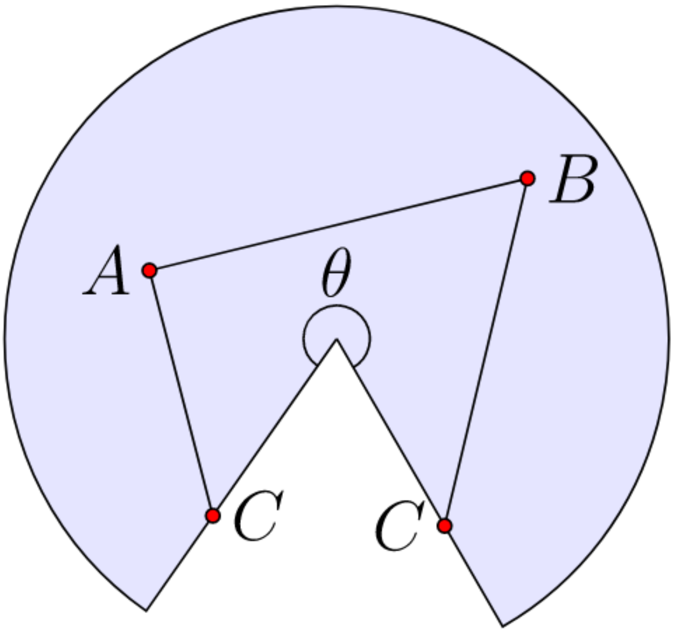

Figure 1.114: edt07.png - A triangle on a cone.

b. Draw the segments connecting the three points. You should get a triangle with the tip of the cone in its interior. (This triangle should actually look like a triangle if you re-form the cone.) If you don't get the tip of the cone on the inside of the triangle, adjust the points accordingly.

c. With your protractor, carefully measure the angle subtended by the circular sector. To emphasize 's role in the shape of the cone, we let S)(denote the cone surface determined by.

d. With your protractor, carefully measure the three angles of your triangle. The angle at point C is the sum of the angles formed by the triangle legs and the radial segments. Let denote the sum of these three angles.

e. State a conjecture about the relationship between the angle and , the sum of the angles of the triangle. Your conjecture can be in the form of an equation. Then prove your conjecture. Hint: if you draw a segment connecting the 2 copies of point C, what is the angle sum of the quadrilateral ABCC?

Example 1.3.7 Saddleland

Repeat the previous exercise but with circle wedges having > 2 .

Identifying the radial edges in this case produces a saddle-shaped surface. [To create such a circle wedge we can tape together two wedges of equal radius. One idea: Start with a disk with one radial cut, and a wedge of equal radius. Tape one radial edge of the wedge to one of the slit radial edges of the disk. Then, identifying the other radial edges should produce Saddleland.]

Remember, a homogeneous surface is a space that has the same local geometry at every point. Our flat torus is homogeneous, having Euclidean geometry at every point. However, our cones S)(in the previous exercises are not homogeneous (unless happens to be 2). If a triangle in S( ) does not contain the tip of the cone in its interior, then the angles of the triangle will add to radians, but if the triangle does contain the tip of the cone in its interior, then the angle sum will not be radians. A two-dimensional bug, then, could conclude that S() is not homogeneous.

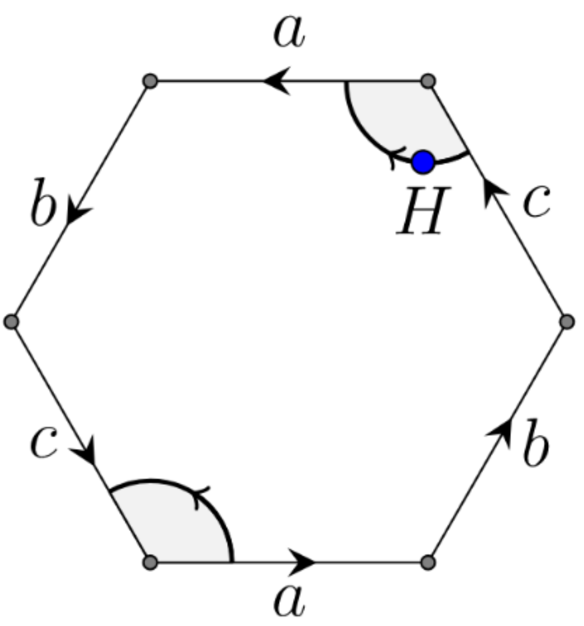

Figure 1.115: edt08.png - A hexagonal video screen

Example 1.3.9 A non-Euclidean surface

Consider the surface obtained by identifying the edges of the hexagon as indicated in image (A hexagonal video screen). In particular, the edges are matched according to their labels and arrow orientation. So, if a ship flies off the hexagonal screen at a spot on the edge marked a, say, then it reappears at the matching spot on the other edge marked a.

Suppose the pilot of a ship wants to fly around one of the corners of the hexagon. If she begins at point H, say, and flies counterclockwise around the upper right corner as indicated in the diagram, she would fly off the screen at the top near the start of an a edge. So, as she made her journey, she would reappear in the lower left corner near the start of the other a edge. Continuing around she would complete her journey after circling this second corner.

However, the angle of each corner is 120o, and gluing them together will create a cone point, as pictured below. Similarly, she would find that the other corners of the hexagon meet in groups of two, creating two additional cone points. As with the Coneland , the pilot can distinguish a corner point from an interior point here. She can look at triangles: a triangle containing one of the cone points will have angle sum greater than 180o; any other triangle will have angle sum equal to 180o.

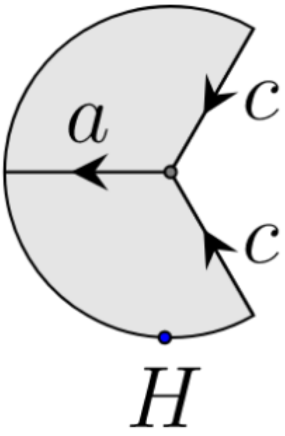

Figure 1.116: edt09.png - A hexagonal video screen

So the surface is not homogeneous, if it is drawn in the plane. However, the surface does admit a homogeneous geometry. We can get rid of the cone points if we can increase each corner angle of the hexagon to 180o. Then, two corners would come together to form a perfect 360o patch about the point.

But how can we increase the corner angles? Put the hexagon on the sphere! Imagine stretching the hexagon onto the northern hemisphere of a sphere. In this case we can think of the 6 points of our hexagon as lying on the equator. Then each corner angle is 180o, each edge is still a line (geodesic), and when we glue the edges, each pair of corner angles adds up to exactly 360o, so the surface is homogeneous. The homogeneous geometry of this surface is the geometry of the sphere (elliptic geometry), not the geometry of the plane (Euclidean geometry).

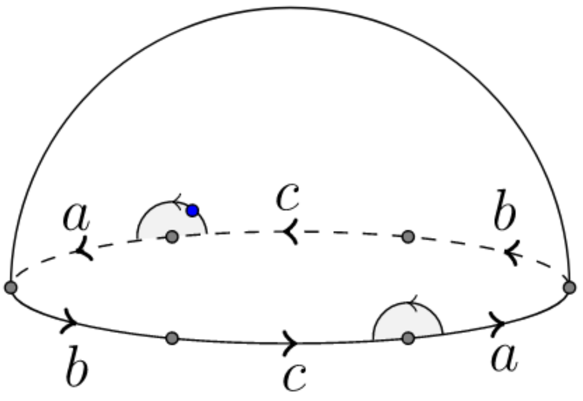

Figure 1.117: edt10.png - A surface with homogeneous elliptic geometry.

It turns out every surface can be given one of three types of homogeneous geometry: Euclidean, hyperbolic, or elliptic. We will return to the geometry of surfaces (and of our universe) after we develop hyperbolic and elliptic geometry. If it doesn't make a whole lot of sense right now, don't sweat it, but please use these facts as motivation for learning about these non-Euclidean geometries.

Exercises

1. Work through the Coneland - Example 1.3.5.

2. Work through the Saddleland - Example 1.3.7.

3. Circumference vs Radius in Coneland and Saddleland. In addition to triangles, a two-dimensional bug can use circles to screen for different geometries. In particular, a bug can study the relationship between the radius and the circumference of a circle. To make sure we think like the bug, here's how we define a circle on a surface: Given a point P on the surface, and a real number $r > 0$, the circle centered at P with radius r is the set of all points r units away from P, where the distance between two points is the length of the shortest path connecting them (the geodesic).

a. Pick your favorite circle in the plane. What is the relationship between the circle's radius and circumference? Is your answer true for any circle in the plane?

b. Consider the Coneland surface of Example 1.3.5. Construct a circle centered at the tip of the cone and derive a relationship between its circumference and its radius. Is $C = 2\pi r$ here? If not, which is true: $C > 2\pi r$ or $C < 2\pi r$?

c. Consider the Saddleland surface of Example 1.3.7. Construct a circle centered at the tip of the saddle and derive a relationship between its circumference and its radius. Is $C = 2 r$ here? If not, which is true: $C > 2 r$ or $C < 2 r$?

1.1 Projetive Geometry - Divided Spheres

Date: 20200730

1) C:/ARQ-IMPORTANT-08/Important-02/Divided Spheres Geodesics and the Orderly Subdivision of the Sphere by Edward S. Popko.pdf

Pag. 202(223) - 8.5.2 Edge Reference Points Class I subdivision begins at the PPT's edges. A series of reference points is located along the edges, dividing the edges into segments equal in number to the subdivision frequency. Reference points have a regular pattern. Their spacing may be equal or unequal, but all three PPT edges will have the same pattern regardless of the spacing used. There are two approaches to defining reference points: Equal-chords and Equal-arcs. Each approach can produce several different grids. For Equal-chords, the PPT's apex-to-apex chords (all three are the same length) are subdivided with equally spaced reference points. These reference points are on the PPT's edge chord; thus, they are inside the sphere. They must be projected to the surface of the sphere before they can be used as subdivision

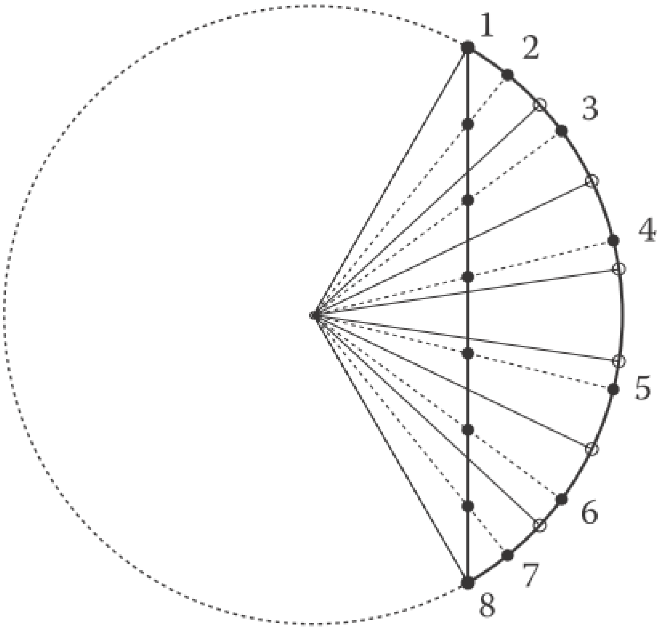

Figure 1.1: ds05-01.png - 7v Equal-chords, Equal-arcs subdivision.

references. For Equal-arcs, the PPT's arc edge (not its chords) is evenly subdivided with points, which are used as references, as is. No projection is needed because these points are already on the surface of the sphere. Figure 8.8 illustrates the difference between these two approaches with a 7v subdivision of a tetrahedron's chord. We use an odd frequency so that reference points from the two approaches will not be superimposed on one another. This makes the figure easier to read. We also use the chord of a tetrahedron, the longest of any Platonic with a unit circumsphere, to make comparisons between Equal-chords and Equal-arcs more vivid. Referring to the figure, points 1 and 8 are the chord's end points on the surface of the circumscribing sphere represented in the cross section by the circumscribing circle. For grids based on equal chord reference points, the chord between points 1 and 8 is divided into seven equal segments (7v) with points located between them. The dashed lines show chord points projected from the center of the sphere to its surface. They are numbered 2 through 7 (1 and 8 are vertices of the tetrahedron's PPT edge and are already on the sphere's surface). By inspecting the figure, you can easily see the arc spacing between projected chord points is not equal. The difference between the largest and smallest arc length is more than 2:1 in this example. To put some numbers to this, the tetrahedron's overall edge arc is approximately 109.5°, and the seven arcs resulting from Equal-chords subdivision are 9.4°, 14.1°, 19.8°, 22.8°, 19.8°, 14.1°, and 9.4°, in that order. It is also evident that the arc lengths are symmetrical; that is, arc 1-2 equals 7-8, arc 2-3 equals 6-7, and so on. The equal-arc points in Figure 8.8 are marked with small hollow circles on the surface of the sphere. They do not have to be projected. Each is spaced at 15.6o.Note that lines between them and the center of the sphere divide the chord into unequal segments. Appendix C lists simple formulas for dividing chords and arcs between any two points on the sphere into equal segments and projecting points to the surface of the sphere.

Radian Measure Another commonly used angle measurement is the radian. To define a radian, first consider a circle of radius r and two radii OA and OB. The angle formed by the two radii is a central angle. The portion of the circle between and is an arc of the circle and is written $\overline{AB}$. We say that $\overline{AB}$ subtends the angle . The length of $\overline{AB}$ is s (see Figure 5.19).

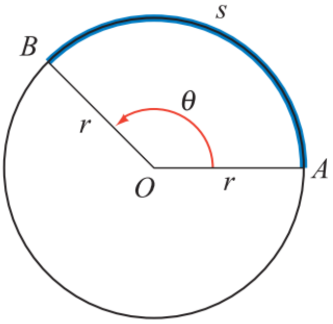

Figure 1.2: ds05-02a.png

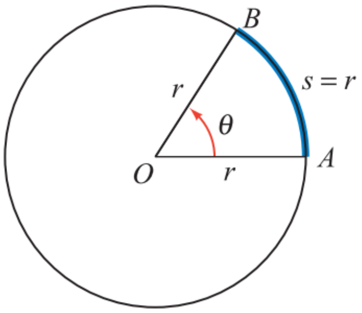

Figure 1.3: ds05-02b.png

One radian is the measure of the central angle subtended by an arc of length r on a circle of radius r.

Definition of Radian Measure

Given an arc of length s on a circle of radius r, the measure of the central angle subtended by the arc is = $\frac{s}{r}$ radians.

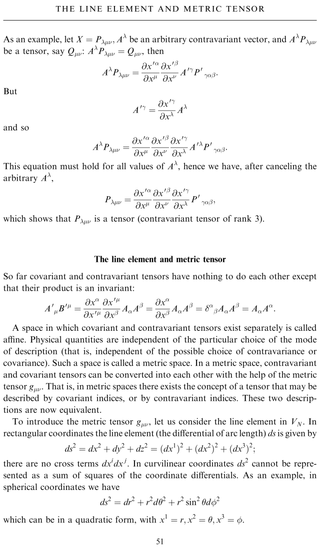
Source: https://en.wikipedia.org/wiki/Pythagorean-theorem

Differential geometry On an infinitesimal level, in three dimensional space, Pythagoras's theorem describes the distance between two infinitesimally separated points as:

$$ds^2 = dx^2 + dy^2 + dz^2 \tag{1.1}$$

with ds the element of distance and (dx, dy, dz) the components of the vector separating the two points. Such a space is called a Euclidean space. However, in Riemannian geometry, a generalization of this expression useful for general coordinates (not just Cartesian) and general spaces (not just Euclidean) takes the form[1]. Source:

https://physics.bgu.ac.il/ gedalin/Teaching/Mater/mmp.pdf



THE LINE ELEMENT AND METRIC TENSOR

As an example, let $X = P_{\lambda\mu\nu}$, A^λ be an arbitrary contravariant vector, and $A^\lambda P_{\lambda\mu\nu}$ be a tensor, say $Q_{\mu\nu}$: $A^\lambda P_{\lambda\mu\nu} = Q_{\mu\nu}$, then

$$A^\lambda P_{\lambda\mu\nu} = \frac{\partial x'^\alpha}{\partial x^\mu}\frac{\partial x'^\beta}{\partial x^\nu} A'^\gamma P'_{\ \gamma\alpha\beta}.$$

But

$$A'^\gamma = \frac{\partial x'^\gamma}{\partial x^\lambda} A^\lambda$$

and so

$$A^\lambda P_{\lambda\mu\nu} = \frac{\partial x'^\alpha}{\partial x^\mu}\frac{\partial x'^\beta}{\partial x^\nu}\frac{\partial x'^\gamma}{\partial x^\lambda} A'^\lambda P'_{\ \gamma\alpha\beta}.$$

This equation must hold for all values of A^λ, hence we have, after canceling the arbitrary A^λ,

$$P_{\lambda\mu\nu} = \frac{\partial x'^\alpha}{\partial x^\mu}\frac{\partial x'^\beta}{\partial x^\nu}\frac{\partial x'^\gamma}{\partial x^\lambda} P'_{\ \gamma\alpha\beta},$$

which shows that $P_{\lambda\mu\nu}$ is a tensor (contravariant tensor of rank 3).

The line element and metric tensor

So far covariant and contravariant tensors have nothing to do each other except that their product is an invariant:

$$A'_{\ \mu}B'^\mu = \frac{\partial x^\alpha}{\partial x'^\mu}\frac{\partial x'^\mu}{\partial x^\beta} A_\alpha A^\beta = \frac{\partial x^\alpha}{\partial x^\beta} A_\alpha A^\beta = \delta^\alpha_{\ \beta} A_\alpha A^\beta = A_\alpha A^\alpha.$$

A space in which covariant and contravariant tensors exist separately is called affine. Physical quantities are independent of the particular choice of the mode of description (that is, independent of the possible choice of contravariance or covariance). Such a space is called a metric space. In a metric space, contravariant and covariant tensors can be converted into each other with the help of the metric tensor $g_{\mu\nu}$. That is, in metric spaces there exists the concept of a tensor that may be described by covariant indices, or by contravariant indices. These two descriptions are now equivalent.

To introduce the metric tensor $g_{\mu\nu}$, let us consider the line element in V_N. In rectangular coordinates the line element (the differential of arc length) ds is given by

$$ds^2 = dx^2 + dy^2 + dz^2 = (dx^1)^2 + (dx^2)^2 + (dx^3)^2;$$

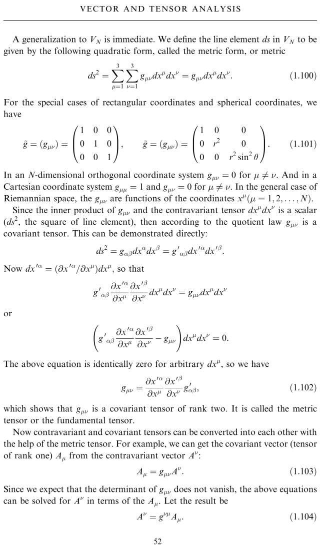
there are no cross terms $dx^i dx^j$. In curvilinear coordinates ds^2 cannot be represented as a sum of squares of the coordinate differentials. As an example, in spherical coordinates we have

$$ds^2 = dr^2 + r^2 d\theta^2 + r^2 \sin^2\theta d\phi^2$$

which can be in a quadratic form, with $x^1 = r, x^2 = \theta, x^3 = \phi$.

51

Figure 1.18: mmp01.png



VECTOR AND TENSOR ANALYSIS

A generalization to V_N is immediate. We define the line element ds in V_N to be given by the following quadratic form, called the metric form, or metric

$$ds^2 = \sum_{\mu=1}^{3}\sum_{\nu=1}^{3} g_{\mu\nu} dx^\mu dx^\nu = g_{\mu\nu} dx^\mu dx^\nu. \tag{1.100}$$

For the special cases of rectangular coordinates and spherical coordinates, we have

$$\tilde{g} = (g_{\mu\nu}) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \qquad \tilde{g} = (g_{\mu\nu}) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & r^2 & 0 \\ 0 & 0 & r^2\sin^2\theta \end{pmatrix}. \tag{1.101}$$

In an N-dimensional orthogonal coordinate system $g_{\mu\nu} = 0$ for $\mu \neq \nu$. And in a Cartesian coordinate system $g_{\mu\mu} = 1$ and $g_{\mu\nu} = 0$ for $\mu \neq \nu$. In the general case of Riemannian space, the $g_{\mu\nu}$ are functions of the coordinates $x^\mu (\mu = 1, 2, \ldots, N)$.

Since the inner product of $g_{\mu\nu}$ and the contravariant tensor $dx^\mu dx^\nu$ is a scalar (ds^2, the square of line element), then according to the quotient law $g_{\mu\nu}$ is a covariant tensor. This can be demonstrated directly:

$$ds^2 = g_{\alpha\beta} dx^\alpha dx^\beta = g'_{\ \alpha\beta} dx'^\alpha dx'^\beta.$$

Now $dx'^\alpha = (\partial x'^\alpha / \partial x^\mu) dx^\mu$, so that

$$g'_{\ \alpha\beta}\frac{\partial x'^\alpha}{\partial x^\mu}\frac{\partial x'^\beta}{\partial x^\nu} dx^\mu dx^\nu = g_{\mu\nu} dx^\mu dx^\nu$$

or

$$\left(g'_{\ \alpha\beta}\frac{\partial x'^\alpha}{\partial x^\mu}\frac{\partial x'^\beta}{\partial x^\nu} - g_{\mu\nu}\right) dx^\mu dx^\nu = 0.$$

The above equation is identically zero for arbitrary dx^μ, so we have

$$g_{\mu\nu} = \frac{\partial x'^\alpha}{\partial x^\mu}\frac{\partial x'^\beta}{\partial x^\nu} g'_{\alpha\beta}, \tag{1.102}$$

which shows that $g_{\mu\nu}$ is a covariant tensor of rank two. It is called the metric tensor or the fundamental tensor.

Now contravariant and covariant tensors can be converted into each other with the help of the metric tensor. For example, we can get the covariant vector (tensor of rank one) A_μ from the contravariant vector A^ν:

$$A_\mu = g_{\mu\nu} A^\nu. \tag{1.103}$$

Since we expect that the determinant of $g_{\mu\nu}$ does not vanish, the above equations can be solved for A^ν in terms of the A_μ. Let the result be

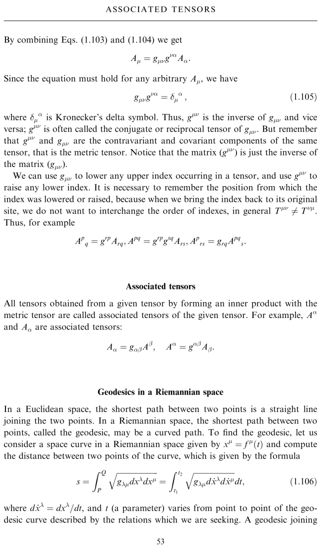
$$A^\nu = g^{\nu\mu} A_\mu. \tag{1.104}$$

52

Figure 1.19: mmp02.png

---

[1] Mathematical methods for physicists - Chow; Source: C:/DATA-NovoVivo-129-2020/Books-129-2020/The Pythagorean Proposition/mmp.pdf - Pag. 51 (66) - The line element and metric tensor



By combining Eqs. (1.103) and (1.104) we get

$$A_\mu = g_{\mu\nu} g^{\nu\alpha} A_\alpha.$$

Since the equation must hold for any arbitrary A_μ, we have

$$g_{\mu\nu} g^{\nu\alpha} = \delta_\mu{}^\alpha, \tag{1.105}$$

where $\delta_\mu{}^\alpha$ is Kronecker's delta symbol. Thus, $g^{\mu\nu}$ is the inverse of $g_{\mu\nu}$ and vice versa; $g^{\mu\nu}$ is often called the conjugate or reciprocal tensor of $g_{\mu\nu}$. But remember that $g^{\mu\nu}$ and $g_{\mu\nu}$ are the contravariant and covariant components of the same tensor, that is the metric tensor. Notice that the matrix $(g^{\mu\nu})$ is just the inverse of the matrix $(g_{\mu\nu})$.

We can use $g_{\mu\nu}$ to lower any upper index occurring in a tensor, and use $g^{\mu\nu}$ to raise any lower index. It is necessary to remember the position from which the index was lowered or raised, because when we bring the index back to its original site, we do not want to interchange the order of indexes, in general $T^{\mu\nu} \neq T^{\nu\mu}$. Thus, for example

$$A^p{}_q = g^{rp} A_{rq}, A^{pq} = g^{rp} g^{sq} A_{rs}, A^p{}_{rs} = g_{rq} A^{pq}{}_s.$$

Associated tensors

All tensors obtained from a given tensor by forming an inner product with the metric tensor are called associated tensors of the given tensor. For example, A^α and A_α are associated tensors:

$$A_\alpha = g_{\alpha\beta} A^\beta, \quad A^\alpha = g^{\alpha\beta} A_\beta.$$

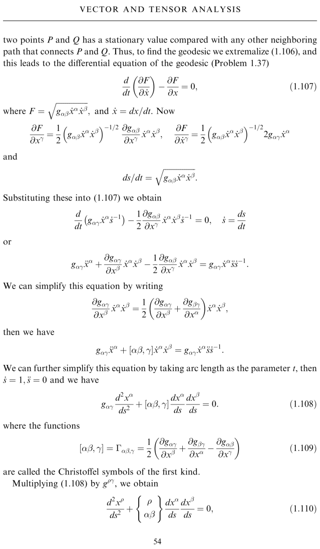
Geodesics in a Riemannian space

In a Euclidean space, the shortest path between two points is a straight line joining the two points. In a Riemannian space, the shortest path between two points, called the geodesic, may be a curved path. To find the geodesic, let us consider a space curve in a Riemannian space given by $x^\mu = f^\mu(t)$ and compute the distance between two points of the curve, which is given by the formula

$$s = \int_P^Q \sqrt{g_{\lambda\mu} dx^\lambda dx^\mu} = \int_{t_1}^{t_2} \sqrt{g_{\lambda\mu} d\dot{x}^\lambda d\dot{x}^\mu} dt, \tag{1.106}$$

where $d\dot{x}^\lambda = dx^\lambda / dt$, and t (a parameter) varies from point to point of the geodesic curve described by the relations which we are seeking. A geodesic joining

Figure 1.20: mmp03.png



two points P and Q has a stationary value compared with any other neighboring path that connects P and Q. Thus, to find the geodesic we extremalize (1.106), and this leads to the differential equation of the geodesic (Problem 1.37)

$$\frac{d}{dt}\left(\frac{\partial F}{\partial \dot{x}}\right) - \frac{\partial F}{\partial x} = 0, \tag{1.107}$$

where $F = \sqrt{g_{\alpha\beta} \dot{x}^\alpha \dot{x}^\beta}$, and $\dot{x} = dx/dt$. Now

$$\frac{\partial F}{\partial x^\gamma} = \frac{1}{2}\left(g_{\alpha\beta} \dot{x}^\alpha \dot{x}^\beta\right)^{-1/2} \frac{\partial g_{\alpha\beta}}{\partial x^\gamma} \dot{x}^\alpha \dot{x}^\beta, \quad \frac{\partial F}{\partial \dot{x}^\gamma} = \frac{1}{2}\left(g_{\alpha\beta} \dot{x}^\alpha \dot{x}^\beta\right)^{-1/2} 2 g_{\alpha\gamma} \dot{x}^\alpha$$

and

$$ds/dt = \sqrt{g_{\alpha\beta} \dot{x}^\alpha \dot{x}^\beta}.$$

Substituting these into (1.107) we obtain

$$\frac{d}{dt}\left(g_{\alpha\gamma} \dot{x}^\alpha \dot{s}^{-1}\right) - \frac{1}{2} \frac{\partial g_{\alpha\beta}}{\partial x^\gamma} \dot{x}^\alpha \dot{x}^\beta \dot{s}^{-1} = 0, \quad \dot{s} = \frac{ds}{dt}$$

or

$$g_{\alpha\gamma} \ddot{x}^\alpha + \frac{\partial g_{\alpha\gamma}}{\partial x^\beta} \dot{x}^\alpha \dot{x}^\beta - \frac{1}{2} \frac{\partial g_{\alpha\beta}}{\partial x^\gamma} \dot{x}^\alpha \dot{x}^\beta = g_{\alpha\gamma} \dot{x}^\alpha \ddot{s} \dot{s}^{-1}.$$

We can simplify this equation by writing

$$\frac{\partial g_{\alpha\gamma}}{\partial x^\beta} \dot{x}^\alpha \dot{x}^\beta = \frac{1}{2}\left(\frac{\partial g_{\alpha\gamma}}{\partial x^\beta} + \frac{\partial g_{\beta\gamma}}{\partial x^\alpha}\right) \dot{x}^\alpha \dot{x}^\beta,$$

then we have

$$g_{\alpha\gamma} \ddot{x}^\alpha + [\alpha\beta, \gamma] \dot{x}^\alpha \dot{x}^\beta = g_{\alpha\gamma} \dot{x}^\alpha \ddot{s} \dot{s}^{-1}.$$

We can further simplify this equation by taking arc length as the parameter t, then $\dot{s} = 1, \ddot{s} = 0$ and we have

$$g_{\alpha\gamma} \frac{d^2 x^\alpha}{ds^2} + [\alpha\beta, \gamma] \frac{dx^\alpha}{ds} \frac{dx^\beta}{ds} = 0. \tag{1.108}$$

where the functions

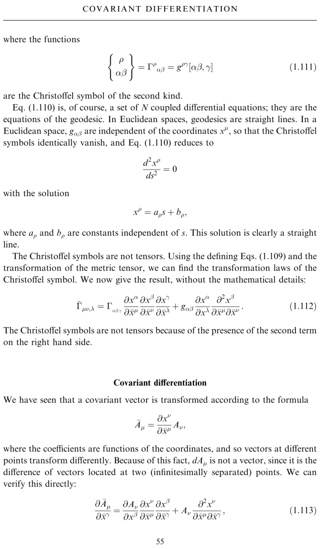
$$[\alpha\beta, \gamma] = \Gamma_{\alpha\beta,\gamma} = \frac{1}{2}\left(\frac{\partial g_{\alpha\gamma}}{\partial x^\beta} + \frac{\partial g_{\beta\gamma}}{\partial x^\alpha} - \frac{\partial g_{\alpha\beta}}{\partial x^\gamma}\right) \tag{1.109}$$

are called the Christoffel symbols of the first kind.

Multiplying (1.108) by $g^{\rho\gamma}$, we obtain

$$\frac{d^2 x^\rho}{ds^2} + \left\{ \begin{matrix} \rho \\ \alpha\beta \end{matrix} \right\} \frac{dx^\alpha}{ds} \frac{dx^\beta}{ds} = 0, \tag{1.110}$$

Figure 1.21: mmp04.png



where the functions

$$\left\{ \begin{matrix} \rho \\ \alpha\beta \end{matrix} \right\} = \Gamma^\rho{}_{\alpha\beta} = g^{\rho\gamma} [\alpha\beta, \gamma] \tag{1.111}$$

are the Christoffel symbol of the second kind.

Eq. (1.110) is, of course, a set of N coupled differential equations; they are the equations of the geodesic. In Euclidean spaces, geodesics are straight lines. In a Euclidean space, $g_{\alpha\beta}$ are independent of the coordinates x^μ, so that the Christoffel symbols identically vanish, and Eq. (1.110) reduces to

$$\frac{d^2 x^\rho}{ds^2} = 0$$

with the solution

$$x^\rho = a_\rho s + b_\rho,$$

where a_ρ and b_ρ are constants independent of s. This solution is clearly a straight line.

The Christoffel symbols are not tensors. Using the defining Eqs. (1.109) and the transformation of the metric tensor, we can find the transformation laws of the Christoffel symbol. We now give the result, without the mathematical details:

$$\bar{\Gamma}_{\mu\nu,\lambda} = \Gamma_{\alpha\beta,\gamma} \frac{\partial x^\alpha}{\partial \bar{x}^\mu} \frac{\partial x^\beta}{\partial \bar{x}^\nu} \frac{\partial x^\gamma}{\partial \bar{x}^\lambda} + g_{\alpha\beta} \frac{\partial x^\alpha}{\partial x^\lambda} \frac{\partial^2 x^\beta}{\partial \bar{x}^\mu \partial \bar{x}^\nu}. \tag{1.112}$$

The Christoffel symbols are not tensors because of the presence of the second term on the right hand side.

Covariant differentiation

We have seen that a covariant vector is transformed according to the formula

$$\bar{A}_\mu = \frac{\partial x^\nu}{\partial \bar{x}^\mu} A_\nu,$$

where the coefficients are functions of the coordinates, and so vectors at different points transform differently. Because of this fact, dA_μ is not a vector, since it is the difference of vectors located at two (infinitesimally separated) points. We can verify this directly:

$$\frac{\partial \bar{A}_\mu}{\partial \bar{x}^\gamma} = \frac{\partial A_\nu}{\partial x^\beta} \frac{\partial x^\nu}{\partial \bar{x}^\mu} \frac{\partial x^\beta}{\partial \bar{x}^\gamma} + A_\nu \frac{\partial^2 x^\nu}{\partial \bar{x}^\mu \partial \bar{x}^\gamma}, \tag{1.113}$$

Figure 1.22: mmp05.png

$$ds^2 = \sum_{i;j}^{n} g_{ij}\, dx_i\, dx_j$$

which is called the metric tensor. (Sometimes, by abuse of language, the same term is applied to the set of coefficients gij.) It may be a function of position, and often describes curved space. A simple example is Euclidean (flat) space expressed in curvilinear coordinates. For example, in polar coordinates:

$$ds^2 = dr^2 + r^2 d\ ^2:$$

O .:

Very small triangles

For any uniform curvature K (positive, zero, or negative), in very small right triangles ($j\ K\ j\ a^2; j\ K\ j\ b^2 << 1$) with hypotenuse c, it can be shown that

$$c^2 = a^2 + b^2 \quad \frac{K}{3}a^2b^2 \quad \frac{K^2}{45}a^2b^2\ \ a^2 + b^2 \quad \frac{2K^3}{945}a^2b^2\ \ a^2\ \ \ b^2\ ^2 + O\ \ K^4c^{10}\ \ : \tag{1.2}$$

Chapter 1
Diophantus of Alexandria

Diophantus is like an island in the history of mathematics. He lived in Alexandria around 250 C.E. Nobody before him had ever tackled a study of arithmetic over the field of rational numbers. It was 1,300 years before Western[1] mathematicians to become interested in this type of problem (Bombelli, Viète, Bachet, Fermat), . . . on reading Diophantus to be precise. He also introduced new methods and a special symbol to express an unknown, which makes him an essential precursor of algebraic notation.

1.1 Pythagorean Triangles

Columbia University in New York owns a cuneiform tablet (known as *Plimpton 322*), which dates back to the ancient Babylonian period (between 1900 and 1600 B.C.E.). This clay tablet contains a long list of *Pythagorean triangles*, that is, right-angled triangles whose sides have integer lengths, such as $\langle 3, 4, 5\rangle$, but also $\langle 65, 72, 97\rangle$, $\langle 4961, 6480, 8161\rangle$, etc. (Figures 1.1 and 1.2).

We do not know how these triangles were found, but Diophantus had complete mastery of the problem and was able to produce solutions *ad libitum.* This resolution of the problem is given at the beginning of his work ([Di], Problem II.8), so that throughout he could refer to it as something familiar.

For instance, for Problem 7.13 of the Arabic text (see [Ses]), he first splits 100 as $36 + 64$, which corresponds to the Pythagorean triangle $(6, 8, 10)$, then 64 in $\left(8 \cdot \frac{20}{29}\right)^2 + \left(8 \cdot \frac{21}{29}\right)^2$, only explaining that the reader has already seen (that is, in Problem II.8) "how to split any square number into two squares" (of rational numbers).

---

[1] But we know that in the tenth century Arab mathematicians (among others abu'l-Wafa and al-Karajī) were already studying and commenting on Diophantus.

Figure 1.24: noga01.png

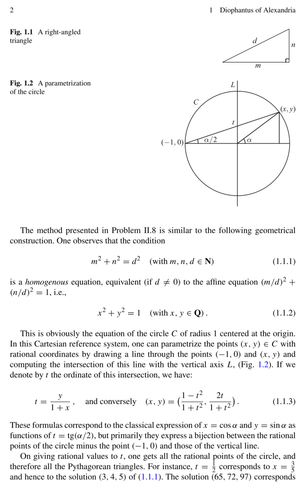

Fig. 1.1 A right-angled triangle

Fig. 1.2 A parametrization of the circle

The method presented in Problem II.8 is similar to the following geometrical construction. One observes that the condition

$$m^2 + n^2 = d^2 \quad (\text{with } m, n, d \in \mathbf{N}) \tag{1.1.1}$$

is a *homogenous* equation, equivalent (if $d \neq 0$) to the affine equation $(m/d)^2 + (n/d)^2 = 1$, i.e.,

$$x^2 + y^2 = 1 \quad (\text{with } x, y \in \mathbf{Q})\,. \tag{1.1.2}$$

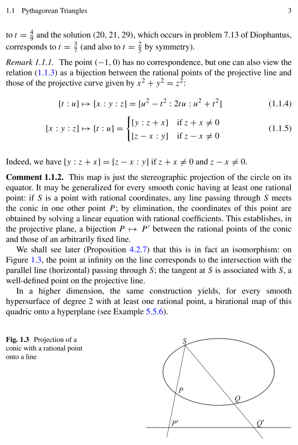
This is obviously the equation of the circle C of radius 1 centered at the origin. In this Cartesian reference system, one can parametrize the points $(x, y) \in C$ with rational coordinates by drawing a line through the points $(-1, 0)$ and (x, y) and computing the intersection of this line with the vertical axis L, (Fig. 1.2). If we denote by t the ordinate of this intersection, we have:

$$t = \frac{y}{1+x}\,, \quad \text{and conversely} \quad (x, y) = \Big(\frac{1-t^2}{1+t^2}, \frac{2t}{1+t^2}\Big)\,. \tag{1.1.3}$$

These formulas correspond to the classical expression of $x = \cos\alpha$ and $y = \sin\alpha$ as functions of $t = \mathrm{tg}(\alpha/2)$, but primarily they express a bijection between the rational points of the circle minus the point $(-1, 0)$ and those of the vertical line.

On giving rational values to t, one gets all the rational points of the circle, and therefore all the Pythagorean triangles. For instance, $t = \frac{1}{2}$ corresponds to $x = \frac{3}{5}$ and hence to the solution $(3, 4, 5)$ of (1.1.1). The solution $(65, 72, 97)$ corresponds

Figure 1.25: noga02.png



to $t = \frac{4}{9}$ and the solution $(20, 21, 29)$, which occurs in problem 7.13 of Diophantus, corresponds to $t = \frac{3}{7}$ (and also to $t = \frac{2}{5}$ by symmetry).

Remark 1.1.1. The point $(-1, 0)$ has no correspondence, but one can also view the relation (1.1.3) as a bijection between the rational points of the projective line and those of the projective curve given by $x^2 + y^2 = z^2$:

$$[t : u] \mapsto [x : y : z] = [u^2 - t^2 : 2tu : u^2 + t^2] \tag{1.1.4}$$

$$[x : y : z] \mapsto [t : u] = \begin{cases} [y : z + x] & \text{if } z + x \neq 0 \\ [z - x : y] & \text{if } z - x \neq 0 \end{cases} \tag{1.1.5}$$

Indeed, we have $[y : z + x] = [z - x : y]$ if $z + x \neq 0$ and $z - x \neq 0$.

Comment 1.1.2. This map is just the stereographic projection of the circle on its equator. It may be generalized for every smooth conic having at least one rational point: if S is a point with rational coordinates, any line passing through S meets the conic in one other point P; by elimination, the coordinates of this point are obtained by solving a linear equation with rational coefficients. This establishes, in the projective plane, a bijection $P \mapsto P'$ between the rational points of the conic and those of an arbitrarily fixed line.

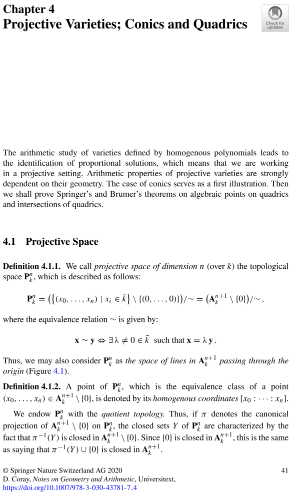
We shall see later (Proposition 4.2.7) that this is in fact an isomorphism: on Figure 1.3, the point at infinity on the line corresponds to the intersection with the parallel line (horizontal) passing through S; the tangent at S is associated with S, a well-defined point on the projective line.

In a higher dimension, the same construction yields, for every smooth hypersurface of degree 2 with at least one rational point, a birational map of this quadric onto a hyperplane (see Example 5.5.6).

Fig. 1.3 Projection of a conic with a rational point onto a line

Figure 1.26: noga03.png

Pag. 41 (50) - 4.1 Projective Space



Chapter 4
Projective Varieties; Conics and Quadrics

The arithmetic study of varieties defined by homogenous polynomials leads to the identification of proportional solutions, which means that we are working in a projective setting. Arithmetic properties of projective varieties are strongly dependent on their geometry. The case of conics serves as a first illustration. Then we shall prove Springer's and Brumer's theorems on algebraic points on quadrics and intersections of quadrics.

4.1 Projective Space

Definition 4.1.1. We call *projective space of dimension n* (over k) the topological space $\mathbf{P}_k^n$, which is described as follows:

$$\mathbf{P}_k^n = \big(\big\{(x_0, \ldots, x_n) \mid x_i \in \bar{k}\big\} \setminus \{(0, \ldots, 0)\}\big)/\!\sim\; = \big(\mathbf{A}_k^{n+1} \setminus \{0\}\big)/\!\sim ,$$

where the equivalence relation $\sim$ is given by:

$$\mathbf{x} \sim \mathbf{y} \Leftrightarrow \exists\, \lambda \neq 0 \in \bar{k} \text{ such that } \mathbf{x} = \lambda\, \mathbf{y} .$$

Thus, we may also consider $\mathbf{P}_k^n$ as *the space of lines in* $\mathbf{A}_k^{n+1}$ *passing through the origin* (Figure 4.1).

Definition 4.1.2. A point of $\mathbf{P}_k^n$, which is the equivalence class of a point $(x_0, \ldots, x_n) \in \mathbf{A}_k^{n+1} \setminus \{0\}$, is denoted by its *homogenous coordinates* $[x_0 : \cdots : x_n]$.

We endow $\mathbf{P}_k^n$ with the *quotient topology*. Thus, if π denotes the canonical projection of $\mathbf{A}_k^{n+1} \setminus \{0\}$ on $\mathbf{P}_k^n$, the closed sets Y of $\mathbf{P}_k^n$ are characterized by the fact that $\pi^{-1}(Y)$ is closed in $\mathbf{A}_k^{n+1} \setminus \{0\}$. Since $\{0\}$ is closed in $\mathbf{A}_k^{n+1}$, this is the same as saying that $\pi^{-1}(Y) \cup \{0\}$ is closed in $\mathbf{A}_k^{n+1}$.

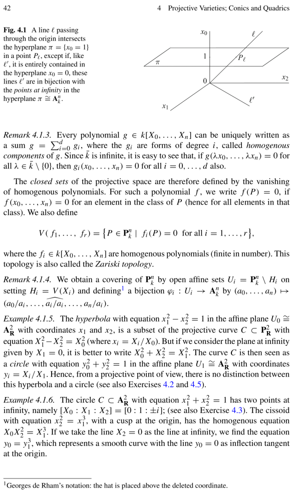
D. Coray, *Notes on Geometry and Arithmetic*, Universitext,
https://doi.org/10.1007/978-3-030-43781-7_4

Figure 1.27: noga04.png



42 4 Projective Varieties; Conics and Quadrics

Fig. 4.1 A line ℓ passing through the origin intersects the hyperplane $\pi = \{x_0 = 1\}$ in a point P_ℓ, except if, like ℓ', it is entirely contained in the hyperplane $x_0 = 0$, these lines ℓ' are in bijection with the *points at infinity* in the hyperplane $\pi \cong \mathbf{A}_k^n$.

Remark 4.1.3. Every polynomial $g \in k[X_0, \ldots, X_n]$ can be uniquely written as a sum $g = \sum_{i=0}^{d} g_i$, where the g_i are forms of degree i, called *homogenous components* of g. Since $\bar{k}$ is infinite, it is easy to see that, if $g(\lambda x_0, \ldots, \lambda x_n) = 0$ for all $\lambda \in \bar{k} \setminus \{0\}$, then $g_i(x_0, \ldots, x_n) = 0$ for all $i = 0, \ldots, d$ also.

The *closed sets* of the projective space are therefore defined by the vanishing of homogenous polynomials. For such a polynomial f, we write $f(P) = 0$, if $f(x_0, \ldots, x_n) = 0$ for an element in the class of P (hence for all elements in that class). We also define

$$V(f_1, \ldots, f_r) = \big\{P \in \mathbf{P}_k^n \mid f_i(P) = 0 \text{ for all } i = 1, \ldots, r\big\},$$

where the $f_i \in k[X_0, \ldots, X_n]$ are homogenous polynomials (finite in number). This topology is also called the *Zariski topology*.

Remark 4.1.4. We obtain a covering of $\mathbf{P}_k^n$ by open affine sets $U_i = \mathbf{P}_k^n \setminus H_i$ on setting $H_i = V(X_i)$ and defining[1] a bijection $\varphi_i : U_i \to \mathbf{A}_k^n$ by $(a_0, \ldots, a_n) \mapsto (a_0/a_i, \ldots, \widehat{a_i/a_i}, \ldots, a_n/a_i)$.

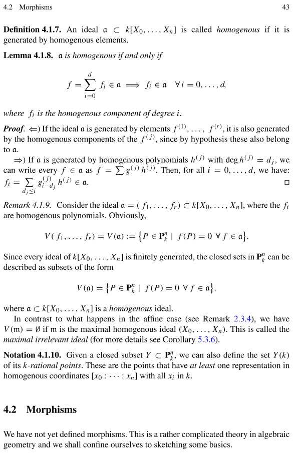
Example 4.1.5. The *hyperbola* with equation $x_1^2 - x_2^2 = 1$ in the affine plane $U_0 \cong \mathbf{A}_{\mathbf{R}}^2$ with coordinates x_1 and x_2, is a subset of the projective curve $C \subset \mathbf{P}_{\mathbf{R}}^2$ with equation $X_1^2 - X_2^2 = X_0^2$ (where $x_i = X_i/X_0$). But if we consider the plane at infinity given by $X_1 = 0$, it is better to write $X_0^2 + X_2^2 = X_1^2$. The curve C is then seen as a *circle* with equation $y_0^2 + y_2^2 = 1$ in the affine plane $U_1 \cong \mathbf{A}_{\mathbf{R}}^2$ with coordinates $y_i = X_i/X_1$. Hence, from a projective point of view, there is no distinction between this hyperbola and a circle (see also Exercises 4.2 and 4.5).

Example 4.1.6. The circle $C \subset \mathbf{A}_{\mathbf{R}}^2$ with equation $x_1^2 + x_2^2 = 1$ has two points at infinity, namely $[X_0 : X_1 : X_2] = [0 : 1 : \pm i]$; (see also Exercise 4.3). The cissoid with equation $x_2^2 = x_1^3$, with a cusp at the origin, has the homogenous equation $X_0 X_2^2 = X_1^3$. If we take the line $X_2 = 0$ as the line at infinity, we find the equation $y_0 = y_1^3$, which represents a smooth curve with the line $y_0 = 0$ as inflection tangent at the origin.

---

[1] Georges de Rham's notation: the hat is placed above the deleted coordinate.

Figure 1.28: noga05.png



4.2 Morphisms 43

Definition 4.1.7. An ideal $\mathfrak{a} \subset k[X_0, \ldots, X_n]$ is called *homogenous* if it is generated by homogenous elements.

Lemma 4.1.8. $\mathfrak{a}$ *is homogenous if and only if*

$$f = \sum_{i=0}^{d} f_i \in \mathfrak{a} \implies f_i \in \mathfrak{a} \quad \forall\, i = 0, \ldots, d,$$

where f_i *is the homogenous component of degree* i.

Proof. $\Leftarrow$) If the ideal $\mathfrak{a}$ is generated by elements $f^{(1)}, \ldots, f^{(r)}$, it is also generated by the homogenous components of the $f^{(j)}$, since by hypothesis these also belong to $\mathfrak{a}$.

$\Rightarrow$) If $\mathfrak{a}$ is generated by homogenous polynomials $h^{(j)}$ with $\deg h^{(j)} = d_j$, we can write every $f \in \mathfrak{a}$ as $f = \sum g^{(j)} h^{(j)}$. Then, for all $i = 0, \ldots, d$, we have: $f_i = \sum_{d_j \leq i} g_{i-d_j}^{(j)} h^{(j)} \in \mathfrak{a}$. □

Remark 4.1.9. Consider the ideal $\mathfrak{a} = (f_1, \ldots, f_r) \subset k[X_0, \ldots, X_n]$, where the f_i are homogenous polynomials. Obviously,

$$V(f_1, \ldots, f_r) = V(\mathfrak{a}) := \big\{P \in \mathbf{P}_k^n \mid f(P) = 0\ \forall\, f \in \mathfrak{a}\big\}.$$

Since every ideal of $k[X_0, \ldots, X_n]$ is finitely generated, the closed sets in $\mathbf{P}_k^n$ can be described as subsets of the form

$$V(\mathfrak{a}) = \big\{P \in \mathbf{P}_k^n \mid f(P) = 0\ \forall\, f \in \mathfrak{a}\big\},$$

where $\mathfrak{a} \subset k[X_0, \ldots, X_n]$ is a *homogenous* ideal.

In contrast to what happens in the affine case (see Remark 2.3.4), we have $V(\mathfrak{m}) = \emptyset$ if $\mathfrak{m}$ is the maximal homogenous ideal $(X_0, \ldots, X_n)$. This is called the *maximal irrelevant ideal* (for more details see Corollary 5.3.6).

Notation 4.1.10. Given a closed subset $Y \subset \mathbf{P}_k^n$, we can also define the set $Y(k)$ of its *k-rational points*. These are the points that have *at least* one representation in homogenous coordinates $[x_0 : \cdots : x_n]$ with all x_i in k.

4.2 Morphisms

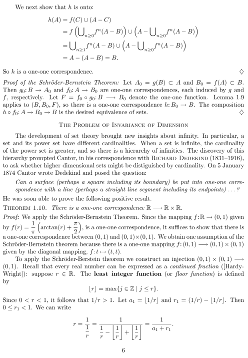
We have not yet defined morphisms. This is a rather complicated theory in algebraic geometry and we shall confine ourselves to sketching some basics.

Figure 1.29: noga06.png

3) C:/DATA-NovoVivo-129-2020/Books-129-2020/Topology/0821838849-A.pdf

Pag. 02 - As a separate branch of mathematics, topology is relatively young. It was isolated as a collection of methods and problems by Henri Poincare (1854{1912) in his pioneering paper Analysis situs of 1895. The subsequent development of the subject was dramatic and topology was deeply influential in shaping the mathematics of the twentieth century and today. So what is topology? In the popular understanding, objects like the Mobius band, the Klein bottle, and knots and links are the first to be mentioned (or maybe the second after the misunderstanding about topography is cleared up). Some folks can cite the joke that topologists are mathematicians who cannot tell their donut from their coffee cups. When I taught my first undergraduate courses in topology, I found I spent too much time developing a hierarchy of definitions and too little time on the objects, tools, and intuitions that are central to the subject. I wanted to teach a course that would follow a path more directly to the heart of topology. I wanted to tell a story that is coherent, motivating, and significant enough to form the basis for future study. To get an idea of what is studied by topology, let's examine its prehistory, that is, the vague notions that led Poincare to identify its foundations. Gottfried W. Leibniz (1646{1716), in a letter to Christiaan Huygens (1629{1695) in the 1670's, described a concept that has become a goal of the study of topology: I believe that we need another analysis properly geometric or linear, which treats PLACE directly the way that algebra treats MAGNITUDE. Leibniz envisioned a calculus of figures in which one might combine figures with the ease of numbers, operate on them as one might with polynomials, and produce new and rigorous geometric results. This science of PLACE was to be called Analysis situs ([Pont]). We don't know what Leibniz had in mind. It was Leonhard Euler (1701{1783) who made the first contributions to the infant subject, which he preferred to call geometria situs. His solution to the Bridges of Konigsberg problem and the celebrated Euler formula, V E + F = 2 (Chapter 11) were results that depended on the relative positions of geometric figures and not on their magnitudes ([Pont], [Lakatos]). In the nineteenth century, Carl-Friedrich Gauss (1777-1855) became interested in geometria situs when he studied knots and links as generalizations of the orbits of planets ([Epple]). By labeling figures of knots and links Gauss developed a rudimentary calculus that distinguished certain knots from each other by combinatorial means. Students who studied with Gauss and went on to develope some of the threads associated with geometria situs were Johann Listing (1808{1882), Augustus Mobius (1790{1868), and Bernhard Riemann (1826{1866). Listing extended Gauss's informal census of knots and links and he coined the term topology (from the Greek o o o o&, which in Latin is analysis situs). Mobius extended Euler's formula to surfaces and polyhedra in three-space. Riemann identified the methods of the infant analysis situs as fundamental in the study of complex functions. During the nineteenth century analysis was developed into a deep and subtle science. The notions of continuity of functions and the convergence of sequences were studied in increasingly general situations, beginning with the work of Georg Cantor (1845–1918) and finalized in the twentieth century by Felix Hausdorff (1869–1942) who proposed the general notion of a topological space in 1914 ([Hausdorff]). The central concept in topology is continuity, defined for functions between sets equipped with a notion of nearness (topological spaces) which is preserved by a continuous function. Topology is a kind of geometry in which the important properties of a figure are those that are preserved under continuous motions (homeomorphisms, Chapter 2). The popular image of topology as rubber sheet geometry is captured in this characterization. Topology provides a language of continuity that is general enough to include a vast array of phenomena while being precise enough to be developed in new ways. A motivating problem from the earliest struggles with the notion of continuity is the problem of dimension. In modern physics, higher dimensional manifolds play a fundamental role in describing theories with properties that combine the large and the small. Already in Poincaré's time the question of the physicality of dimension was on philosophers' minds, including Poincaré. Cantor had noticed in 1877 that as sets finite dimensional Euclidean spaces were indistinguishable (Chapter 1). If these identifications were possible in a continuous manner, a requirement of physical phenomena, then the role of dimension would need a critical reappraisal. The problem of dimension was important to the development of certain topological notions, including a strictly topological definition of dimension introduced by Henri Lebesgue (1875-1941) [Lebesgue]. The solution to the problem of dimension was found by L. E. J. Brouwer (1881–1966) and published in 1912 [Brouwer]. The methods introduced by Brouwer reshaped the subject. The story I want to tell in this book is based on the problem of dimension. This fundamental question from the early years of the subject organizes the exposition and provides the motivation for the choices of mathematical tools to develop. I have not chosen to follow the path of Lebesgue into dimension theory (see the classic text [Hurewicz-Wallman]) but the further ranging path of Poincaré and Brouwer. The fundamental group (Chapters 7 and 8) and simplicial methods (Chapters 10 and 11) provide tools that establish an approach to topological questions that has proven to be deep and is still developing. It is this approach that best fits Leibniz's wish. In what follows, we will cut a swath through the varied and beautiful landscape that is the field of topology with the goal of solving the problem of invariance of dimension. Along the way we will acquire the necessary vocabulary to make our way easily from one landmark to the next (without staying too long anywhere to pick up an accent). The first chapter reviews the set theory with which the problem of dimension can be posed. The next five chapters treat the basic point-set notions of topology; these ideas are closest to analysis, including connectedness and compactness. The next two chapters treat the fundamental group of a space, an idea introduced by Poincaré to associate a group to a space in such a way that equivalent spaces lead to isomorphic groups. The next chapter treats the Jordan Curve theorem, first stated by Jordan in 1882, and given a complete proof in 1905 by Oswald Veblen (1880{1960). The method of proof here mixes the point-set and the combinatorial to develop approximations and comparisons. The last two chapters take up the combinatorial theme and focus on simplicial complexes. To these conveniently constructed spaces we associate their homology, a sequence of vector spaces, which turn out to be isomorphic for equivalent complexes. We finish a proof of the topological invariance of dimension using homology. Though the motivation for this book is historical, I have not followed the history in the choice of methods or proofs. First proofs of significant results can be difficult. However, I have tried to imitate the mix of point-set and combinatorial ideas that was topology before 1935, what I call classical topology. Some beautiful results of this time are included, such as the Borsuk-Ulam theorem (see [Borsuk] and [Matousek]).

Pag. 06(11)- The Problem of Invariance of Dimension Theorem 1.10. There is a one-one correspondence R ! RXR .



We next show that h is onto:

$$\begin{aligned} h(A) &= f(C) \cup (A - C) \\ &= f\left(\bigcup_{n\geq 0} f^n(A-B)\right) \cup \left(A - \bigcup_{n\geq 0} f^n(A-B)\right) \\ &= \bigcup_{n\geq 1} f^n(A-B) \cup \left(A - \bigcup_{n\geq 0} f^n(A-B)\right) \\ &= A - (A-B) = B. \end{aligned}$$

So h is a one-one correspondence. ◇

Proof of the Schröder-Bernstein Theorem: Let $A_0 = g(B) \subset A$ and $B_0 = f(A) \subset B$. Then $g_0: B \to A_0$ and $f_0: A \to B_0$ are one-one correspondences, each induced by g and f, respectively. Let $F = f_0 \circ g_0: B \longrightarrow B_0$ denote the one-one function. Lemma 1.9 applies to (B, B_0, F), so there is a one-one correspondence $h: B_0 \to B$. The composition $h \circ f_0: A \to B_0 \to B$ is the desired equivalence of sets. ◇

THE PROBLEM OF INVARIANCE OF DIMENSION

The development of set theory brought new insights about infinity. In particular, a set and its power set have different cardinalities. When a set is infinite, the cardinality of the power set is greater, and so there is a hierarchy of infinities. The discovery of this hierarchy prompted Cantor, in his correspondence with RICHARD DEDEKIND (1831–1916), to ask whether higher-dimensional sets might be distiguished by cardinality. On 5 January 1874 Cantor wrote Dedekind and posed the question:

> *Can a surface (perhaps a square including its boundary) be put into one-one correspondence with a line (perhaps a straight line segment including its endpoints) . . . ?*

He was soon able to prove the following positive result.

THEOREM 1.10. *There is a one-one correspondence* $\mathbb{R} \longrightarrow \mathbb{R} \times \mathbb{R}$.

Proof: We apply the Schröder-Bernstein Theorem. Since the mapping $f: \mathbb{R} \to (0,1)$ given by $f(r) = \frac{1}{\pi}\left(\arctan(r) + \frac{\pi}{2}\right)$, is a one-one correspondence, it suffices to show that there is a one-one correspondence between $(0,1)$ and $(0,1)\times(0,1)$. We obtain one assumption of the Schröder-Bernstein theorem because there is a one-one mapping $f: (0,1) \longrightarrow (0,1) \times (0,1)$ given by the diagonal mapping, $f: t \mapsto (t,t)$.

To apply the Schröder-Berstein theorem we construct an injection $(0,1) \times (0,1) \longrightarrow (0,1)$. Recall that every real number can be expressed as a *continued fraction* ([Hardy-Wright]): suppose $r \in \mathbb{R}$. The **least integer function** (or *floor function*) is defined by

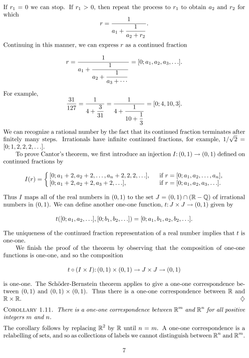
$$\lfloor r \rfloor = \max\{j \in \mathbb{Z} \mid j \leq r\}.$$

Since $0 < r < 1$, it follows that $1/r > 1$. Let $a_1 = \lfloor 1/r \rfloor$ and $r_1 = (1/r) - \lfloor 1/r \rfloor$. Then $0 \leq r_1 < 1$. We can write

$$r = \frac{1}{\frac{1}{r}} = \frac{1}{\frac{1}{r} - \left\lfloor \frac{1}{r} \right\rfloor + \left\lfloor \frac{1}{r} \right\rfloor} = \frac{1}{a_1 + r_1}.$$

6

Figure 1.30: t01.png



If $r_1 = 0$ we can stop. If $r_1 > 0$, then repeat the process to r_1 to obtain a_2 and r_2 for which

$$r = \cfrac{1}{a_1 + \cfrac{1}{a_2 + r_2}}.$$

Continuing in this manner, we can express r as a continued fraction

$$r = \cfrac{1}{a_1 + \cfrac{1}{a_2 + \cfrac{1}{a_3 + \cdots}}} = [0; a_1, a_2, a_3, \ldots].$$

For example,

$$\frac{31}{127} = \cfrac{1}{4 + \cfrac{3}{31}} = \cfrac{1}{4 + \cfrac{1}{10 + \cfrac{1}{3}}} = [0; 4, 10, 3].$$

We can recognize a rational number by the fact that its continued fraction terminates after finitely many steps. Irrationals have infinite continued fractions, for example, $1/\sqrt{2} = [0; 1, 2, 2, 2, \ldots]$.

To prove Cantor's theorem, we first introduce an injection $I: (0,1) \to (0,1)$ defined on continued fractions by

$$I(r) = \begin{cases} [0; a_1+2, a_2+2, \ldots, a_n+2, 2, 2, \ldots], & \text{if } r = [0; a_1, a_2, \ldots, a_n], \\ [0; a_1+2, a_2+2, a_3+2, \ldots], & \text{if } r = [0; a_1, a_2, a_3, \ldots]. \end{cases}$$

Thus I maps all of the real numbers in $(0,1)$ to the set $J = (0,1) \cap (\mathbb{R} - \mathbb{Q})$ of irrational numbers in $(0,1)$. We can define another one-one function, $t: J \times J \to (0,1)$ given by

$$t([0; a_1, a_2, \ldots], [0; b_1, b_2, \ldots]) = [0; a_1, b_1, a_2, b_2, \ldots].$$

The uniqueness of the continued fraction representation of a real number implies that t is one-one.

We finish the proof of the theorem by observing that the composition of one-one functions is one-one, and so the composition

$$t \circ (I \times I): (0,1) \times (0,1) \to J \times J \to (0,1)$$

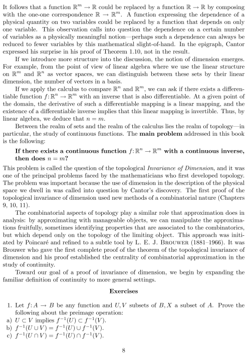
is one-one. The Schöder-Bernstein theorem applies to give a one-one correspondence between $(0,1)$ and $(0,1) \times (0,1)$. Thus there is a one-one correspondence between $\mathbb{R}$ and $\mathbb{R} \times \mathbb{R}$. ◇

COROLLARY 1.11. *There is a one-one correspondence between* $\mathbb{R}^m$ *and* $\mathbb{R}^n$ *for all positive integers* m *and* n.

The corollary follows by replacing $\mathbb{R}^2$ by $\mathbb{R}$ until $n = m$. A one-one correspondence is a relabelling of sets, and so as collections of labels we cannot distinguish between $\mathbb{R}^n$ and $\mathbb{R}^m$.

7

Figure 1.31: t02.png



It follows that a function $\mathbb{R}^m \to \mathbb{R}$ could be replaced by a function $\mathbb{R} \to \mathbb{R}$ by composing with the one-one correspondence $\mathbb{R} \to \mathbb{R}^m$. A function expressing the dependence of a physical quantity on two variables could be replaced by a function that depends on only one variable. This observation calls into question the dependence on a certain number of variables as a physically meaningful notion—perhaps such a dependence can always be reduced to fewer variables by this mathematical slight-of-hand. In the epigraph, Cantor expressed his surprise in his proof of Theorem 1.10, not in the result.

If we introduce more structure into the discussion, the notion of dimension emerges. For example, from the point of view of linear algebra where we use the linear structure on $\mathbb{R}^m$ and $\mathbb{R}^n$ as vector spaces, we can distinguish between these sets by their linear dimension, the number of vectors in a basis.

If we apply the calculus to compare $\mathbb{R}^n$ and $\mathbb{R}^m$, we can ask if there exists a differentiable function $f: \mathbb{R}^n \to \mathbb{R}^m$ with an inverse that is also differentiable. At a given point of the domain, the derivative of such a differentiable mapping is a linear mapping, and the existence of a differentiable inverse implies that this linear mapping is invertible. Thus, by linear algebra, we deduce that $n = m$.

Between the realm of sets and the realm of the calculus lies the realm of topology—in particular, the study of continuous functions. The **main problem** addressed in this book is the following:

> **If there exists a continuous function $f: \mathbb{R}^n \to \mathbb{R}^m$ with a continuous inverse, then does $n = m$?**

This problem is called the question of the topological *Invariance of Dimension*, and it was one of the principal problems faced by the mathematicians who first developed topology. The problem was important because the use of dimension in the description of the physical space we dwell in was called into question by Cantor's discovery. The first proof of the topological invariance of dimension used new methods of a combinatorial nature (Chapters 9, 10, 11).

The combinatorial aspects of topology play a similar role that approximation does in analysis: by approximating with manageable objects, we can manipulate the approximations fruitfully, sometimes identifying properties that are associated to the combinatorics, but which depend only on the topology of the limiting object. This approach was initiated by Poincaré and refined to a subtle tool by L. E. J. Brouwer (1881–1966). It was Brouwer who gave the first complete proof of the theorem of the topological invariance of dimension and his proof established the centrality of combinatorial approximation in the study of continuity.

Toward our goal of a proof of invariance of dimension, we begin by expanding the familiar definition of continuity to more general settings.

Exercises

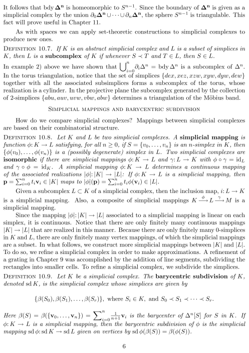
1. Let $f: A \to B$ be any function and U, V subsets of B, X a subset of A. Prove the following about the preimage operation:

a) $U \subset V$ implies $f^{-1}(U) \subset f^{-1}(V)$.
b) $f^{-1}(U \cup V) = f^{-1}(U) \cup f^{-1}(V)$.
c) $f^{-1}(U \cap V) = f^{-1}(U) \cap f^{-1}(V)$.

Figure 1.32: t03.png

Pag. 77 - 8. Computations and covering spaces

Pag. 109 - Simplicial mappings and barycentric subdivision



It follows that bdy $\mathbf{\Delta^n}$ is homeomorphic to S^{n-1}. Since the boundary of $\mathbf{\Delta^n}$ is given as a simplicial complex by the union $\partial_0\mathbf{\Delta^n} \cup \cdots \cup \partial_n\mathbf{\Delta^n}$, the sphere S^{n-1} is triangulable. This fact will prove useful in Chapter 11.

As with spaces we can apply set-theoretic constructions to simplicial complexes to produce new ones.

Definition 10.7. *If K is an abstract simplicial complex and L is a subset of simplices in K, then L is a* **subcomplex** *of K if whenever $S \prec T$ and $T \in L$, then $S \in L$.*

In example 2) above we have shown that $\bigcup_{i=0}^{n} \partial_i \Delta^n = \operatorname{bdy} \Delta^n$ is a subcomplex of Δ^n. In the torus triangulation, notice that the set of simplices $\{dex, xez, xzw, xyw, dyw, dew\}$ together with all the associated subsimplices forms a subcomplex of the torus, whose realization is a cylinder. In the projective plane the subcomplex generated by the collection of 2-simplices $\{abu, auv, uvw, vbw, abw\}$ determines a triangulation of the Möbius band.

Simplicial mappings and barycentric subdivision

How do we compare simplicial complexes? Mappings between simplicial complexes are based on their combinatorial structure.

Definition 10.8. *Let K and L be two simplicial complexes. A* **simplicial mapping** *is function $\phi: K \to L$ satisfying, for all $n \geq 0$, if $S = \{v_0, \ldots, v_n\}$ is an n-simplex in K, then $\{\phi(v_0), \ldots, \phi(v_n)\}$ is a (possibly degenerate) simplex in L. Two simplicial complexes are* **isomorphic** *if there are simplicial mappings $\phi: K \to L$ and $\gamma: L \to K$ with $\phi \circ \gamma = \mathrm{id}_L$ and $\gamma \circ \phi = \mathrm{id}_K$. A simplicial mapping $\phi: K \to L$ determines a continuous mapping of the associated realizations $|\phi|: |K| \to |L|$: If $\phi: K \to L$ is a simplicial mapping, then $\mathbf{p} = \sum_{i=0}^{n} t_i \mathbf{v}_i \in |K|$ maps to $|\phi|(\mathbf{p}) = \sum_{i=0}^{n} t_i \phi(\mathbf{v}_i) \in |L|$.*

Given a subcomplex $L \subset K$ of a simplicial complex, then the inclusion map, $i: L \to K$ is a simplicial mapping. Also, a composite of simplicial mappings $K \xrightarrow{\phi} L \xrightarrow{\gamma} M$ is a simplicial mapping.

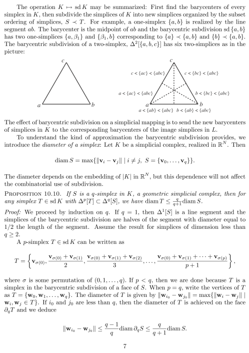
Since the mapping $|\phi|: |K| \to |L|$ associated to a simplicial mapping is linear on each simplex, it is continuous. Notice that there are only finitely many continuous mappings $|K| \to |L|$ that are realized in this manner. Because there are only finitely many 0-simplices in K and L, there are only finitely many vertex mappings, of which the simplicial mappings are a subset. In what follows, we construct more simplicial mappings between $|K|$ and $|L|$. To do so, we refine a simplicial complex in order to make approximations. A refinement of a grating in Chapter 9 was accomplished by the addition of line segments, subdividing the rectangles into smaller cells. To refine a simplicial complex, we subdivide the simplices.

Definition 10.9. *Let K be a simplicial complex. The* **barycentric subdivision** *of K, denoted $\operatorname{sd} K$, is the simplicial complex whose simplices are given by*

$$\{\beta(S_0), \beta(S_1), \ldots, \beta(S_r)\}, \text{ where } S_i \in K, \text{ and } S_0 \prec S_1 \prec \cdots \prec S_r.$$

Here $\beta(S) = \beta(\{\mathbf{v}_0, \ldots, \mathbf{v}_n\}) = \sum_{i=0}^{n} \frac{1}{n+1} \mathbf{v}_i$ is the barycenter of $\Delta^n[S]$ for S in K. If $\phi: K \to L$ is a simplicial mapping, then the barycentric subdivision of ϕ is the simplicial mapping $\operatorname{sd}\phi: \operatorname{sd} K \to \operatorname{sd} L$ given on vertices by $\operatorname{sd}\phi(\beta(S)) = \beta(\phi(S))$.

Figure 1.33: t04.png



The operation $K \mapsto \operatorname{sd} K$ may be summarized: First find the barycenters of every simplex in K, then subdivide the simplices of K into new simplices organized by the subset ordering of simplices, $S \prec T$. For example, a one-simplex $\{a, b\}$ is realized by the line segment ab. The barycenter is the midpoint of ab and the barycentric subdivision $\operatorname{sd}\{a, b\}$ has two one-simplices $\{a, \beta_1\}$ and $\{\beta_1, b\}$ corresponding to $\{a\} \prec \{a, b\}$ and $\{b\} \prec \{a, b\}$. The barycentric subdivision of a two-simplex, $\Delta^2[\{a, b, c\}]$ has six two-simplices as in the picture:

The effect of barycentric subdivision on a simplicial mapping is to send the new barycenters of simplices in K to the corresponding barycenters of the image simplices in L.

To understand the kind of approximation the barycentric subdivision provides, we introduce the *diameter of a simplex*: Let K be a simplicial complex, realized in $\mathbb{R}^N$. Then

$$\operatorname{diam} S = \max\{\|\mathbf{v}_i - \mathbf{v}_j\| \mid i \neq j,\ S = \{\mathbf{v}_0, \ldots, \mathbf{v}_q\}\}.$$

The diameter depends on the embedding of $|K|$ in $\mathbb{R}^N$, but this dependence will not affect the combinatorial use of subdivision.

Proposition 10.10. *If S is a q-simplex in K, a geometric simplicial complex, then for any simplex $T \in \operatorname{sd} K$ with $\Delta^p[T] \subset \Delta^q[S]$, we have $\operatorname{diam} T \leq \frac{q}{q+1} \operatorname{diam} S$.*

Proof: We proceed by induction on q. If $q = 1$, then $\Delta^1[S]$ is a line segment and the simplices of the barycentric subdivision are halves of the segment with diameter equal to 1/2 the length of the segment. Assume the result for simplices of dimension less than $q \geq 2$.

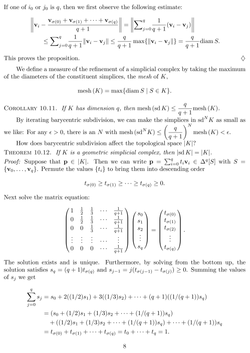
A p-simplex $T \in \operatorname{sd} K$ can be written as

$$T = \left\{\mathbf{v}_{\sigma(0)}, \frac{\mathbf{v}_{\sigma(0)} + \mathbf{v}_{\sigma(1)}}{2}, \frac{\mathbf{v}_{\sigma(0)} + \mathbf{v}_{\sigma(1)} + \mathbf{v}_{\sigma(2)}}{3}, \ldots, \frac{\mathbf{v}_{\sigma(0)} + \mathbf{v}_{\sigma(1)} + \cdots + \mathbf{v}_{\sigma(p)}}{p+1}\right\},$$

where σ is some permutation of $(0, 1, \ldots, q)$. If $p < q$, then we are done because T is a simplex in the barycentric subdivision of a face of S. When $p = q$, write the vertices of T as $T = \{\mathbf{w}_0, \mathbf{w}_1, \ldots, \mathbf{w}_q\}$. The diameter of T is given by $\|\mathbf{w}_{i_0} - \mathbf{w}_{j_0}\| = \max\{\|\mathbf{w}_i - \mathbf{w}_j\| \mid \mathbf{w}_i, \mathbf{w}_j \in T\}$. If i_0 and j_0 are less than q, then the diameter of T is achieved on the face $\partial_q T$ and we deduce

$$\|\mathbf{w}_{i_0} - \mathbf{w}_{j_0}\| \leq \frac{q-1}{q} \operatorname{diam} \partial_q S \leq \frac{q}{q+1} \operatorname{diam} S.$$

Figure 1.34: t05.png



If one of i_0 or j_0 is q, then we first observe the following estimate:

$$\begin{aligned}\left\|\mathbf{v}_i - \frac{\mathbf{v}_{\sigma(0)} + \mathbf{v}_{\sigma(1)} + \cdots + \mathbf{v}_{\sigma(q)}}{q+1}\right\| &= \left\|\sum\nolimits_{j=0}^{q} \frac{1}{q+1}(\mathbf{v}_i - \mathbf{v}_j)\right\| \\ &\leq \sum\nolimits_{j=0}^{q} \frac{1}{q+1}\|\mathbf{v}_i - \mathbf{v}_j\| \leq \frac{q}{q+1}\max\{\|\mathbf{v}_i - \mathbf{v}_j\|\} = \frac{q}{q+1}\operatorname{diam} S.\end{aligned}$$

This proves the proposition. ◊

We define a measure of the refinement of a simplicial complex by taking the maximum of the diameters of the constituent simplices, the *mesh* of K,

$$\operatorname{mesh}(K) = \max\{\operatorname{diam} S \mid S \in K\}.$$

Corollary 10.11. *If K has dimension q, then* $\operatorname{mesh}(\operatorname{sd} K) \leq \frac{q}{q+1}\operatorname{mesh}(K)$.

By iterating barycentric subdivision, we can make the simplices in $\operatorname{sd}^N K$ as small as we like: For any $\epsilon > 0$, there is an N with $\operatorname{mesh}(\operatorname{sd}^N K) \leq \left(\frac{q}{q+1}\right)^N \operatorname{mesh}(K) < \epsilon$.

How does barycentric subdivision affect the topological space $|K|$?

Theorem 10.12. *If K is a geometric simplicial complex, then* $|\operatorname{sd} K| = |K|$.

Proof: Suppose that $\mathbf{p} \in |K|$. Then we can write $\mathbf{p} = \sum_{i=0}^{q} t_i \mathbf{v}_i \in \Delta^q[S]$ with $S = \{\mathbf{v}_0, \ldots, \mathbf{v}_q\}$. Permute the values $\{t_i\}$ to bring them into descending order

$$t_{\sigma(0)} \geq t_{\sigma(1)} \geq \cdots \geq t_{\sigma(q)} \geq 0.$$

Next solve the matrix equation:

$$\begin{pmatrix} 1 & \frac{1}{2} & \frac{1}{3} & \cdots & \frac{1}{q+1} \\ 0 & \frac{1}{2} & \frac{1}{3} & \cdots & \frac{1}{q+1} \\ 0 & 0 & \frac{1}{3} & \cdots & \frac{1}{q+1} \\ \vdots & \vdots & \vdots & \cdots & \vdots \\ 0 & 0 & 0 & \cdots & \frac{1}{q+1} \end{pmatrix} \begin{pmatrix} s_0 \\ s_1 \\ s_2 \\ \vdots \\ s_q \end{pmatrix} = \begin{pmatrix} t_{\sigma(0)} \\ t_{\sigma(1)} \\ t_{\sigma(2)} \\ \vdots \\ t_{\sigma(q)} \end{pmatrix}.$$

The solution exists and is unique. Furthermore, by solving from the bottom up, the solution satisfies $s_q = (q+1)t_{\sigma(q)}$ and $s_{j-1} = j(t_{\sigma(j-1)} - t_{\sigma(j)}) \geq 0$. Summing the values of s_j we get

$$\begin{aligned}\sum_{j=0}^{q} s_j &= s_0 + 2((1/2)s_1) + 3((1/3)s_2) + \cdots + (q+1)((1/(q+1))s_q) \\ &= (s_0 + (1/2)s_1 + (1/3)s_2 + \cdots + (1/(q+1))s_q) \\ &\quad + ((1/2)s_1 + (1/3)s_2 + \cdots + (1/(q+1))s_q) + \cdots + (1/(q+1))s_q \\ &= t_{\sigma(0)} + t_{\sigma(1)} + \cdots + t_{\sigma(q)} = t_0 + \cdots + t_q = 1.\end{aligned}$$

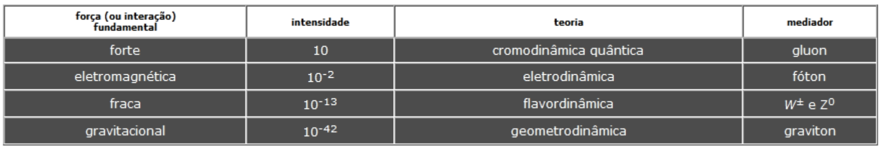
Sabemos que existem apenas 4 forcas, ou interacões, fundamentais na natureza. São elas a interacão gravitacional, a interacão eletromagnética, a interacão forte e a interacão fraca. A tabela mostra detalhes sobre estas forcas que serão logo explicados:



força (ou interação) fundamental	intensidade	teoria	mediador
forte	10	cromodinâmica quântica	gluon
eletromagnética	10^{-2}	eletrodinâmica	fóton
fraca	10^{-13}	flavordinâmica	$W^{\pm}$ e Z^0
gravitacional	10^{-42}	geometrodinâmica	graviton

Figure 1.36: 4f01.png

Vamos explicar o conteúdo da tabela.

Intensidade: Os valores acima atribuidos para as intensidade das forças não devem ser considerados de modo absoluto. Voce verá valores bastante diferentes em vários livros, em particular no que diz respeito à força fraca. O cálculo desta intensidade depende da natureza da fonte e a que distância estamos fazendo a medição. O que importante notar é a razão entre elas: a força gravitacional é, de longe, a mais fraca entre todas, porém é a de maior alcance, sendo a responsável pela estabilidade dinâmica de todo o Universo. Teoria: Vemos na tabela que cada força está associada a uma teoria física. Vejamos alguns detalhes: Força gravitacional: A teoria clássica da gravitação é a lei de Newton da Gravitação Universal. Sua generalização relativística é a teoria da Gravitação de Einstein, também chamada de Teoria da Relatividade Geral de Einstein. O melhor termo para ela seria Geometrodinâmica, uma vez que a relatividade geral geometriza a gravitação. Para descrever os estágios iniciais da formação do Universo precisamos de uma teoria quântica da gravitação, algo que os físicos ainda não possuem, apesar dos enormes esforços desenvolvidos para isto. Eletrodinâmica: Esta é a teoria física que descreve os fenômenos elétricos e magnéticos, ou seja as forças eletromagnéticas. A formulação clássica da Eletrodinâmica foi feita por James Clerk Maxwell. A teoria clássica construída por Maxwell já era consistente com a teoria da relatividade especial de Einstein. O "casamento" desta teoria com a mecânica quântica, ou seja, a construção de uma "Eletrodinâmica Quântica", foi realizada por grandes nomes da física tais como Feynman, Tomonaga e Schwinger nos anos que compõem a década de 1940. Fraca: As forças fracas são aquelas que explicam os processos de decaimento radiativo, tais como o decaimento beta nuclear, o decaimento do pion, do muon e de várias partículas "estranhas". É interessante notar que esta força não era conhecida pela física clássica e que sua formulação como teoria é estritamente quântica. A primeira teoria das interações fracas foi apresentada por Fermi em 1933. Mais tarde ela foi aperfeiçoada por Lee, Yang, Feynman, Gell-Mann e vários outros nos anos da década de 1950. Sua forma atual é devida a Glashow, Weinberg e Salam, que a propuseram nos anos da década de 1960. A nova teoria das interações fracas, que é chamada de flavordinâmica por causa de uma das propriedades intrínsecas das partículas elementares, é mais justamente conhecida como Teoria de Glashow-Weinberg-Salam. Nesta teoria, as interações fraca e eletromagnética são apresentadas como manifestações diferentes de uma única força, a força eletrofraca. Esta unificação entre a interação fraca e a interação eletromagnética reduz o número de forças existentes no Universo a apenas 3: força gravitacional, força forte e força eletrofraca. Forte: As forças fortes são aquelas responsáveis pelos fenômenos que ocorrem a curta distância no interior do núcleo atômico. A estabilidade nuclear está associada a forca forte. E ela que mantém o núcleo unido evitando que os prótons que os constituem, por possuirem a mesma carga elétrica, simplesmente sofram uma intensa repulsão e destruam o próprio atomo. Se a forca forte não existisse a matéria que forma o Universo, tal como o conhecemos, também não existiria. Protons e neutrons não conseguiriam se formar. Nós, seres humanos, não poderíamos existir. O trabalho pioneiro sobre as forcas fortes foi realizado por Yukawa em 1934 mas até meados da década de 1970 não havia, realmente, uma teoria capaz de explicar os fenômenos nuclear. Foi então que surgiu a cromodinâmica quântica. Mediadores: Após a física ter abandonado o conceito de "ação-a-distância", foi introduzido o conceito de "campo". Cada partícula criava a sua volta uma perturbação, seu "campo", que era sentido pelas outras partículas. A Teoria Quântica de Campos (TQC) introduziu o conceito de "mediadores". Segundo a TQC cada uma das forcas que existem na natureza e mediada pela troca de uma partícula que e chamada de "mediador". Estes mediadores transmitem a forca entre uma partícula e outra. Assim, a forca gravitacional e mediada por uma partícula chamada graviton. A forca eletromagnética e mediada pelo fóton, a forca forte pelos gluons e as forcas fracas pelas partículas W e Z0, que são chamadas de bósons vetoriais intermediários. Isto complica ainda mais o estudo das interações entre as partículas. Veja que antes descrevamos a interação entre dois prótons como sendo a interação entre duas partículas. Hoje, sabendo que os prótons são partículas compostas por 3 quarks, vemos que a interação entre dois prótons e, na verdade, uma interação entre 6 quarks que trocam gluons incessantemente durante todo o processo. Só para te avisar, existem 8 tipos de gluons. Como voce pode ver, aqui não existe simplicidade.

Forca Fraca

Em 1896, Henry Becquerel obteve os primeiros indícios da forca nuclear fraca na descoberta da radioatividade. Nos anos 30 houve um grande impulso no entendimento desta forca: naquele tipo particular de radioatividade descoberto por Becquerel um nêutron dentro do núcleo atômico se transforma em um próton , criando, ao mesmo tempo, um elétron e uma outra partícula conhecida como antineutrino, ambas lancadas para fora do núcleo. Esse evento, conhecido como decaimento beta não podia ser consequencia de outros tipos de forcas. A forca nuclear forte mantém os prótons e nêutrons juntos no núcleo e a eletromagnética tenta separar os prótons. A forca gravitacional não faz nada do gênero.

Inicialmente houve grande confusão em relação a essa forca. Os físicos não gostavam da teoria: ela funcionava bem para o decaimento beta , mas quando era aplicada a processos mais exóticos fornecia resultados sem sentido.

Em 1967, o paquistanês radicado na Inglaterra Abdus Salam e o americano Steven Weinberg propuseram teorias que unificavam estas interações com a forca eletromagnetica , exatamente como Maxwell unificara eletricidade e magnetismo cerca de cem anos antes.

Ambos sugeriram que, alem dos fotons, existiam outras partículas, tipo fotons, que eram previstas teoricamente: partículas W eletricamente carregadas, positivamente e negativamente, cuja troca induz a forca fraca da radioatividade beta e partículas Z, neutras. o W significa fraco, em inglês weak. A partícula irmã, foi batizada de Z por Weinberg porque tinha carga zero e por ser Z a ultima letra do alfabeto. (Weinberg esperava que esta fosse a ultima partícula da família).

Na teoria de Weinberg e Salam, o foton, cuja emissão e absorcão produz a forca eletromagnetica, e as partículas W e Z , sob energias maiores do que 100 GeV, atuariam da mesma maneira. Sob energias mais baixas, esta simetria entre as partículas W positivo, W negativo e Z nulo seria quebrada e todas elas ganhariam massas volumosas tornando o alcance das forcas que carregam muito pequeno. Naquela epoca poucas pessoas acreditavam na teoria e, alem disso, não existia acelerador de partículas potente o suficiente para atingir 100 GeV.

Em 1978, um novo experimento em Stanford mediu a forca fraca entre eletrons e nucleos atômicos confirmando o que a teoria tinha previsto e em 1979 Weinberg e Salam foram indicados para o Prêmio Nobel de Física. Em 1983 um grupo de varias centenas de físicos, sob a batuta de Carlos Rubbia, descobriu a partícula W, e em 1984, a partícula Z cujas existências e propriedades ja haviam sido previstas na teoria original. Rubbia recebeu o Prêmio Nobel em 1984.

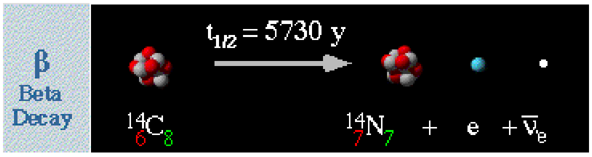


Figure 1.37: 4f02.png

Forca Forte

Essa forca mantem os quarks juntos no proton e no nêutron, e estes reunidos no nucleo do atomo. Provavelmente essa forca deve ser conduzida por outra partícula de spin-1, conhecida como gluon, que interage consigo mesma e com os quarks.

A forca nuclear forte apresenta uma curiosa propriedade, chamada confinamento: ela sempre liga partículas reunidas em combinacões incolores. Não se pode ter um unico quark em si mesmo porque ele teria uma cor (vermelha, verde ou azul). Em vez disso, um quark vermelho tem que ser ligado a um verde e a outro azul por uma 'fileira' de glúons (vermelho + verde + azul = branco). Tal trio constitui um próton ou um nêutron.

Outra possibilidade é um par composto de um quark e um antiquark (vermelho + antivermelho, ou verde+antiverde, ou azul + antiazul = branco). Tais combinações produzem as partículas conhecidas como mésons, que são instaveis porque o quark e o antiquark podem se anular, produzindo elétrons e outras partículas. Da mesma forma, o confinamento evita que se tenha um único glúon em si mesmo, porque os glúons também têm cor. Em vez disso, é preciso que se tenha um conjunto de glúons cujas cores se somem no branco. Tal conjunto forma uma partícula instável, chamada glueball.

O fato de que o confinamento evita que se observe um quark isolado, ou um glúon, pode parecer criar toda a noção dos quarks e glúons como partículas de alguma forma metafísicas. Entretanto, há uma outra propriedade da força nuclear forte, chamada liberdade assintótica, que torna bem definidos os conceitos de quarks e glúons. A energias normais, a força nuclear forte é realmente forte e liga os quarks muito intimamente. Entretanto, experimentos com grandes aceleradores de partículas indicam que, em altas energias, a força forte se torna muito mais fraca, e que os quarks e gluons se comportam como partículas independentes.

Gravidade

Uma definição fácil para essa força: tudo atrai todo o resto. Alem disso, essa força é universal, isto é, age sobre qualquer partícula.

A força gravitacional é, de longe, a mais fraca de todas. É muito, muito fraca mesmo. Tão fraca que seria praticamente impossível percebê-la, não fosse duas propriedades fundamentais: 1-é sempre atrativa 2- age através de grandes distâncias. (o que quero dizer por grandes distâncias? Imensas. Há indícios que sua ação se prolonga para muito longe de nossa galáxia, até os confins do universo)

A essa força devemos a explicação de muitos fenômenos: a Terra orbitando o Sol, por exemplo. Também explica as marés. Sim, a lua atrai a água para cima sob ela e provoca as marés. Havia muitas dúvidas devido ao fato da maré subir e descer em 12 horas. Foi Newton que explicou o fenômeno em detalhes. O mecanismo é assim: a lua atrai a Terra e a água sobre sua superfície. Mas o ponto de equilíbrio se encontra no centro. Só que temos que atentar para os vários níveis de profundidades da água. Assim, a água mais próxima da lua é atraída mais do que a restante. Consequentemente, a água mais afastada é atraída menos que a média. Soma-se a isso o fato de a água conseguir fluir, ao contrário da Terra, que é rígida. A combinação dessas duas coisas formam as marés.

A terra é redonda porque tudo atrai todo o resto, juntando-se ao máximo possível. Na verdade a Terra não e 100% esférica por que está girando e produz efeitos centrífugos que tendem a se opor a gravidade na região do equador. Então, o sol, a Terra e a lua são quase esferas.

Você pode pensar: então, quando caminho perto de outra pessoa, nossos corpos se atraem? Sim, e exatamente isso que acontece, e não precisa estar perto dessa outra pessoa. Você atrai qualquer corpo, vivo ou inanimado. Eu sei que estou te atraindo agora. Mas atrair e uma coisa, e colocar em movimento e outra. A forca gravitacional e muito fraca, e seus efeitos, apesar de existirem em qualquer lugar, só são observados na interacão entre corpos muito macicos, como dois planetas por exemplo.

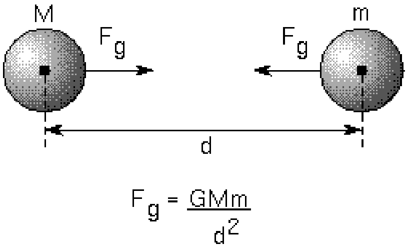

Figure 1.38: 4f03.png

Forca Eletromagnética

A forca electromagnética determina as maneiras em que partículas com carga eléctrica interactuam umas com as outras, e com campos magnéticos. Esta forca pode ser atrativa ou repulsiva. Cargas eléctricas com o mesmo sinal (duas positivas ou duas negativas) repelem-se; com sinais diferentes atraem-se.

A forca electromagnética segura os electrões [cargas negativas] nas suas orbitais, a volta do núcleo [carga positiva] do atomo. Esta forca mantem os atomos em existencia.

A forca electromagnética controla o comportamento de partículas com carga eléctrica e de plasmas (um plasma e uma mistura de quantidades iguais de iões positivos e electrões, negativos) como, por exemplo, em proeminencias solares, lacos coronais, luminancias, e outros tipos de actividade solar.

A forca electromagnética também governa a emissão e absorpcão de luz e outras formas de radiacão electromagnética. Luz e emitida quando uma partícula com carga eléctrica e acelerada (por exemplo, quando um electrão passa perto dum ião, ou interactua com um campo magnético) ou quando um electrão desce dum nível de energia mais alto para um mais baixo, num atomo (duma orbita' afastada para uma orbita' proxima a volta do nucleo do atomo).

Chapter 7

Even Isometries

§7.1 Parity

A product of two reflections is a translation or a rotation. By considering the fixed points of each, we see that neither a translation nor a rotation can be equal to a reflection. Thus, $\sigma_n\sigma_m \neq \sigma_l$ for lines l, m, n. When a given isometry is expressed as a product of reflections, the number of reflections is not invariant; indeed, we can always add 2 to the number of reflections in a given product by inserting "$\sigma_l\sigma_l$" into the product. Although a product of two reflections cannot be a reflection, we know that in some cases a product of three reflections is a reflection. We shall see this is possible only because both 3 and 1 are odd integers. In mathematics, *parity* refers to the property of an integer being either even or odd. An isometry that is a product of an even number of reflections is said to be ***even***; an isometry that is a product of an odd number of reflections is said to be ***odd***. Since an isometry is a product of reflections, then an isometry is even or odd. However, the definition will be useful only if we show that no isometry is both even and odd. Of course no integer can be both even and odd, but is it not conceivable some product of ten reflections could be equal to some product of seven reflections? To show this is impossible, we first show that a product of four reflections is always equal to a product of two reflections.

Our argument that a product of four reflections is a product of two reflections depends on two applications of the lemma: If P is a point and a and b are lines, then there are lines c and d with c passing through P such that $\sigma_b\sigma_a = \sigma_d\sigma_c$. Suppose a, b, P are given. If $a \parallel b$, let c be the line through P that is parallel to a; if a and b intersect at C, let c be a line through P and C. So a, b, c are either parallel to each other or else concurrent. In either case, there is a line d such that $\sigma_b\sigma_a\sigma_c = \sigma_d$. Then $\sigma_b\sigma_a = \sigma_d\sigma_c$ and we have the

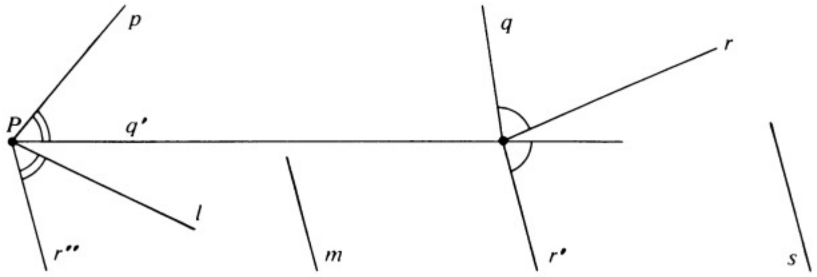

Figure 7.1

desired lemma. Now, suppose product $\sigma_s\sigma_r\sigma_q\sigma_p$ is given. We want to show this product is equal to a product of two reflections. Let P be a point on line p. See Figure 7.1 for an example. By the lemma, there are lines q' and r' such that $\sigma_r\sigma_q = \sigma_{r'}\sigma_{q'}$ with P on q'. Again by the lemma, there are lines r'' and m such that $\sigma_s\sigma_{r'} = \sigma_m\sigma_{r''}$ with P on r''. Since p, q', r'' are concurrent at P, then there is a line l such that $\sigma_{r''}\sigma_{q'}\sigma_p = \sigma_l$. Therefore,

$$\sigma_s\sigma_r\sigma_q\sigma_p = \sigma_s\sigma_{r'}\sigma_{q'}\sigma_p = \sigma_m\sigma_{r''}\sigma_{q'}\sigma_p = \sigma_m\sigma_l.$$

Not only are there lines such that the given product of four reflections is equal to $\sigma_m\sigma_l$, but our proof even tells how to find such lines.

Theorem 7.1. *A product of four reflections is a product of two reflections.*

Given a long product of reflections, we can use this theorem repeatedly to replace the first four reflections by two reflections until we have obtained a product with less than four reflections. By repeated application of the theorem to an even isometry, we can reduce the even isometry to a product of two reflections. Also, by repeated application of the theorem to an odd isometry, we can reduce the odd isometry to a product of three reflections or to a reflection. Therefore, to show an isometry cannot be both even and odd, we need to show only that a product of two reflections cannot equal a reflection or a product of three reflections. Assume there are lines p, q, r, s, t such that $\sigma_r\sigma_q\sigma_p = \sigma_s\sigma_t$. Then, we have shown above that there are lines l and m such that $\sigma_m\sigma_l = \sigma_s\sigma_r\sigma_q\sigma_p = \sigma_s\sigma_s\sigma_t = \sigma_t$. We have a contradiction since $\sigma_m\sigma_l$ is a translation or a rotation and cannot be equal to reflection σ_t. A product of two reflections is never equal to a reflection or a product of three reflections. We have our desired theorem concerning parity.

Theorem 7.2. *An even isometry is a product of two reflections. An odd isometry is a reflection or a product of three reflections. No isometry is both even and odd.*

The even isometries are the translations and the rotations. Since the involutory isometries are the halfturns and the reflections, the theorem above gives the following partition of these involutions.

Theorem 7.3. *An even involutory isometry is a halfturn; an odd involutory isometry is a reflection.*

An isometry and its inverse have the same parity, since the inverse of a product of reflections is the product of the reflections in reverse order. So the set $\mathscr{E}$ of all even isometries has the inverse property. Further, the set $\mathscr{E}$ has the closure property since the sum of two even integers is even. That's all we need to show that $\mathscr{E}$ forms a group.

Theorem 7.4. *The even isometries form a group* $\mathscr{E}$.

$\mathscr{E}$ will always denote the group of even isometries. So $\mathscr{E}$ consists of the translations and the rotations. Since some persons call only these isometries in $\mathscr{E}$ *motions* while others call any isometry in $\mathscr{I}$ a *motion*, we shall get along without using the term at all.

$\alpha\sigma_P\alpha^{-1} = \sigma_{\alpha(P)}$ for any isometry α since $\alpha\sigma_P\alpha^{-1}$ is an even involutory isometry that fixes $\alpha(P)$. That's true but a little fast. Suppose α and β are isometries. Then, $\alpha\beta\alpha^{-1}$ is an involution iff β is an involution since $(\alpha\beta\alpha^{-1})^2 = \alpha\beta^2\alpha^{-1} = \iota$ iff $\beta^2 = \iota$ and since $\alpha\beta\alpha^{-1} = \iota$ iff $\beta = \iota$. For example, since σ_P and σ_m are involutions, then $\alpha\sigma_P\alpha^{-1}$ and $\alpha\sigma_m\alpha^{-1}$ are involutions. Further, $\alpha\beta\alpha^{-1}$ and β must have the same parity since α and its inverse α^{-1} have the same parity. For example, $\alpha\sigma_P\alpha^{-1}$ is even because σ_P is even, and $\alpha\sigma_m\alpha^{-1}$ is odd because σ_m is odd. Since $\alpha\sigma_P\alpha^{-1}$ is an even involution, then $\alpha\sigma_P\alpha^{-1}$ must be a halfturn (Theorem 7.3). Hence, since halfturn $\alpha\sigma_P\alpha^{-1}$ clearly fixes point $\alpha(P)$, then $\alpha\sigma_P\alpha^{-1}$ must be the halfturn about $\alpha(P)$. That is, $\alpha\sigma_P\alpha^{-1} = \sigma_{\alpha(P)}$. In similar fashion, since $\alpha\sigma_m\alpha^{-1}$ is an odd involutory isometry, then $\alpha\sigma_m\alpha^{-1}$ is a reflection. Hence, since $\alpha\sigma_m\alpha^{-1}$ clearly fixes every point $\alpha(P)$ on line $\alpha(m)$, then $\alpha\sigma_m\alpha^{-1}$ must be the reflection in the line $\alpha(m)$. That is, $\alpha\sigma_m\alpha^{-1} = \sigma_{\alpha(m)}$.

Theorem 7.5. *If P is a point, m is a line, and α is an isometry, then*

$$\alpha\sigma_m\alpha^{-1} = \sigma_{\alpha(m)} \quad \textit{and} \quad \alpha\sigma_P\alpha^{-1} = \sigma_{\alpha(P)}.$$

Figure 7.2 illustrates an example of the first equation in the theorem with α taken to be $\rho_{P,60}$. The theorem says that if we rotate the points of the plane about P through $-60°$, then reflect in line m, and then rotate about P through $+60°$, the effect of all this is just the same as only reflecting in line n where $n = \rho_{P,60}(m)$. That seems truly amazing.

In general, $\alpha\beta\alpha^{-1}$ is called the ***conjugate*** of β by α. We next look at the conjugate $\alpha\tau_{A,B}\alpha^{-1}$ of translation $\tau_{A,B}$ by isometry α. If M is the midpoint of A and B, then point $\alpha(M)$ is the midpoint of points $\alpha(A)$ and $\alpha(B)$. Also, $\tau_{A,B} = \sigma_M\sigma_A$ and $\tau_{\alpha(A),\alpha(B)} = \sigma_{\alpha(M)}\sigma_{\alpha(A)}$. Using our method of inserting the identity in a useful form, we then have

$$\alpha\tau_{A,B}\alpha^{-1} = \alpha\sigma_M\sigma_A\alpha^{-1} = \alpha\sigma_M\alpha^{-1}\alpha\sigma_A\alpha^{-1} = \sigma_{\alpha(M)}\sigma_{\alpha(A)} = \tau_{\alpha(A),\alpha(B)}.$$

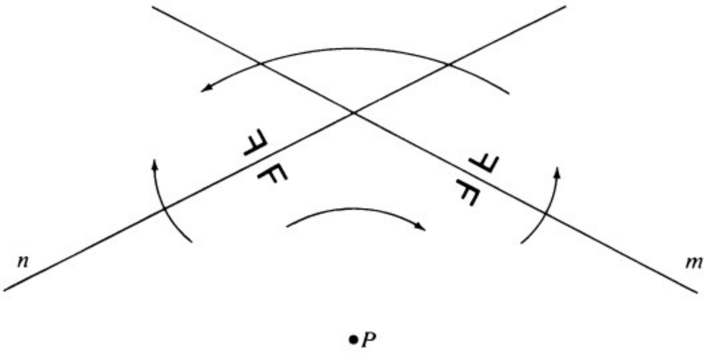

Figure 7.2

What could be nicer than the result $\alpha\tau_{A,B}\alpha^{-1} = \tau_{\alpha(A),\alpha(B)}$? Finding the conjugate of a rotation is slightly more complicated. We first examine the conjugate of $\rho_{C,\Theta}$ by σ_l. Let m be the line through C that is perpendicular to l. Then there is a line n through C such that $\rho_{C,\Theta} = \sigma_n\sigma_m$. See Figure 7.3. Now $\sigma_l(m)$ and $\sigma_l(n)$ intersect at $\sigma_l(C)$, and a directed angle from $\sigma_l(m)$ to $\sigma_l(n)$ is the negative of a directed angle from m to n. This explains the negative sign on the far right in the following calculation:

$$\sigma_l\rho_{C,\Theta}\sigma_l^{-1} = \sigma_l\sigma_n\sigma_m\sigma_l^{-1} = \sigma_l\sigma_n\sigma_l^{-1}\sigma_l\sigma_m\sigma_l^{-1} = \sigma_{\sigma_l(n)}\sigma_{\sigma_l(m)} = \rho_{\sigma_l(C),-\Theta}.$$

If $\alpha = \sigma_t\sigma_s$, then $\alpha\rho_{C,\Theta}\alpha^{-1} = \sigma_t(\sigma_s\rho_{C,\Theta}\sigma_s^{-1})\sigma_t^{-1} = \rho_{\alpha(C),+\Theta}$ with a positive sign replacing two negative signs in front of Θ. If $\alpha = \sigma_t\sigma_s\sigma_r$ then the sign in front of Θ is back to a negative sign again. We summarize our results as follows.

Theorem 7.6. *If α is an isometry, then*

$$\alpha\tau_{A,B}\alpha^{-1} = \tau_{\alpha(A),\alpha(B)} \quad \textit{and} \quad \alpha\rho_{C,\Theta}\alpha^{-1} = \rho_{\alpha(C),\pm\Theta},$$

where the positive sign applies when α is even and the negative sign applies when α is odd.

By taking $\alpha = \rho_{D,\Phi}$ in the theorem, we can show nonidentity rotation $\rho_{D,\Phi}$ does not commute with nonidentity rotation $\rho_{C,\Theta}$ unless $D = C$. We

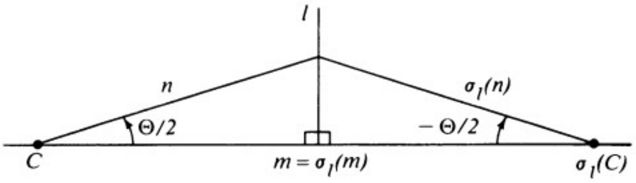

Figure 7.3

state this as a theorem here but leave the details of the argument as Exercise 7.1.

Theorem 7.7. *Nonidentity rotations with different centers do not commute.*

We are also in a position to answer the question, "When do reflections commute?" For any lines m and n, the following five statements are seen to be equivalent. (1) $\sigma_m \sigma_n = \sigma_n \sigma_m$. (2) $\sigma_n \sigma_m \sigma_n = \sigma_m$. (3) $\sigma_{\sigma_n(m)} = \sigma_m$. (4) $\sigma_n(m) = m$. (5) $m = n$ or $m \perp n$. Comparing (1) and (5), we have the answer to our question.

Theorem 7.8. $\sigma_m \sigma_n = \sigma_n \sigma_m$ *iff* $m = n$ *or* $m \perp n$.

Several equivalences between algebraic equations and geometric relations similar to that in Theorem 7.8 are indicated in Exercise 7.3. These are verified in the same manner.

We now consider products of even isometries. We already know (Theorem 3.4) that the product of two translations is a translation. We also know (Theorem 3.6) that the product of two rotations can be a translation in some cases. For example, $\sigma_B \sigma_A = \tau^2_{A,B}$; don't forget that a halfturn is a rotation of 180°. We know $\rho_{C,\Phi}\rho_{C,\Theta} = \rho_{C,\Theta+\Phi}$ by Theorem 5.10. Let's consider the product $\rho_{B,\Phi}\rho_{A,\Theta}$ of two nonidentity rotations with different centers. With $c = \overleftrightarrow{AB}$, there is a line a through A and a line b through B such that $\rho_{A,\Theta} = \sigma_c \sigma_a$ and $\rho_{B,\Phi} = \sigma_b \sigma_c$. So $\rho_{B,\Phi}\rho_{A,\Theta} = \sigma_b \sigma_c \sigma_c \sigma_a = \sigma_b \sigma_a$. When $(\Theta + \Phi)^\circ = 0^\circ$, then the lines a and b are parallel and our product is a translation. This is easier to see when the directed angles are chosen as interior angles on the same side of c; for example, in Figure 7.4 we have $\Theta/2 + \Phi/2 = -180$. On the other hand, when $(\Theta + \Phi)^\circ \neq 0^\circ$, then the lines a and b intersect at some point C and our product is a rotation.

More than that, with the directed angles chosen as interior angles on the same side of c as C, we can see by the Exterior Angle Theorem from elementary geometry that one directed angle from a to b is $(\Theta/2 + \Phi/2)^\circ$. See Figure 7.5. Hence our product $\sigma_b \sigma_a$ is a rotation about C through an angle of $(\Theta + \Phi)^\circ$. That is, $\rho_{B,\Phi}\rho_{A,\Theta} = \rho_{C,\Theta+\Phi}$. Now, what is the product of a translation

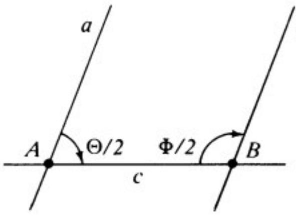

Figure 7.4

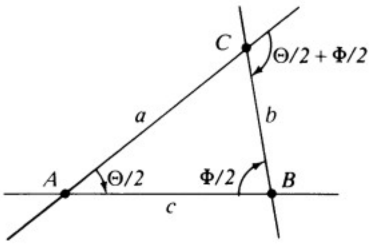

Figure 7.5

and a nonidentity rotation? In such a product we replace the translation by a product of two rotations of 180° each and obtain as the product of the three rotations a rotation of $(\Theta + 180 + 180)^\circ$, which is just a rotation of Θ°. We have proved ***The Angle-addition Theorem.***

Theorem 7.9. *A rotation of* Θ° *followed by a rotation of* Φ° *is a rotation of* $(\Theta + \Phi)^\circ$ *unless* $(\Theta + \Phi)^\circ = 0^\circ$, *in which case the product is a translation. A translation followed by a nonidentity rotation of* Θ° *is a rotation of* Θ°. *A nonidentity rotation of* Θ° *followed by a translation is a rotation of* Θ°. *A translation followed by a translation is a translation.*

The Angle-addition Theorem can also be proved by using the equations for the even isometries that will be developed in Section 9.1.

§7.2 The Dihedral Groups

We are going to compute the symmetry group of a regular polygon. As a specific example of what we are going to do, we first consider the square. We suppose the square is centered at the origin in the Cartesian plane and that one vertex lies on the positive X-axis. With the notation as in Figure 7.6, we see that the square is fixed by ρ and by σ where $\rho = \rho_{O,90}$ and $\sigma = \sigma_h$. Note that $\rho^4 = \sigma^2 = \iota$. Since the symmetries of the square form a group, then the square must be fixed by the four distinct rotations $\rho, \rho^2, \rho^3, \rho^4$ and by the four distinct odd isometries $\rho\sigma, \rho^2\sigma, \rho^3\sigma, \rho^4\sigma$. Let V_1 and V_2 be adjacent vertices of the square. Under a symmetry, V_1 may go to any one of the four vertices, but then V_2 must go to one of the two vertices adjacent to that one and the images of all remaining vertices are then determined. So

2.7 Coordinate frames and transformations

Orthogonal frames such as Cartesian, cylindrical and spherical are commonly used. In these frames, the axes are orthogonal and the basis (unit vectors along the orthogonal axes) is used to describe quantities of interest in the frame. Cartesian frame or x-frame is simplest of the three. The x-frame can be transformed into y-frame through a coordinate transformation T. In doing so, we also transform the quantities defined in x-frame to y-frame, referred to as induced transformation. In continuum mechanics, the nature of transformation T and the nature of induced transformation on various quantities defined in x-frame are important classes of studies. We also consider non-orthogonal curvilinear frames in which the coordinate axes are curved and are not orthogonal. An important case is a Cartesian x-frame that transforms into a non-orthogonal curvilinear frame due to coordinate transformation T. Just like orthogonal frames, a curvilinear frame has a basis. We consider details in the following sections.

2.7.1 Cartesian frame and orthogonal coordinate transformations

For now, we consider x-frame to be Cartesian frame and transformation T (2.72) to be such that it causes translation and rigid rotation of x-frame into y-frame. For simplicity, consider a two-dimensional case.

Consider two sets of Cartesian frames in a plane: the x-frame o-x_1x_2 and the y-frame o'-y_1y_2. If the y-frame is obtained from the x-frame by a shift of the origin and without a rotation of the axes, then the transformation from the x-frame to the y-frame is a translation. If the point P has coordinates (x_1, x_2) and (y_1, y_2) in x-frame and y-frame and if (c_1, c_2) are the coordinates of the origin of y-frame with respect to x-frame, then

$$\begin{aligned} x_1 &= y_1 + c_1 \\ x_2 &= y_2 + c_2 \end{aligned} \tag{2.73}$$

or in compact form

$$x_i = y_i + c_i \quad ; \quad i = 1, 2 \tag{2.74}$$

If the origin remains fixed and the y-frame is obtained by rotating the x-frame through an angle θ in the counter clockwise direction about a line perpendicular to the plane of the x-frame but at its origin (see Figure 2.2), then the transformation relating the frames can be derived as follows. Consider a fixed point P with coordinates (x_1, x_2) and (y_1, y_2) in x-frame and y-frame. From Figure 2.2, it is rather straightforward to see that

$$\begin{aligned} x_1 &= y_1 cos\theta - y_2 sin\theta \\ x_2 &= y_1 sin\theta + y_2 cos\theta \end{aligned} \tag{2.75}$$

Let us define

$$[Q] = \begin{bmatrix} Q_{11} & Q_{12} \\ Q_{21} & Q_{22} \end{bmatrix} = \begin{bmatrix} \cos\theta & \sin\theta \\ -\sin\theta & \cos\theta \end{bmatrix} \tag{2.76}$$

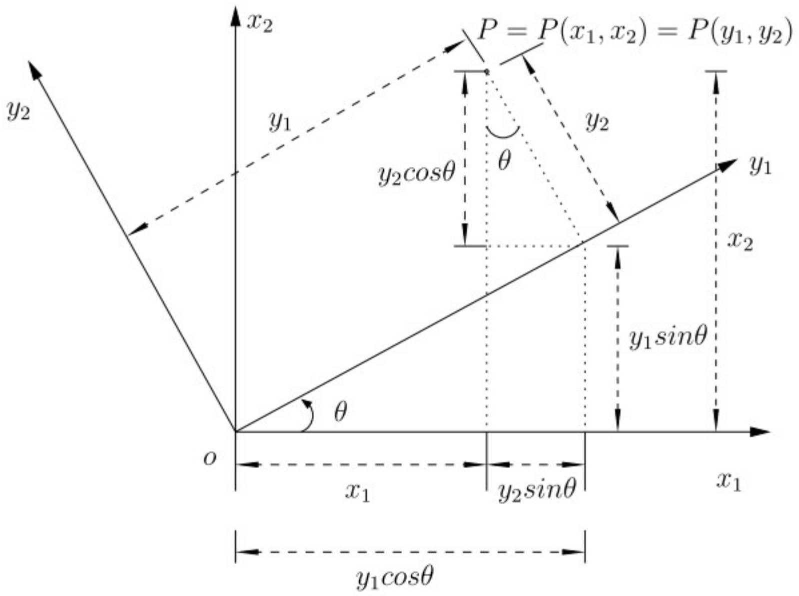

Figure 2.2: Rigid rotation of x-frame to y-frame by an angle θ

Then (2.75) can be written as

$$\begin{Bmatrix} x_1 \\ x_2 \end{Bmatrix} = [Q]^T \begin{Bmatrix} y_1 \\ y_2 \end{Bmatrix} \quad ; \quad x_i = x_i(y_j) \quad ; \quad i,j = 1,2 \tag{2.77}$$

We note that $[Q]$ defines pure rotation of x-frame to y-frame and is orthogonal, i.e.,

$$[Q]^T = [Q]^{-1} \quad \text{hence} \quad [Q]^T[Q] = [Q][Q]^T = [I] \tag{2.78}$$

Using (2.78), we obtain the following from either (2.75) or (2.77).

$$\begin{Bmatrix} y_1 \\ y_2 \end{Bmatrix} = [Q] \begin{Bmatrix} x_1 \\ x_2 \end{Bmatrix} \quad ; \quad y_i = y_i(x_j) \quad ; \quad i,j = 1,2 \tag{2.79}$$

That is, the coordinate transformation T defined by $[Q]$ in (2.79) is such that x-frame is transformed into y-frame. We note that both x-frame and y-frame are Cartesian frames and the transformation T defined by $[Q]$ in (2.79) is orthogonal.

Remarks

(1) In the rotation of the x-frame to y-frame, the point P remains fixed. Thus, if point P is a material point in a volume of matter, then every such point in the volume of matter has coordinates in x- and y-frames that are related through (2.79). It is important to note that in this process, the x-frame is rotated to y-frame, but the volume of matter containing point(s) P remains undisturbed.

(2) In contrast to (1), if we rotate the volume of matter through a rigid rotation, then its coordinate changes from x_i to y_i. Both are measured in the x-frame. The relationship between the new coordinates y_i and the original coordinates

x_i is not (2.79), but instead is given by (analogous to (2.79))

$$\begin{Bmatrix} y_1 \\ y_2 \end{Bmatrix} = [Q]^T \begin{Bmatrix} x_1 \\ x_2 \end{Bmatrix} \tag{2.80}$$

(3) Thus, the rotation of coordinate system or frame is quite different than the rigid rotation of the volume of matter. In this book, we always consider rotation of the frame and not the rigid rotation of the volume of matter regardless of the configuration.

The relationship (2.79) can also be derived in an alternate way using unit vectors (base vectors) in x-frame and y-frame. Let $\boldsymbol{e}_1^x$, $\boldsymbol{e}_2^x$ and $\boldsymbol{e}_1^y$, $\boldsymbol{e}_2^y$ be bases in x-frame and y-frame. Then the vector $\boldsymbol{OP}$ (Figure 2.2) can be written as (using bases in x- and y-frames, i.e., index notation)

$$\boldsymbol{OP} = \boldsymbol{e}_1^x x_1 + \boldsymbol{e}_2^x x_2 = \boldsymbol{e}_1^y y_1 + \boldsymbol{e}_2^y y_2 \tag{2.81}$$

Using (2.81) it is possible to derive the transformation T relating x-frame to y-frame and y-frame to x-frame. Consider the dot products $\boldsymbol{e}_1^x \cdot \boldsymbol{OP}$ and $\boldsymbol{e}_2^x \cdot \boldsymbol{OP}$.

$$\begin{aligned} \boldsymbol{e}_1^x \cdot \boldsymbol{e}_1^x x_1 + \boldsymbol{e}_1^x \cdot \boldsymbol{e}_2^x x_2 &= \boldsymbol{e}_1^x \cdot \boldsymbol{e}_1^y y_1 + \boldsymbol{e}_1^x \cdot \boldsymbol{e}_2^y y_2 \\ \boldsymbol{e}_2^x \cdot \boldsymbol{e}_1^x x_2 + \boldsymbol{e}_2^x \cdot \boldsymbol{e}_2^x x_2 &= \boldsymbol{e}_2^x \cdot \boldsymbol{e}_1^y y_1 + \boldsymbol{e}_2^x \cdot \boldsymbol{e}_2^y y_2 \end{aligned} \tag{2.82}$$

Using $\boldsymbol{e}_1^x \cdot \boldsymbol{e}_1^x = 1$, $\boldsymbol{e}_2^x \cdot \boldsymbol{e}_2^x = 1$ and $\boldsymbol{e}_1^x \cdot \boldsymbol{e}_2^x = \boldsymbol{e}_2^x \cdot \boldsymbol{e}_1^x = 0$ in (2.82) we obtain

$$\begin{Bmatrix} x_1 \\ x_2 \end{Bmatrix} = \begin{bmatrix} \boldsymbol{e}_1^x \cdot \boldsymbol{e}_1^y & \boldsymbol{e}_1^x \cdot \boldsymbol{e}_2^y \\ \boldsymbol{e}_2^x \cdot \boldsymbol{e}_1^y & \boldsymbol{e}_2^x \cdot \boldsymbol{e}_2^y \end{bmatrix} \begin{Bmatrix} y_1 \\ y_2 \end{Bmatrix} \tag{2.83}$$

In a similar fashion, if we take the dot products $\boldsymbol{e}_1^y \cdot \boldsymbol{OP}$ and $\boldsymbol{e}_2^y \cdot \boldsymbol{OP}$ and use the properties $\boldsymbol{e}_1^y \cdot \boldsymbol{e}_1^y = 1$, $\boldsymbol{e}_2^y \cdot \boldsymbol{e}_2^y = 1$ and $\boldsymbol{e}_1^y \cdot \boldsymbol{e}_2^y = \boldsymbol{e}_2^y \cdot \boldsymbol{e}_1^y = 0$, then we obtain

$$\begin{Bmatrix} y_1 \\ y_2 \end{Bmatrix} = \begin{bmatrix} \boldsymbol{e}_1^y \cdot \boldsymbol{e}_1^x & \boldsymbol{e}_1^y \cdot \boldsymbol{e}_2^x \\ \boldsymbol{e}_2^y \cdot \boldsymbol{e}_1^x & \boldsymbol{e}_2^y \cdot \boldsymbol{e}_2^x \end{bmatrix} \begin{Bmatrix} x_1 \\ x_2 \end{Bmatrix} \tag{2.84}$$

Let us define

$$[Q] = \begin{bmatrix} \boldsymbol{e}_1^y \cdot \boldsymbol{e}_1^x & \boldsymbol{e}_1^y \cdot \boldsymbol{e}_2^x \\ \boldsymbol{e}_2^y \cdot \boldsymbol{e}_1^x & \boldsymbol{e}_2^y \cdot \boldsymbol{e}_2^x \end{bmatrix} \tag{2.85}$$

Then (2.84) and (2.83) can be written as

$$\begin{Bmatrix} y_1 \\ y_2 \end{Bmatrix} = [Q] \begin{Bmatrix} x_1 \\ x_2 \end{Bmatrix} \tag{2.86}$$

$$\begin{Bmatrix} x_1 \\ x_2 \end{Bmatrix} = [Q]^T \begin{Bmatrix} y_1 \\ y_2 \end{Bmatrix} \tag{2.87}$$

That is, $[Q]$ in (2.85) is orthogonal. This form of $[Q]$ can be easily extended to the three-dimensional case as done subsequently. First, we derive a special form of $[Q]$ in (2.76) using (2.85) that corresponds to a rigid notation of the x-frame to the y-frame by an angle θ, i.e., we derive $[Q]$ of (2.76) from (2.85).

o
$\boldsymbol{e}_1^y cos\theta$

Figure 2.3: Base vectors $\boldsymbol{e}_1^y$, $\boldsymbol{e}_2^y$ of y-frame and their projections in x-frame

Consider Figure 2.3 showing unit vectors $\boldsymbol{e}_1^y$ and $\boldsymbol{e}_2^y$ of the y-frame and their projection in the x-frame. The unit vectors in the x-frame, i.e., $\boldsymbol{e}_1^x$ and $\boldsymbol{e}_2^x$, are the algebraic sum of these projections. Hence we have

$$\begin{aligned} \boldsymbol{e}_1^x &= \boldsymbol{e}_1^y \cos\theta - \boldsymbol{e}_2^y \sin\theta \\ \boldsymbol{e}_2^x &= \boldsymbol{e}_1^y \sin\theta + \boldsymbol{e}_2^y \cos\theta \end{aligned} \tag{2.88}$$

and substituting from (2.88) into (2.85) and using the properties of the dot products of $\boldsymbol{e}_1^y$ and $\boldsymbol{e}_2^y$ we obtain

$$[Q] = \begin{bmatrix} \cos\theta & \sin\theta \\ -\sin\theta & \cos\theta \end{bmatrix} \tag{2.89}$$

which is the same as (2.76). This second approach of relating x-frame and y-frame through an orthogonal transformation in (2.85) can be easily extended to three dimensions. Consider a point $P(x_1, x_2, x_3)$ in the x-frame. Let $\boldsymbol{e}_i^x$ be the unit base vectors in the x-frame. Let T be an orthogonal transformation such that

$$T \ : \ y_i = y_i(x_j) \tag{2.90}$$

That is, T transforms x-frame into y-frame. Let $\boldsymbol{e}_i^y$ be the unit base vectors in the y-frame. We consider T to be an orthogonal transformation. We want to find how x- and y-frames are related through T and the specific form of T. Let y_1, y_2, y_3 be the coordinates of the point P in the y-frame. The vector $\boldsymbol{OP}$ can be represented in x- and y-frames.

$$\boldsymbol{OP} = \boldsymbol{e}_i^x x_i = \boldsymbol{e}_i^y y_i \tag{2.91}$$

As in the two-dimensional case, here also, if we use the relations

$$\begin{aligned} \boldsymbol{e}_i^x \cdot \boldsymbol{e}_j^x &= \delta_{ij} \\ \boldsymbol{e}_i^y \cdot \boldsymbol{e}_j^y &= \delta_{ij} \end{aligned} \tag{2.92}$$

and if we take the dot product of (2.91) with $\boldsymbol{e}_1^y$, $\boldsymbol{e}_2^y$ and $\boldsymbol{e}_3^y$, we can derive the following:

$$\begin{Bmatrix} y_1 \\ y_2 \\ y_3 \end{Bmatrix} = \begin{bmatrix} \boldsymbol{e}_1^y \cdot \boldsymbol{e}_1^x & \boldsymbol{e}_1^y \cdot \boldsymbol{e}_2^x & \boldsymbol{e}_1^y \cdot \boldsymbol{e}_3^x \\ \boldsymbol{e}_2^y \cdot \boldsymbol{e}_1^x & \boldsymbol{e}_2^y \cdot \boldsymbol{e}_2^x & \boldsymbol{e}_2^y \cdot \boldsymbol{e}_3^x \\ \boldsymbol{e}_3^y \cdot \boldsymbol{e}_1^x & \boldsymbol{e}_3^y \cdot \boldsymbol{e}_2^x & \boldsymbol{e}_3^y \cdot \boldsymbol{e}_3^x \end{bmatrix} \begin{Bmatrix} x_1 \\ x_2 \\ x_3 \end{Bmatrix} \tag{2.93}$$

Let

$$[Q] = \begin{bmatrix} \boldsymbol{e}_1^y \cdot \boldsymbol{e}_1^x & \boldsymbol{e}_1^y \cdot \boldsymbol{e}_2^x & \boldsymbol{e}_1^y \cdot \boldsymbol{e}_3^x \\ \boldsymbol{e}_2^y \cdot \boldsymbol{e}_1^x & \boldsymbol{e}_2^y \cdot \boldsymbol{e}_2^x & \boldsymbol{e}_2^y \cdot \boldsymbol{e}_3^x \\ \boldsymbol{e}_3^y \cdot \boldsymbol{e}_1^x & \boldsymbol{e}_3^y \cdot \boldsymbol{e}_2^x & \boldsymbol{e}_3^y \cdot \boldsymbol{e}_3^x \end{bmatrix} \tag{2.94}$$

then

$$\begin{Bmatrix} y_1 \\ y_2 \\ y_3 \end{Bmatrix} = [Q] \begin{Bmatrix} x_1 \\ x_2 \\ x_3 \end{Bmatrix} \tag{2.95}$$

in which $[Q]$ is orthogonal (check as an exercise), i.e.,

$$[Q]^T = [Q]^{-1} \quad \text{and} \quad [Q]^T[Q] = [Q][Q]^T = [I] \tag{2.96}$$

Hence

$$\begin{aligned} \det([Q]^T[Q]) &= \det[I] && (2.97) \\ \det[Q]^T \det[Q] &= 1 \\ \det[Q] \det[Q] &= 1 \\ (\det[Q])^2 &= 1 \\ \det[Q] &= \pm 1 && (2.98) \end{aligned}$$

If the orthogonal matrix $[Q]$ is such that $\det[Q] = +1$, then we refer to $[Q]$ as a proper orthogonal matrix and the transformation of x- to y-frame is a proper orthogonal transformation. In such transformations, a right-handed orthogonal system (say x-frame) is transformed into another right-handed orthogonal frame (say y-frame). An orthogonal matrix whose determinant is -1 is called an improper orthogonal matrix. An improper orthogonal matrix transforms a right-handed orthogonal frame into a left-handed orthogonal frame.

2.7.2 Curvilinear coordinates (or frame)

Let x_1, x_2, x_3 or x_i $(i = 1, 2, 3)$ be the coordinates of a material point P (in fixed Cartesian x-frame) and y_1, y_2, y_3 or y_j $(j = 1, 2, 3)$ be three variables. If we can establish a correspondence between x_i and y_j, then we say that there is a transformation T or a coordinate transformation between x_i and y_j, and we can write

$$T \ : \ y_j = y_j(x_1, x_2, x_3) \quad ; \quad j = 1, 2, 3 \tag{2.99}$$

If this correspondence is one-to-one, then there exists a unique inverse of (2.99), in the following form

$$T^{-1} \,:\, x_i = x_i(y_1, y_2, y_3) \quad ; \quad i = 1, 2, 3 \tag{2.100}$$

We can show this inverse (i.e., T^{-1}) exists, and is unique, if the determinant of the Jacobian of transformation is not equal to zero.

$$\det[J] = \det\left[\frac{y_1, y_2, y_3}{x_1, x_2, x_3}\right] = \begin{vmatrix} \dfrac{\partial y_1}{\partial x_1} & \dfrac{\partial y_1}{\partial x_2} & \dfrac{\partial y_1}{\partial x_3} \\ \dfrac{\partial y_2}{\partial x_1} & \dfrac{\partial y_2}{\partial x_2} & \dfrac{\partial y_2}{\partial x_3} \\ \dfrac{\partial y_3}{\partial x_1} & \dfrac{\partial y_3}{\partial x_2} & \dfrac{\partial y_3}{\partial x_3} \end{vmatrix} \neq 0 \tag{2.101}$$

For a fixed set of values x_1, x_2, x_3, the transformation (2.100) gives three non-coincident surfaces called curvilinear surfaces. These interact at a single point P with fixed y_1, y_2, y_3. Thus, to point P, we can assign values y_1, y_2, y_3 called curvilinear coordinates of P (Figure 2.4). From Figure 2.4, we note that the intersection of any two surfaces gives a curve through P called a curvilinear coordinate line.

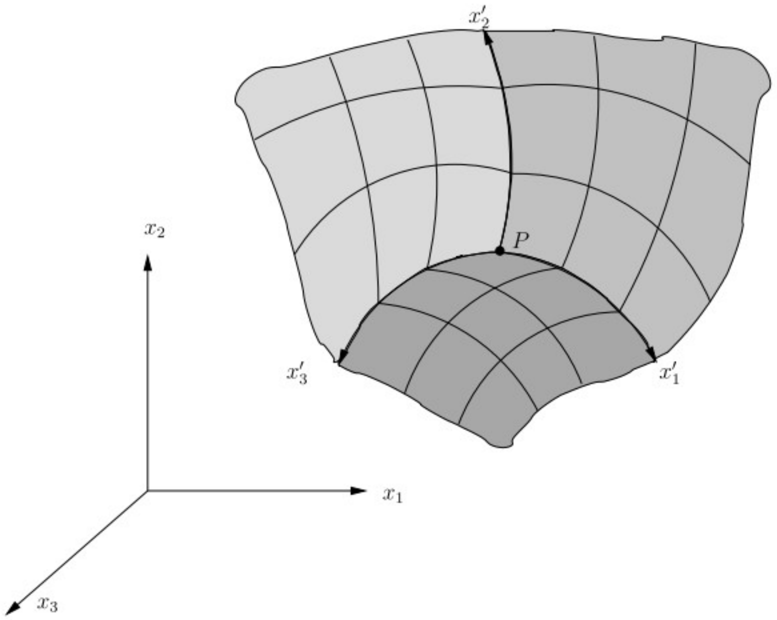

Figure 2.4: Curvilinear coordinates

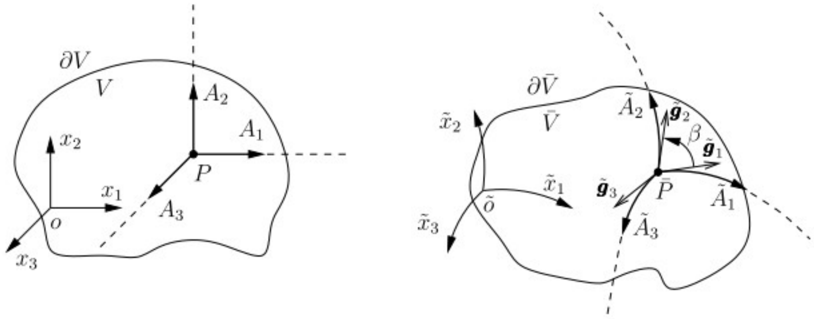
2.8 Curvilinear frames, covariant and contravariant bases

To quantify the motion and deformation of matter, we need a fundamental understanding of the motion of the material particles. Consider undeformed volume

V with boundary ∂V at time t_0 as constituting the reference configuration. The reference configuration could be different than the configuration of the matter at time t_0, but assumed to be the same for the sake of simplicity. Let o-$x_1x_2x_3$ be the x-frame. Let each material particle in the reference configuration be assigned unique coordinates (x_1, x_2, x_3) in the x-frame. We assume that the matter is *homogeneous and isotropic.* Consider a material point $P(x_1, x_2, x_3)$ in this configuration. We draw lines parallel to ox_1, ox_2, ox_3 axes in the reference configuration representing material lines PA_1, PA_2, PA_3 (Figure 2.5(a)). The deformed or current configuration, i.e., volume $\bar{V}$ with boundary $\partial\bar{V}$ at time t is shown in Figure 2.5(b). Let $\bar{x}_i$ be the deformed coordinates of the material point $P(x_1, x_2, x_3)$ in the fixed coordinate x-frame. Naturally $\bar{x}_i = x_i + u_i$; u_i being displacements of the point $P(x_1, x_2, x_3)$ in the fixed x-frame. The deformed material lines $\bar{P}\tilde{A}_1$, $\bar{P}\tilde{A}_2$, $\bar{P}\tilde{A}_3$, coordinate axes $\tilde{o}\tilde{x}_1$, $\tilde{o}\tilde{x}_2$, $\tilde{o}\tilde{x}_3$ and the location of point P (i.e., $\bar{P}$) are also shown in Figure 2.5(b). The coordinate system $\tilde{o}$-$\tilde{x}_1\tilde{x}_2\tilde{x}_3$ ($\tilde{x}$-frame) is called *convected coordinate system.* This coordinate system and various measures of the state of deforming matter in this coordinate system are crucial in developing constitutive theories (considered in later chapters) because, in this coordinate system, we have deformed material lines.



(a) Undeformed configuration

(b) Deformed configuration: covariant basis

Figure 2.5: Material lines in reference and current configurations: covariant basis

We note that at time t_0, the convected coordinate system coincides with the Cartesian coordinate system o-$x_1x_2x_3$. The convected coordinate system continuously changes in time in such a way that coordinates of a material particle in this coordinate system remain the same for all values of time. If $\tilde{x}_i$ are the coordinates of the material particle in $\tilde{o}$-$\tilde{x}_1\tilde{x}_2\tilde{x}_3$ coordinate system, then $\tilde{x}_i$ remain fixed for all values of time. An important conclusion is that coordinates x_i of a material particle $P(x_i)$ in the configuration at time $t_0 = 0$ in x-frame have exactly the same numerical values as the material particle $\bar{P}$ coordinates $\tilde{x}_i$ in $\tilde{x}$-frame. We can write the following:

$$\bar{x}_i = \bar{x}_i(\tilde{x}_1, \tilde{x}_2, \tilde{x}_3, t) \quad ; \quad i = 1, 2, 3 \tag{2.102}$$

But the material point with coordinates $\tilde{x}_i$ are the same as x_i, hence

$$\bar{x}_i = \bar{x}_i(x_1, x_2, x_3, t) \quad \text{or} \quad \bar{\boldsymbol{r}} = \bar{\boldsymbol{r}}(\boldsymbol{r}, t) \tag{2.103}$$

where $\bar{\boldsymbol{r}}$ and $\boldsymbol{r}$ are vectors with components $\bar{x}_i$ and x_i ; $i = 1, 2, 3$ respectively. Inverse of (2.103) gives

$$x_i = x_i(\bar{x}_1, \bar{x}_2, \bar{x}_3, t) \quad ; \quad \boldsymbol{r} = \boldsymbol{r}(\bar{\boldsymbol{r}}, t) \tag{2.104}$$

2.8.1 Covariant basis

Let the vectors $\tilde{\boldsymbol{g}}_1$, $\tilde{\boldsymbol{g}}_2$ and $\tilde{\boldsymbol{g}}_3$ be tangent to the material lines $\bar{P}\tilde{A}_1$, $\bar{P}\tilde{A}_2$ and $\bar{P}\tilde{A}_3$ at material point $\bar{P}$. The vectors $\tilde{\boldsymbol{g}}_1$, $\tilde{\boldsymbol{g}}_2$ and $\tilde{\boldsymbol{g}}_3$ are covariant vectors and form a non-orthogonal basis generally called *covariant basis.* Using this basis, we can define the coordinates of point $\bar{P}$ in $\tilde{x}$-frame.

In the following, we determine the explicit form of the covariant base vectors. Since $\tilde{\boldsymbol{g}}_i$ are tangent vectors to $\tilde{x}_1$, $\tilde{x}_2$ and $\tilde{x}_3$ axes, these can be obtained by differentiating the position vector $\bar{\boldsymbol{r}}$ with respect to $\tilde{x}_i$.

$$\tilde{\boldsymbol{g}}_i = \frac{\partial \bar{\boldsymbol{r}}}{\partial \tilde{x}_i} \quad ; \quad (\text{Def. of } \; \tilde{\boldsymbol{g}}_i) \tag{2.105}$$

But $\tilde{x}_i = x_i$, therefore

$$\tilde{\boldsymbol{g}}_i = \frac{\partial(\bar{\boldsymbol{r}})}{\partial x_i} \tag{2.106}$$

$$\tilde{\boldsymbol{g}}_i = \frac{\partial(\boldsymbol{e}_j \bar{x}_j)}{\partial x_i} \tag{2.107}$$

$$\text{or} \quad \tilde{\boldsymbol{g}}_i = \boldsymbol{e}_j \frac{\partial \bar{x}_j}{\partial x_i} \tag{2.108}$$

Expanding for $i = 1, 2, 3$

$$\begin{aligned}
\tilde{\boldsymbol{g}}_1 &= \frac{\partial \bar{x}_1}{\partial x_1}\boldsymbol{e}_1 + \frac{\partial \bar{x}_2}{\partial x_1}\boldsymbol{e}_2 + \frac{\partial \bar{x}_3}{\partial x_1}\boldsymbol{e}_3 \quad ; \quad \{\tilde{g}_1\}^T = \left[\frac{\partial \bar{x}_1}{\partial x_1} \, , \, \frac{\partial \bar{x}_2}{\partial x_1} \, , \, \frac{\partial \bar{x}_3}{\partial x_1}\right] \\
\tilde{\boldsymbol{g}}_2 &= \frac{\partial \bar{x}_1}{\partial x_2}\boldsymbol{e}_1 + \frac{\partial \bar{x}_2}{\partial x_2}\boldsymbol{e}_2 + \frac{\partial \bar{x}_3}{\partial x_2}\boldsymbol{e}_3 \quad ; \quad \{\tilde{g}_2\}^T = \left[\frac{\partial \bar{x}_1}{\partial x_2} \, , \, \frac{\partial \bar{x}_2}{\partial x_2} \, , \, \frac{\partial \bar{x}_3}{\partial x_2}\right] \\
\tilde{\boldsymbol{g}}_3 &= \frac{\partial \bar{x}_1}{\partial x_3}\boldsymbol{e}_1 + \frac{\partial \bar{x}_2}{\partial x_3}\boldsymbol{e}_2 + \frac{\partial \bar{x}_3}{\partial x_3}\boldsymbol{e}_3 \quad ; \quad \{\tilde{g}_3\}^T = \left[\frac{\partial \bar{x}_1}{\partial x_3} \, , \, \frac{\partial \bar{x}_2}{\partial x_3} \, , \, \frac{\partial \bar{x}_3}{\partial x_3}\right]
\end{aligned} \tag{2.109}$$

Let us introduce a new matrix notation $[J]$ containing $\tilde{\boldsymbol{g}}_i$.

$$[J] = \left[\frac{\partial\{\bar{x}\}}{\partial\{x\}}\right] = \left[\frac{\bar{\boldsymbol{x}}}{\boldsymbol{x}}\right] = \left[\frac{\bar{x}_1, \bar{x}_2, \bar{x}_3}{x_1, x_2, x_3}\right] = \begin{bmatrix} \frac{\partial \bar{x}_1}{\partial x_1} & \frac{\partial \bar{x}_1}{\partial x_2} & \frac{\partial \bar{x}_1}{\partial x_3} \\ \frac{\partial \bar{x}_2}{\partial x_1} & \frac{\partial \bar{x}_2}{\partial x_2} & \frac{\partial \bar{x}_2}{\partial x_3} \\ \frac{\partial \bar{x}_3}{\partial x_1} & \frac{\partial \bar{x}_3}{\partial x_2} & \frac{\partial \bar{x}_3}{\partial x_3} \end{bmatrix} \tag{2.110}$$

$$\text{or} \quad \boldsymbol{J} = \boldsymbol{e}_i \boldsymbol{e}_j J_{ij} = \boldsymbol{e}_i \boldsymbol{e}_j \bar{x}_{i,j}$$

This notation is due to Murnaghan [64]. In this notation, the position of the letter above the bar (–) indicates a row and those below the bar signify a column. Thus, (2.108) or (2.109) can be written as

.3 #) ; 9 $ $. < $%. %(% # %#
'$#) !$# ($ $. < 4$%.4 %(% # %#4'$#) !$# (4".-
F/4 A0 3 4 4 ,) %# $. (# % % *$ % /)# % "$(

Thus we appear to have proved both a sentence and its negation using an obviously true axiom (scheme) and elementary propositional logic.[9]

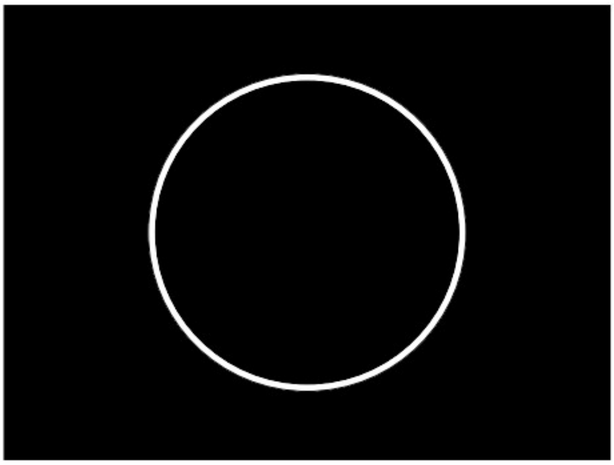
The paradoxes are no trick.[10] Listen to Tarski:

> In my judgment, it would be quite wrong and dangerous from the standpoint of scientific progress to depreciate the importance of this and other antinomies, and to treat them as jokes or sophistries. It is a fact that *we are here in the presence of an absurdity*, that we have been compelled to assert a false statement . . . *[Tarski, 1944, emphasis added]*

The paradoxes are there in the most basic places: sets; truth; raindrops. If there were no genuine paradoxes, only apparent ones, then there would still be a psychosociological project of explaining why so many people have found the paradoxes compelling. But after a while, there being a sufficient number of lucid expert witnesses should start to suggest that maybe they have all witnessed something real. Consider, then, one very gentle and elegant move. The paradoxes look unavoidable, cannot be eliminated, because they are "what they always seemed to be, proofs" [Routley, 1979, p. 302]. The conclusions of the paradoxical arguments are *true*.

0.1.2 There Are Contradictions in Plain Sight in Space

Paradoxes are not confined to abstruse contemplation of self-referring sentences or vague predicates. They have a simple visual presentation. Here is a circle:



It divides the plane in which it sits into an interior and an exterior. There is a continuous path between any two points in the exterior, and any two points in the interior. But a path from a point in the exterior will not be able to reach a point in the interior without crossing the circle, which forms the *boundary* of the two parts. It looks like the plane is divided

---

[9] See Section 1.1.2, [Priest, 2006b, ch. 1], and book-length treatment in [Beall, 2009].

[10] "There are scarcely any philosophical problems of greater urgency than the liar paradox, for there are scarcely any concepts more central to our philosophical understanding than the concept of truth. . . . Quite unmistakably, our present way of thinking about truth and reference is inconsistent" [McGee, 1990, p. vii].

exclusively and *exhaustively*: assuming continuity of the plane, every point is either in the interior or the exterior, and not both. Except – what about the points on the boundary itself?

An even simpler version of this problem is in one dimension. Given a continuous line segment,

it is obvious that the line can be perfectly divided into, or is composed of, two perfectly symmetrical halves.[11] But, as your idealized knife comes down to make the cut, it touches the *center point* of the line. There must be a point there, because the line has no gaps. But points themselves have no extension and so cannot be divided; so your knife must slip either to the left or to the right of the center point. Then the resulting two pieces are not perfectly even: one piece has the center point, and the other does not.

Dividing anything in two – e.g. the left side of a line and the not-left side, the truths and the falsities, the babies and the non-babies – calls attention to the logical assumption of bivalence: that every sentence is either true or false. The implications of this assumption have been well appreciated at the "cosmic" level. According to Gödel, paradoxes are in fact due to the (purportedly mistaken) notion of

> dividing the totality of all existing things into two categories. *[Gödel, 1964, p. 519]*

But grand talk about dividing the totality of all existing things,[12] the *universe*, distracts from the fact that we have the very same sort of problem, not at the level of the universe, but at *any* medium-sized object. We do not need special properties of connectedness or closed curves to appreciate a problem here; we just need to look at the sun in the sky (or the moon, since you shouldn't stare at the sun) and wonder how it appears to be a distinct object that is nevertheless smoothly embedded in phenomenal space.

The problem localizes in asking, which portion of reality are your hands, and which portion not? The microscopic particles of matter grazing the surface between your skin and the air are a *question*. There are few things more certain than holding up a hand, and saying "here is a hand," as Moore observed.[13] At the same time, "there are always outlying particles, questionably parts of the thing, not definitely included and not definitely not included" [Lewis, 1999, p. 165]. What looks like a special problem for the universe is a commonplace problem occurring on the end of your arm.

It *seems* like a circle can sit in the plane. It *seems* like there is a universe, in which some things are hands and everything else is not. And – here's the pointy end of the stick – it seems like these things must be able to be true without plunging us into abyssal and vexatious mysteries.

Things are not always as they seem.

---

[11] Gödel once remarked (in an unpublished note; see [Putnam, 1994]) that if a geometric line segment is divided evenly at a point, it would be natural to expect the two halves of the line to be perfectly symmetric mirror images. See Section 9.2.1.

[12] Petersen echoes Gödel's point [Petersen, 2000, p. 384]: "The point is a highly metaphysical one: is it possible, in principle, to divide the world (or the universe, if you prefer) into two disjunct parts, the union of which is the world?"

[13] "Proof of an External World" [1939] in [Moore, 1993, pp. 147–170].

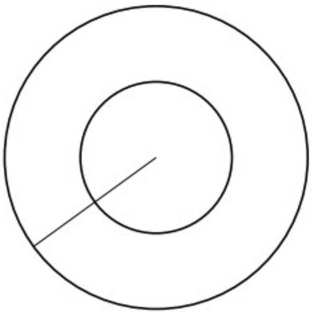
0.1.3 Paradoxes Are Resolved by Reversing the Order of Explanation

Sometimes things are as they seem. Usually, even: accepting things as they are, mostly, is a necessary assumption for getting around in the world. We trust perception, testimony, and the conclusions of informal reasoning as overwhelmingly veridical. Exceptions are exceptional, surprising, unsettling. *Exceptio probat regulam in casibus non exceptis*, my mother always said.

If the first phase of philosophy is to make what is unproblematic into a problem (Cartesian doubt!), then the next phase is to make what is problematic into what is not, to "show the fly the way out of the bottle,"[14] so to speak. There is a place for scientific surprises, but there is also a place for theories that make it possible to understand the world as we find it, theories that do not propound a long story about why everything we seem to see and think is wrong. An account of reality should be available of the reality we live in.[15] Dealing with the paradoxes, it has always seemed to me, should not require an elaborate apology for why the world is not really as it seems.

An impressive practitioner of this method is Richard Dedekind. In 1872, Dedekind famously advanced on the problem of characterizing continuity. In thinking about a geometric line, Dedekind took it as an adequacy condition that the line have no gaps. That is the linear continuum as we find it. And so he proposed, in essence, that *any gap in the line be thought of as itself a point* – indeed that the line is entirely made of "cuts," pairs of sets comprised of everything to the left and everything to the right. Any possible *counter*example is reconsidered as a natural *example*.

Or again, in a magnificent 1888 treatise, Dedekind faced a problem known since Proculus in the third century, that given two concentric circles, a radius cuts each circumference exactly once:



---

[14] [Wittgenstein, 1953, §309].

[15] "...the world as I found it" [Wittgenstein, 1922, §5.631]. This methodology is also found in Husserl and the phenomenological tradition – placing focus on the world of appearance and experience. See Tieszen, 2005, ch. 2, 3; [van Atten, 2007].

Apparently, then, there are exactly as many points on both circumferences, since the radius establishes a one-to-one pairing of the points on the inner circle and the points on the outer circle. But, even if the set of points on both circles is infinite – *obviously* the outer circle is bigger, so its circumference has more points!? Dedekind's move was to treat this anomaly as a *definition*: a set is infinite if and only if "it is similar to a proper part of itself" [Dedekind, 1901, def 64]. He didn't deny the data, or try to "solve" the problem, or fall back on quietism or eliminativism about circles. The anomaly that infinity is "bigger than itself" (captured in the simple $\infty + 1 = \infty$) is what makes infinity infinite. The puzzle is the answer. He took his task to be to describe the world as we find it – to explain, rather than explain away.

"What we see of the things are the things," writes Pessoa. "Why would seeing and hearing be to delude ourselves / when seeing and hearing are seeing and hearing?" The world I live in has days and nights and forests and cities, flocks of birds and bundles of recycling. There are words for these things, names and predicates, but not *only* words; the world has the things the words name, too. So there are sets, and there are properties, and there are boundaries, and some are vague and some are inconsistent. The *ordinary* leads us to an impasse. Dedekind shows how an impasse can be turned in to a way out.

0.2 The Choices

Given a paradox, there are only three options:[16]

- Reject the reasoning of the argument as invalid
- Show one of the premises is false
- Accept that the conclusion is true

A brief and biased review of how these options play out, say in the case of the liar (Section 0.1.1), is in order. (It would mostly carry over for the paradoxes of set theory, as per the next chapter, too.) This is well-worn ground, and I only intend a thumbnail sketch of some vast and important literature; various distinctions, objections, and replies are omitted.[17]

On some very familiar assumptions, truth is what is the case, every proposition is either true or false, and no proposition is both true and false. There must be a set of *all and only* the true propositions, divided out perfectly from the falsities. This is to be an *exclusive* and *exhaustive* division. Except, again – what about propositions on the "boundary"? This is the liar.

---

[16] Of course, not only three. You could excuse yourself and go for a walk. Or in a more philosophical vein, you could try to undercut the trilemma as somehow misconceived or based on some bad presupposition, like "the paradoxical sentences are meaningful." I will assume that the paradoxes are meaningful problems demanding a direct response; and so in that sense, these other options are not options.

[17] More details are in [Priest, 2006b, ch. 1]; see also opening chapters in [Field, 2008; Scharp, 2013], and many other sources, e.g., [Beall et al., 2018].

Inconsistent parallelisms

Fig. 14.1 The Euclidean notion of 'parallel' is likely to be inconsistent on the overlap between coordinate patches.

(a) (b)

Fig. 14.2 Parallelism on the sphere S^2. Choose p at the north pole, with tangent vector $\boldsymbol{v}$ pointing along the Greenwich meridian. Which tangent vectors, at other points of S^2, are we to regard to being 'parallel' to $\boldsymbol{v}$? (a) The direct Euclidean notion of 'parallel', from the embedding of S^2 in $\mathbb{E}^3$, does not work because (except along the meridian perpendicular to the Greenwich meridian) the parallel $\boldsymbol{v}$s do not remain tangent to S^2. (b) Remedy this, moving $\boldsymbol{v}$ parallel along a given curve γ, by continually projecting back to tangency with the sphere. (Think of γ as made up of large number of tiny segments $p_0p_1, p_1p_2, p_2p_3, \ldots,$ projecting back at each stage. Then take the limit as the segments are made smaller and smaller.) This notion of *parallel transport* is indicated for the Greenwich meridian, but also for a general curve γ.

How 'different' are the various groups $O(p, q)$, for $p + q = n$, for fixed n? (The positive-definite and Lorentzian cases are contrasted, for $n = 2$ and $n = 3$, in Fig. 13.18.) They are closely related, all having the same dimension $\frac{1}{2}n(n-1)$; they are what are called *real forms* of one and the same complex group $O(n, \mathbb{C})$, the *complexification* of $O(n)$. This complex group is defined in the same way as $O(n)$ ($= O(n, \mathbb{R})$), but where the linear transformations are allowed to be *complex*. Indeed, although I have phrased my considerations in this chapter in terms of real linear transformations, there is a parallel discussion where 'complex' replaces 'real' throughout. (Thus the coordinates x^a become complex and so do the components of our matrices.) The only essential difference, in what has been said above, arises with the concept of *signature*. There are complex linear coordinate transformations that can convert a -1 in a diagonal realization of g_{ab} into a $+1$ and *vice versa*,[13.52] so we do not now have a

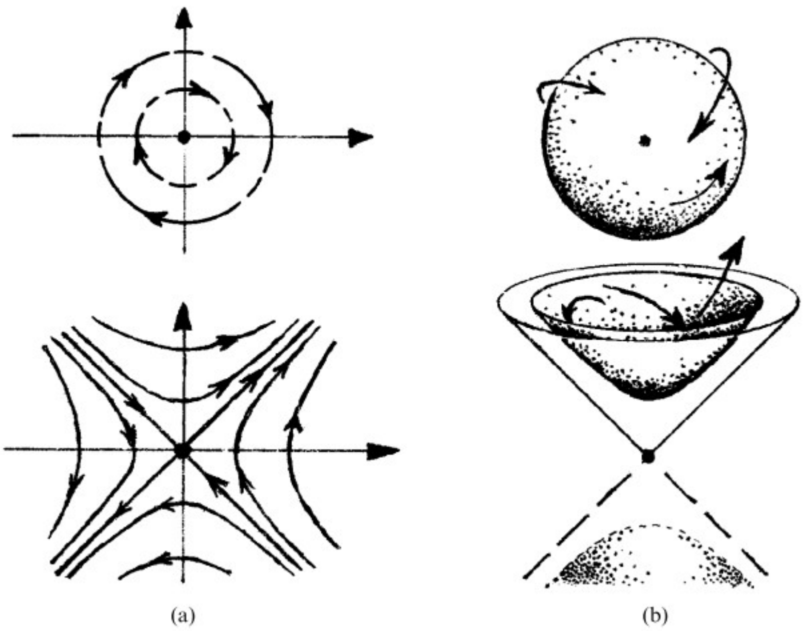

Fig. 13.18 (a) O(2,0) and O(1,1) are contrasted. (b) O(3,0) and O(1,2) are similarly contrasted, the 'unit sphere' being illustrated in each case. For O(1,2) (see §§2.4,5, §18.4), this 'sphere' is a hyperbolic plane (or two copies of such).

meaningful notion of signature. The only invariant[20] of $\boldsymbol{g}$, in the complex case, is what is called its *rank*, which is the number of non-zero terms in its diagonal realization. For a non-singular $\boldsymbol{g}$, the rank has to be maximal, i.e. n.

When is the difference between these various real forms important and when is it not? This can be a delicate question, but physicists are often rather cavalier about the distinctions, even though these can be important. The positive-definite case has the virtue that the group is compact, and much of the mathematics is easier for such situations (see §13.7). Sometimes people blithely carry over results from the compact case to the non-compact cases ($p \neq 0 \neq q$), but this is often not justified. (For example, in the compact case, one need only be concerned with representations that are finite-dimensional, but in the non-compact case additional infinite-dimensional representations arise.) On the other hand, there are other situations in which considerable insights can be obtained by ignoring the distinctions. (We may compare this with Lambert's discovery of the formula, in terms of angles, of the area of a hyperbolic triangle, given in §2.4. He obtained his formula by allowing his sphere to have an imaginary radius. This is similar to a signature change, which amounts to allowing some coordinates to have imaginary values. In §18.4, Fig. 18.9, I shall try to make the case that Lambert's approach to non-Euclidean geometry is perfectly justifiable.)

The different possible real forms of O(n, ℂ) are distinguished by certain set of *inequalities* on the matrix elements (such as det $\boldsymbol{T} > 0$). A feature of *quantum theory* is that such inequalities are often *violated* in physical processes. For example, *imaginary* quantities can, in a sense, have a physically *real* significance in quantum mechanics, so the distinction between different signatures can become blurred. On the other hand, it is my impression that physicists are often somewhat less careful about these matters than they should be. Indeed, this question will have considerable relevance for us in our examination of a number of modern theories (§28.9, §31.11, §32.3). But more of this later. This is the 'can of worms' that I hinted at in §11.2!

F/4 0 3 >4 + . (2 "$ $** * / $! 2 $%. (: $#:

First, in order to build ourselves a parallelogram, let us consider the concept of a *geodesic*, as defined by the connection ∇. Geodesics are important to us for other reasons. They are the analogues of the straight lines of Euclidean geometry. In our example of the sphere S^2, considered above (Figs. 14.2–14.4), the geodesics are great circles on the sphere. More generally, for a curved surface in Euclidean space, the curves of minimum length (as would be taken up by a string stretched taut along the surface) are geodesics. We shall be seeing later (§17.9) that geodesics have a fundamental significance for Einstein's general relativity, representing the paths in spacetime that describe freely falling bodies. How does our

La siguiente discusión presupone cierta familiaridad con las principales propiedades de los números reales. *El sistema de los números reales* fue el resultado de la búsqueda de un sistema (un conjunto abstracto con ciertas reglas) que incluyera a los racionales, pero que también proporcionara soluciones a ecuaciones polinomiales tales como $x^2 - 2 = 0$.

Históricamente, una consideración similar dio origen a la extensión de los números reales. A principios del siglo XVI, Geronimo Cardano consideró ecuaciones cuadráticas (y cúbicas) tales como $x^2 + 2x + 2 = 0$, que no son satisfechas por ningún número real x. La fórmula cuadrática $(-b \pm \sqrt{b^2 - 4ac})/2a$ da expresiones "formales" para las dos soluciones de la ecuación $ax^2 + bx + c = 0$. Pero esta fórmula puede requerir raíces cuadradas de números negativos, por ejemplo, $-1 \pm \sqrt{-1}$ para la ecuación $x^2 + 2x + 2 = 0$. Cardano notó que si estos "números complejos" son tratados como números ordinarios con la regla $\sqrt{-1} \cdot \sqrt{-1} = -1$, estos, resolvían en efecto las ecuaciones. A la importante expresión $\sqrt{-1}$ se le da ahora la ampliamente aceptada designación de $i = \sqrt{-1}$. Una convención alternativa es seguida por muchos ingenieros eléctricos, quienes prefieren el símbolo $j = \sqrt{-1}$, puesto que ellos desean reservar el símbolo i para la corriente eléctrica. Sin embargo, en el pasado se sentía que ningún significado podría realmente ser asignado a tales expresiones, que fueron entonces llamadas "imaginarias". Gradualmente, en especial como resultado del trabajo de Leonhard Euler en el siglo XVIII, estas cantidades imaginarias llegaron a desempeñar un papel importante. Por ejemplo, la fórmula de Euler $e^{i\theta} = \cos\theta + i \operatorname{sen}\theta$ reveló la existencia de una profunda relación entre los números complejos y las funciones trigonométricas. Se encontró que la regla $e^{i(\theta_1 + \theta_2)} = e^{i\theta_1} e^{i\theta_2}$ resumía las reglas para la expansión del seno y del coseno de la suma de dos ángulos de una manera sencilla, y este solo resultado indicó que algún significado debería ser atribuido a estos números "imaginarios".

Sin embargo, no fue hasta los trabajos de Casper Wessel (*circa* 1797), Jean Robert Argand (1806), Karl Friedrich Gauss (1831), Sir William R. Hamilton (1837) y otros, que se clarificó el significado de los números complejos y se comprendió que no hay nada de "imaginario" en ellos (aun cuando este término se emplea todavía.

El análisis complejo, que es el tema de este libro, fue desarrollado en el siglo XIX, principalmente por Augustin Cauchy (1789-1857). Posteriormente, su teoría se hizo más rigurosa y fue extendida por matemáticos como Peter Dirichlet (1805-1859), Karl Weierstrass (1815-1897) y Georg Friedrich Bernhard Riemann (1826-1866).

La búsqueda de un método para describir la conducción del calor influenció el desarrollo de la teoría, la cual encontró muchos usos fuera de las matemáticas. En los capítulos subsecuentes se discutirán algunas de estas aplicaciones a problemas en física e ingeniería, tales como hidrodinámica y electrostática. La teoría tiene también aplicaciones matemáticas en problemas que a primera vista no parecen involucrar números complejos. Por ejemplo, la demostración de que

$$\int_0^\infty \frac{\operatorname{sen}^2 x}{x^2}\,dx = \frac{\pi}{2}$$

o que

$$\int_0^\infty \frac{x^{\alpha-1}}{1+x}\,dx = \frac{\pi}{\operatorname{sen}(\alpha\pi)} \qquad \text{para } 0<\alpha<1$$

o que

$$\int_0^{2\pi} \frac{d\theta}{a+\operatorname{sen}\theta} = \frac{2\pi}{\sqrt{a^2-1}}$$

puede ser difícil o imposible si se usa el cálculo elemental, pero estas identidades pueden ser probadas rápidamente al usar las técnicas de variable compleja.

El análisis complejo se ha vuelto una herramienta usual e indispensable en el trabajo de matemáticos, físicos e ingenieros. El descuido de éste puede ser un serio impedimento en la mayoría de las áreas de investigación y aplicación que involucran ideas y técnicas matemáticas.

Table 4.1.1 Generalizations of surfaces.

	Added structure	Resulting features
Topological space	Open sets	Connectedness, holes
Hausdorff space	Disjoint neighborhoods	Separation between points
Metric space	Metric	Distances between points
Topological manifold	Cartesian charts	Coordinates, dimension
Differentiable manifold	Differentiable structure	Tangent vectors, calculus
Riemannian manifold	Riemannian metric	Length, angles, volumes
Euclidean surface	Embedding in $\mathbb{R}^3$	Relation to a higher space

Notes: There are many more messy details here than with algebra. These will be covered in the following chapters.

F/4 0 1 3

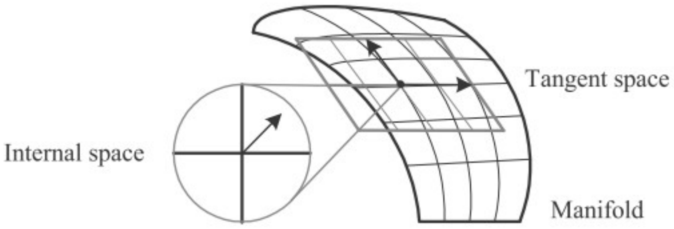

Figure 4.1.2 Generalizing tangents on a manifold.

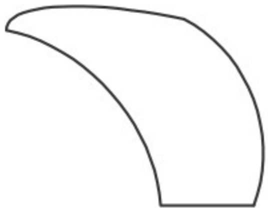
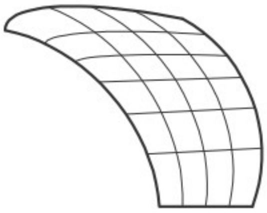
F/4 01 3

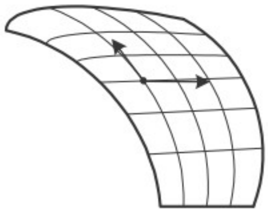
Topological space:
- Structure: Open sets
- Properties: Number of holes, connectedness
- Equivalency: Homeomorphism



Topological manifold:
- Structure: Local cartesian charts
- Properties: Coordinates, dimension
- Equivalency: Homeomorphism



Differentiable manifold:
- Structure: Differentiable structure
- Properties: Tangent vectors, calculus
- Equivalency: Diffeomorphism



Riemannian manifold:
- Structure: Metric
- Properties: Lengths, angles, areas, volumes
- Equivalency: Isometry

9.1.2 *The parallel transporter*

By definition, for a vector w at a point p of an n-dimensional manifold M, **parallel transport** assigns a vector $\|_C(w)$ at another point q that is dependent upon a specific path C in M from p to q.

To see that this dependence upon the path matches our intuition, we can consider a vector transported in what we might consider to be a "parallel" fashion along the edges of an eighth of a sphere. In this example, the sphere is embedded in $\mathbb{R}^3$ and the concept of "parallel" corresponds to incremental vectors along the path having a projection onto the original tangent plane that is parallel to the original vector.

F/4 A0> 3

Extending his idea, in 1917, Einstein postulated that if the photon had to be considered a particle,[9] it ought to have a momentum $\boldsymbol{p}$ so that its kinetic energy would be $\varepsilon = pc$. But Planck's black-body theory and the interpretation of the photoelectric effect required an $\varepsilon = h\nu$ energy for the photon associated with an electromagnetic wave with frequency $\nu = c/\lambda = ck/(2\pi)$, where k is the wave vector. It is therefore clear that some kind of relationship must exist between the photon momentum $\boldsymbol{p}$ and the electromagnetic wave vector $\boldsymbol{k}$:

$$\boldsymbol{p} = \hbar\boldsymbol{k} \tag{1.11}$$

Corollary 5.4 *For any* $t \in \mathbb{R}$, $|\exp(it)| = 1$.

Proof. We have $\exp(it) = \cos t + i \sin t$. Both $\cos t$ and $\sin t$ are real if t is, and therefore $|\exp(it)|^2 = \cos^2 t + \sin^2 t = 1$. $\square$

Remark 5.5 For real x, $\sin x$ and $\cos x$ are also real, and so the relation $\sin^2 x + \cos^2 x = 1$ shows that $|\sin x| \le 1$ and also $|\cos x| \le 1$. These inequalities do not extend to the complex case. For example, if $z = it$, with $t \in \mathbb{R}$, then $\sin z = \sin it = (\exp(-t) - \exp t)/2i$. If t is large (and positive), then $\exp t$ is large, $\exp(-t)$ is small and so $|\sin it|$ is large. A similar remark applies to $\cos z$.

5.6 The Appearance of π

We wish to discuss various properties of $\sin x$ and $\cos x$ for real x. In particular, we would like to introduce the number π.

Theorem 5.2 *If* $x \in (0, 2)$, *then* $\sin x > 0$.

Proof. Suppose that $0 < x \le 1$. Then

$$\begin{aligned} \cos x &= 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \dots \\ &> 1 - \frac{x^2}{2!} - \frac{x^4}{4!} - \frac{x^6}{6!} - \dots \\ &> 1 - \frac{1}{2} - \frac{1}{2^3} - \frac{1}{2^5} - \dots, \end{aligned}$$

since $\dfrac{x^2}{2!} \le \dfrac{1}{2}$, $\dfrac{x^4}{4!} \le \dfrac{1}{4.3.2} < \dfrac{1}{2^3}, \dots$ etc.,

$$= 1 - \frac{\frac{1}{2}}{(1 - \frac{1}{4})} = \tfrac{1}{3}.$$

Hence $\sin' x = \cos x > \frac{1}{3}$ on $[0, 1]$ and so (by the Mean Value Theorem), $\sin x$ is strictly increasing on $[0, 1]$. But $\sin 0 = 0$ and therefore $\sin x > 0$ for $0 < x \le 1$. It follows that

$$\sin x = 2 \sin \tfrac{x}{2} \cos \tfrac{x}{2} > 0$$

whenever $0 < x \le 2$, since, in this case, $\sin \frac{x}{2} > 0$ and $\cos \frac{x}{2} > \frac{1}{3}$. $\square$

Corollary 5.5 *The function* $\cos x$ *is strictly decreasing on* $[0,2]$.

Proof. We have $\cos' x = -\sin x$ which is strictly negative on $(0,2)$, by the theorem. By the Mean Value Theorem, it follows that the function $\cos x$ is strictly decreasing on $[0,2]$. □

Theorem 5.3 $\sin 4 < 0$.

Proof. From the definition of $\sin x$,

$$\begin{aligned}\sin 4 &= 4 - \frac{4^3}{3!} + \frac{4^5}{5!} - \frac{4^7}{7!} + \frac{4^9}{9!} \\ &\qquad - \frac{4^{11}}{11!}\left(1 - \frac{4^2}{12.13}\right) - \frac{4^{15}}{15!}\left(1 - \frac{4^2}{16.17}\right) \\ &\qquad\qquad - \frac{4^{19}}{19!}\left(1 - \frac{4^2}{20.21}\right) - \dots \\ &< 4 - \frac{4^3}{3!} + \frac{4^5}{5!} - \frac{4^7}{7!} + \frac{4^9}{9!} = -\tfrac{268}{405}\end{aligned}$$

and the result follows. □

Theorem 5.4 *There is a unique real number* π *satisfying* $0 < \pi < 4$ *such that* $\sin \pi = 0$. *Furthermore,* $\cos \frac{\pi}{2} = 0$, $\sin \frac{\pi}{2} = 1$ *and* $\cos \pi = -1$.

Proof. We have seen that $\sin x > 0$ for $x \in (0,2)$ and so, in particular, $\sin 1 > 0$. We have also shown that $\sin 4 < 0$. Now, the map $x \mapsto \sin x$ is continuous on $\mathbb{R}$, and so, by the Intermediate Value Theorem, there is some real number, which we will denote by π, with $1 < \pi < 4$ and such that $\sin \pi = 0$.

We must now show that π is the only value in $(0,4)$ obeying $\sin \pi = 0$. To this end, suppose that $\sin \alpha = 0$ with $0 < \alpha < 4$. Then

$$0 = \sin \alpha = 2 \sin \tfrac{\alpha}{2} \cos \tfrac{\alpha}{2}.$$

Hence either $\sin \frac{\alpha}{2} = 0$ or $\cos \frac{\alpha}{2} = 0$ (they cannot both vanish because the sum of their squares is equal to 1). But if $0 < \alpha < 4$, then $0 < \frac{\alpha}{2} < 2$ and we know that $\sin x > 0$ on $(0,2)$, so $\sin \frac{\alpha}{2}$ cannot be zero. Hence, we must have that $\cos \frac{\alpha}{2} = 0$. In particular, $\cos \frac{\pi}{2} = 0$. However, $\cos x$ is strictly decreasing on $[0,2]$ and so there can be at most one solution to $\cos x = 0$ in this interval. Hence $\frac{\alpha}{2} = \frac{\pi}{2}$ so that $\alpha = \pi$, and the uniqueness is established.

Next, $\sin^2 z + \cos^2 z = 1$ implies that $\sin^2 \frac{\pi}{2} = 1$, since $\cos \frac{\pi}{2} = 0$. Hence $\sin \frac{\pi}{2} = 1$ because $\sin \frac{\pi}{2} > 0$ (since $0 < \frac{\pi}{2} < 2$).

Finally, we have $\cos \pi = 2 \cos^2 \frac{\pi}{2} - 1 = -1$. □

What's going on? We have defined the trigonometric functions, out of the blue as it were, by means of power series. This approach avoids any appeal to geometry and right-angled triangles. However, having chosen this route, we must stick with it. In particular, it is necessary to get to π via these definitions rather than by drawing triangles or circles. As we have seen, this is all perfectly possible. Our view here is that the trigonometric functions are as we have defined them. Any results must be deduced as consequences of these power series definitions.

Remark 5.6 Numerical investigation yields $\pi = 3.14159\ldots$. It is known that π is irrational (in fact, transcendental). It is something of a sport (involving some fascinating numerical analysis) to calculate the value of π to a large number of decimal places and this has been done to over a million decimal places. Such programs have been used to test the computational integrity of supercomputers by checking to see whether they get these digits correct or not.

Theorem 5.5 *For any $z \in \mathbb{C}$ and $n \in \mathbb{Z}$,*

$$\begin{aligned}\sin(z + n\pi) &= (-1)^n \sin z\\ \cos(z + n\pi) &= (-1)^n \cos z.\end{aligned}$$

Proof. We use the trigonometric formulae;

$$\begin{aligned}\sin(z + \pi) &= \sin z \cos \pi + \cos z \sin \pi\\ &= -\sin z + 0,\end{aligned}$$

and

$$\begin{aligned}\cos(z + \pi) &= \cos z \cos \pi - \sin z \sin \pi\\ &= -\cos z - 0.\end{aligned}$$

For $n > 0$, the result now follows by induction. Substituting $z = w - n\pi$, the result then follows for $n < 0$. □

Remark 5.7 Particular cases of the above formulae deserve mention. If we set $z = 0$, then we see that $\sin(n\pi) = 0$ and $\cos(n\pi) = (-1)^n$, for any $n \in \mathbb{Z}$. The functions sin and cos are periodic (with period 2π). In particular, for any $x \in \mathbb{R}$ and any $n \in \mathbb{Z}$,

$$\begin{aligned}&\sin(x + 2n\pi) = \sin x \quad \text{and}\\ &\cos(x + 2n\pi) = \cos x.\end{aligned}$$

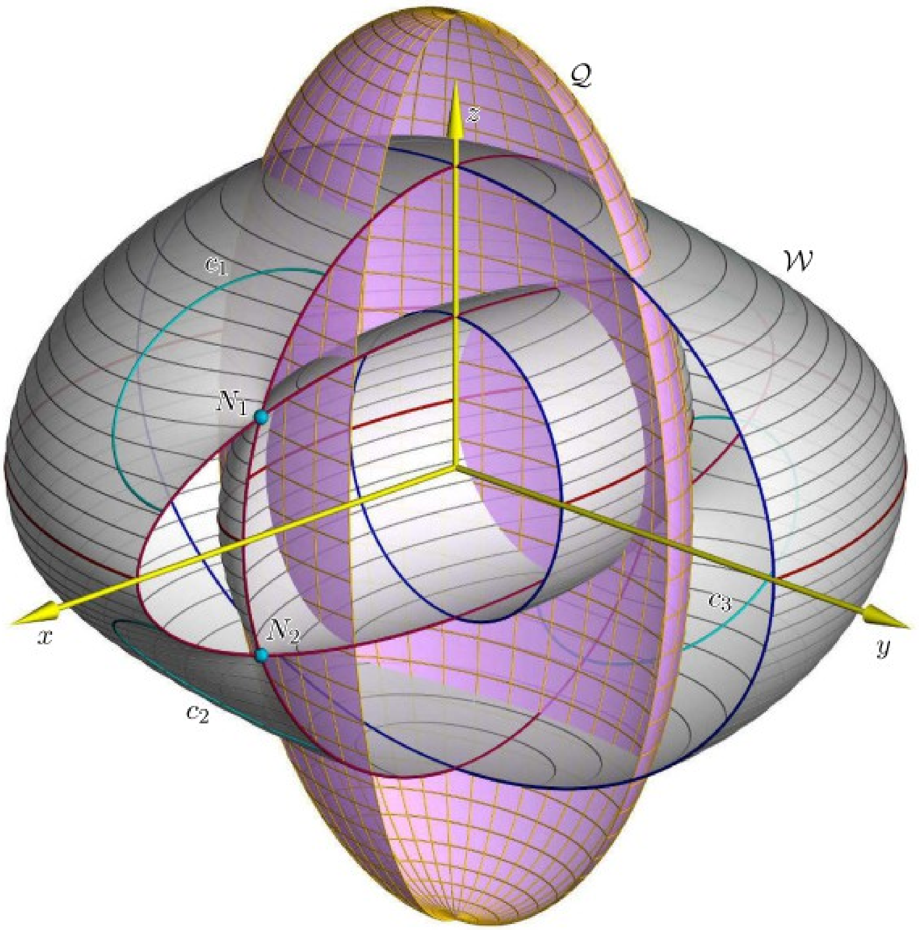

FIGURE 10.16. The quartic Fresnel wave surface $\mathcal{W}$ has four conical nodes N_1, …, N_4 corresponding to the umbilics of an ellipsoid $\mathcal{Q}$. $\mathcal{W}$ intersects its planes of symmetry along circles and ellipses (red and blue). There are four circles c_1, …, c_4 on Fresnel's surface that are the intersection of the four real double tangent planes with $\mathcal{W}$.

Painvin's complex

The tangent planes of a regular quadric $\mathcal{Q}$ form the dual quadric $\mathcal{Q}^\star$. A quadric $\mathcal{Q}$ sends two tangent planes through each line that is not tangent to $\mathcal{Q}$, and thus, a quadric is said to be of *rank* two. This notion of rank is not to be confused with the rank of a matrix, especially with the rank of the coefficient matrix of a quadric. By assumption, $\mathcal{Q}$ is regular, and

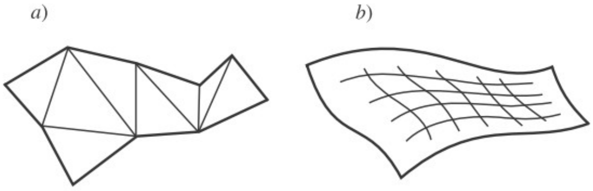

Figure 1.1. Approximate realization (*a*) of a curved surface (*b*).

trying to test spacetime geometry by physical measurements. His/her conclusions will also be valid locally for true gravitational fields, on the basis of the PE. Assume that the observer sits at the centre of the disc, and has two identical clocks: one of them is placed at the centre, the other at some point on the periphery. The observer will see that the clock on the periphery is running slower (time dilatation from SR). Consequently, clocks at various positions in the gravitational field run faster or slower, depending on the local strength of the field. There is no definition of time that is pertinent to the whole spacetime in general. The observer will also conclude that the length of a piece of line orthogonal to the radius of the disc will be shortened (length contraction from SR). Therefore, the ratio of the circumference of the circle to its radius will be smaller than 2π, so that the Euclidean geometry of space does not hold in GR.

Geometry of curved surfaces. We have seen that in spacetime, within a limited region, we can always choose a suitable reference frame, called the local inertial frame. Taking spacetime apart into locally inertial components, we can apply the laws of SR in each such component and derive various dynamical conclusions. Reconstruction of the related global dynamical picture, based on the PE (and some additional, simple geometric assumptions), gives rise to GR.

This procedure for dissecting spacetime into locally inertial components, out of which we can reconstruct, using the PE, the global structure of spacetime containing the gravitational field, can be compared geometrically with an attempt to build a curved surface, approximately, from a lot of small, plane elements 'continuously' bound to each other (figure 1.1). A locally flat surface is a geometric analogue of locally inertial spacetime.

GR makes essential use of curved spaces (or, more accurately curved spacetimes). Since the curved, four-dimensional spacetime cannot be visualized, let us try to understand the basic features of curved spaces by considering a two-dimensional surface X_2. We shall focus our attention on those geometric properties of X_2, which could be determined by an intelligent, two-dimensional being entirely confined to live and measure in the surface, a being that does not know anything about the embedding Euclidean space E_3. Such properties determine the *intrinsic geometry* on X_2.

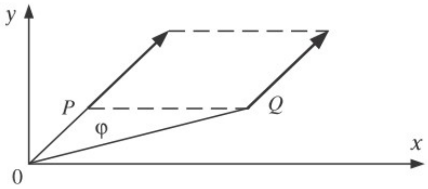

Figure 1.2. Vector components change under the parallel transport.

On a general surface we cannot set up Cartesian coordinates; the best we can do is to introduce two arbitrary families of coordinate lines and label them by $u^\alpha = (u^1, u^2)$. These curvilinear (or Gaussian) coordinates do not always have a direct geometric interpretation.

Let us now imagine a surface X_2 embedded in E_3, and consider a point P in X_2 with Cartesian coordinates (x, y, z) in E_3; since P is in X_2, these coordinates can be expressed as functions of u^α. The squared distance between two neighbouring points in X_2, $P(x, y, z)$ and $Q(x+\mathrm{d}x, y+\mathrm{d}y, z+\mathrm{d}z)$, is given by $\mathrm{d}s^2 = \mathrm{d}x^2 + \mathrm{d}y^2 + \mathrm{d}z^2$. Going over to u^α we obtain

$$\mathrm{d}s^2 = g_{\alpha\beta}\, \mathrm{d}u^\alpha\, \mathrm{d}u^\beta \tag{1.6}$$

where the set of functions $g_{\alpha\beta}(u^1, u^2)$ defines the *metric* on X_2. The metric is an essential intrinsic property of X_2, independent of its embedding in E_3. A two-dimensional continuum X_2, equipped with a squared differential distance according to (1.6), becomes the *metric space*, $G_2 = (X_2, \boldsymbol{g})$ (it is now clear that the symbol X_2 is used to denote an abstract two-dimensional continuum, disregarding all metric properties of the real surface).

Studying the motion of particles in X_2 our observer could have arrived at the idea of the tangent vector, $\boldsymbol{a} = (a^1, a^2)$. Consider, further, two tangent vectors $\boldsymbol{a}$ and $\boldsymbol{b}$, defined at neighbouring points P and Q. If we wish to compare these two vectors we have to know how one of them can be transported to the position of the other. This transport is called *parallel transport*. The continuum X_2 together with the parallel transport law, denoted by Γ, is called a *linearly connected* (or *affine*) space, $L_2 = (X_2, \Gamma)$.

The components of a vector in curvilinear coordinates are expected to change under parallel transport. This can be easily seen by considering the parallel transport of a vector in a plane, using polar coordinates (r, θ). As shown in figure 1.2, if the unit vector $\boldsymbol{a}$ at point P has components $(a^r = 1, a^\theta = 0)$, after parallel transport from P to Q its components become $(a^r = \cos\varphi, a^\theta = \sin\varphi)$.

A two-dimensional observer should determine the rule of parallel transport of vectors in accordance with his/her own experience. This rule is generally independent of the concept of a metric. If X_2 is equipped with a rule of

parallel transport and the independent concept of a metric, we obtain the *linearly connected metric* space $(X_2, \Gamma, \boldsymbol{g}) = (L_2, \boldsymbol{g}) = (G_2, \Gamma)$.

It is very probable that our two-dimensional observer will demand that the lengths of vectors should remain unchanged under parallel transport. After adopting this very natural property, which relates Γ and $\boldsymbol{g}$, the linearly connected metric space becomes the *Riemann–Cartan* space U_2. The usual surfaces have some additional geometric structure, and belong to the class of *Riemann* spaces V_2.

This discussion was slightly more general than strictly necessary for studying surfaces embedded in E_3, in order to emphasize that the intrinsic geometry on X_2 is defined in terms of

- the metric $\boldsymbol{g}$ and
- the rule of parallel transport Γ.

These basic concepts of the intrinsic geometry of surfaces can be extended directly to spaces with higher dimensions, although in this case we lose the intuitive geometric picture.

Any Riemann space is locally Euclidean, i.e. its metric is positive definite ($\mathrm{d}s^2 > 0$). A slight generalization of this case, that consists in admitting metrics that are pseudo-Euclidean, leads to a pseudo-Riemannian geometry or Riemannian geometry with an indefinite metric.

Relativity, covariance and Mach's ideas

Relativity and covariance. We have seen previously that inertial frames play a particularly important role in SR. Einstein considered this to be an expression of the incompleteness of SR. He wanted to generalize the relativity of inertial motions to the relativity of all motions, including accelerated ones. This idea can be formulated as the general principle of relativity:

> *General PR: The form of physical laws is the same in all reference frames.*

Equations expressing physical laws are often formulated using specific coordinates. Thus, for instance, spatial positions in an inertial laboratory L can be determined using Cartesian coordinates (x, y, z) or the coordinates obtained from these by a rotation around the z-axis for a fixed angle φ. If we allow the angle φ to change with time as $\varphi = \omega t$, new coordinates can be naturally attached to a new physical reference frame, rotating relative to L with the angular velocity ω around the z-axis. We see that coordinate transformations can be interpreted as describing transitions from one to another laboratory (the so-called active interpretation). Thus, it becomes clear that the general PR can be realized with the help of the principle of general covariance:

2.1.1 Projective Space and Homogeneous Coordinates

Generally, a projective space $\mathbb{P}^n$ is the set of one-dimensional vector subspaces of a given vector space $\mathbb{R}^{n+1}$. Each one-dimensional vector subspace represents a projective point $\mathbf{x}$ with the *projective* dimension 0.

Assuming $n = 1$, the projective space is the projective line $\mathbb{P}^1$ and is visualized in figure 2.1 (a) on the facing page: the projective points $\mathbf{x}_{1/2} \in \mathbb{P}^1$ can be identified with lines going through the origin of the vector space $\mathbb{R}^2$. Thus these lines are one-dimensional subspaces of $\mathbb{R}^2$. Note that no coordinate system but only the origin is defined here.

A definition of a projective point $\mathbf{x} \in \mathbb{P}^n$ may be given as follows:

Definition 2 (Projective point) *A projective point* $\mathbf{x} \in \mathbb{P}^n$ *of dimension* n *is an element of the quotient of* $\mathbb{R}^{n+1} \setminus \mathbf{0}$ *and the equivalence relation* $\cong$*:*

$$\mathbf{x} \cong \mathbf{y} \quad \Leftrightarrow \quad \exists \lambda \neq 0, \mathbf{x} = \lambda \mathbf{y} \tag{2.1}$$

In other words: all vectors $\lambda \mathbf{x}^h = (\lambda x_1, \ldots, \lambda x_n, \lambda)^\mathsf{T} \in \mathbb{R}^{n+1}$ $\lambda \neq 0$ are equivalent with respect to $\cong$ and define a projective point $\mathbf{x}$. In other words, a projective point $\mathbf{x} \in \mathbb{P}^n$ is defined by representing it with a $n+1$ vector $\mathbf{x}^h \in \mathbb{R}^{n+1}$, the so-called *homogeneous vector* representation. This representation is overdetermined: the equivalence relation states, that the lengths of the vectors $\mathbf{x}^h, \mathbf{y}^h \in \mathbb{R}^{n+1}$ do not matter, only their directions.

them within the Euclidean framework. Therefore we need a more general framework which enables us to deal with infinite points, this mathematical framework is known as *projective geometry*.

In this and the following chapters, we will see that projective geometry provides a simple and consistent way to represent and transform geometric entities, that are important for Euclidean polyhedral reconstruction. One drawback though is the fact that properties such as parallelity or orthogonality can not be directly used; more precisely, they are not invariant with respect to projective transformations. The study of invariance of properties with respect to certain groups of transformation may be regarded as a definition of geometry, as KLEIN 1939 mentioned in his Erlanger Programm. We will come back to the issue of invariance in section 3.3 on page 70, where we investigate possible relations between geometric entities and their invariance properties with respect to Euclidean, similar, affine and projective geometry. We will see that for our application it is possible to infer parallelity and orthogonality of lines and planes from homogeneous vectors by using the Euclidean interpretation thereof.

For a detailed and more precise introduction to projective geometry in the context of Computer Vision, see FAUGERAS AND LUONG 2001 or chapter 23 in MUNDY 1992.

2.1.1 Projective Space and Homogeneous Coordinates

Generally, a projective space $\mathbb{P}^n$ is the set of one-dimensional vector subspaces of a given vector space $\mathbb{R}^{n+1}$. Each one-dimensional vector subspace represents a projective point $\mathbf{x}$ with the *projective* dimension 0.

Assuming $n = 1$, the projective space is the projective line $\mathbb{P}^1$ and is visualized in figure 2.1 (a) on the facing page: the projective points $\mathbf{x}_{1/2} \in \mathbb{P}^1$ can be identified with lines going through the origin of the vector space $\mathbb{R}^2$. Thus these lines are one-dimensional subspaces of $\mathbb{R}^2$. Note that no coordinate system but only the origin is defined here.

A definition of a projective point $\mathbf{x} \in \mathbb{P}^n$ may be given as follows:

Definition 2 (Projective point) *A projective point* $\mathbf{x} \in \mathbb{P}^n$ *of dimension* n *is an element of the quotient of* $\mathbb{R}^{n+1} \setminus \mathbf{0}$ *and the equivalence relation* $\cong$*:*

$$\mathbf{x} \cong \mathbf{y} \quad \Leftrightarrow \quad \exists \lambda \neq 0, \mathbf{x} = \lambda \mathbf{y} \tag{2.1}$$

In other words: all vectors $\lambda \mathbf{x}^h = (\lambda x_1, \ldots, \lambda x_n, \lambda)^\mathsf{T} \in \mathbb{R}^{n+1}$ $\lambda \neq 0$ are equivalent with respect to $\cong$ and define a projective point $\mathbf{x}$. In other words, a projective point $\mathbf{x} \in \mathbb{P}^n$ is defined by representing it with a $n+1$ vector $\mathbf{x}^h \in \mathbb{R}^{n+1}$, the so-called *homogeneous vector* representation. This representation is overdetermined: the equivalence relation states, that the lengths of the vectors $\mathbf{x}^h, \mathbf{y}^h \in \mathbb{R}^{n+1}$ do not matter, only their directions.

Fig. 2.1. Different interpretations of the projective line $\mathbb{P}^1$: in (a), projective points $\mathbf{x}_1, \mathbf{x}_2$ are interpreted as lines going through the origin without defining any coordinate system. In (b), the projective points are homogeneous vectors, that are normalized to the sphere S^2. In (c) the homogeneous vectors intersect the Euclidean axis and define the points $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$ on the Euclidean axis. The role of a hyperplane $\mathbf{l}$ can be visualized by considering the projective plane $\mathbb{P}^2$ in (d): two projective points $\mathbf{x}_1$ and $\mathbf{x}_2$ define two points $\boldsymbol{x}_1, \boldsymbol{x}_2$ on the Euclidean plane $\mathbb{R}^2$. The first point $\boldsymbol{x}_1$ is incident to a line $\boldsymbol{l}$ on the Euclidean plane. The line $\boldsymbol{l}$ in turn is defined by the homogeneous vector $\mathbf{l} \in \mathbb{R}^3 \simeq \mathbb{P}^2$, which is the normal of the plane that contains the origin of $\mathbb{R}^3$ and the line on the Euclidean plane $\mathbb{R}^2$. As the first Euclidean point $\boldsymbol{x}_1$ is incident to the Euclidean line, the homogeneous vector $\mathbf{l}$ is orthogonal to the homogeneous vector $\mathbf{x}_1$, or $\mathbf{l}^{\mathsf{T}}\mathbf{x}_1 = 0$.

To simplify the notation, we identify projective points $\mathbf{x} \in \mathbb{P}^n$ with their (non-unique) coordinate vector representation based on $\mathbf{x}^h \in \mathbb{R}^{n+1}$, i.e. $\mathbf{x} = \mathbf{x}^h$. Therefore we are not strict with respect to mathematical notation and do *not* distinguish between projective points and its coordinate vectors as in FAUGERAS AND LUONG 2001, p. 78. HARTLEY AND ZISSERMAN 2000 take a similar approach, see p. 3f. In the following, we assume that the correct interpretation is clear from the context.

One can *normalize* a homogeneous vector $\mathbf{x}_s := \frac{\mathbf{x}}{|\mathbf{x}|}$ to avoid ambiguities, see fig.2.1(b). The index s in the homogeneous vector $\mathbf{x}_s$ indicates that the vector is normalized and thus lies on the unit sphere. We could use the normalization of a homogeneous vector with its length for an alternative

definition of the equivalence class $\cong$ for two homogeneous vectors $\mathbf{x}, \mathbf{y} \in \mathbb{R}^{n+1} \setminus \mathbf{0}$:

$$\mathbf{x} \cong \mathbf{y} \quad \Leftrightarrow \quad \left(\frac{\mathbf{x}}{|\mathbf{x}|} = \frac{\mathbf{y}}{|\mathbf{y}|} \text{ or } \frac{\mathbf{x}}{|\mathbf{x}|} = -\frac{\mathbf{y}}{|\mathbf{y}|}\right) \quad \Leftrightarrow \quad \frac{\mathbf{x}}{|\mathbf{x}|} = \pm\frac{\mathbf{y}}{|\mathbf{y}|} \tag{2.2}$$

We sometimes denote the spherical normalization by $\mathsf{N}_s(\mathbf{x}) = \frac{\mathbf{x}}{|\mathbf{x}|}$.

The definition of the equivalence class $\cong$ is ambiguous as the orientation of the normalized vectors can be positive or negative. In other words, a projective point from $\mathbb{P}^n$ has two representations on a sphere S^{n+1}. To overcome this ambiguity one may use *oriented* projective geometry, as proposed by STOLFI 1991, where every element has an intrinsic orientation. This is analytically expressed by the specialized definition, that homogeneous vectors are identical if they differ by a *positive* scale factor. But the ambiguity is not critical for our application, so we will keep the definition in equation (2.2).

The link between an original Euclidean space $\mathbb{R}^n$ and the projective space $\mathbb{P}^n$ is now quite easy: a simple mapping $\mathbb{R}^n \to \mathbb{P}^n$ of the Euclidean space to the projective space can be written as follows:

$$\boldsymbol{x} = (x_1, \ldots, x_n)^\mathsf{T} \in \mathbb{R}^n \to \mathbf{x}_e = (x_1, \ldots, x_n, 1)^\mathsf{T} \in \mathbb{P}^n \tag{2.3}$$

We will denote vectors from $\mathbb{R}^n$ with italic bold letters such as $\boldsymbol{x}, \boldsymbol{y}$, whereas homogeneous vectors from $\mathbb{P}^n \simeq \mathbb{R}^{(n+1)}$ are denoted with upright bold letters, $\mathbf{x}, \mathbf{y}$.

The index e in the homogeneous vector $\mathbf{x}_e$ denotes that we can directly extract the Euclidean information from the homogeneous vector. It is a unique member of the equivalence class defined by $\mathbf{x} \cong \mathbf{x}_e$. In figure 2.1(c) one may interpret the fixing of the last coordinate of the homogeneous vector to 1 as follows: take the line parallel to the first axis, intersecting the second axis in 1. This line represents the real axis $\mathbb{R}^1$, on which the Euclidean numbers $\boldsymbol{x}_{1/2}$ are fixed. Connecting the origin with $\boldsymbol{x}_{1/2}$ on the constructed line yield the projective points.

For the inverse direction of (2.3), any projective point $\mathbf{x} \in \mathbb{P}^n$ (except of ideal points) can be mapped to an euclidized version, see also figure 2.2:

$$\mathbf{x} = (x_1, \ldots, x_n, x_{n+1})^\mathsf{T} \in \mathbb{P}^n \to \mathbf{x}_e = 1/x_{n+1}\,(x_1, \ldots, x_n, 1)^\mathsf{T} \in \mathbb{P}^n \tag{2.4}$$

For lower dimensions, we will replace the coordinates x_1, x_2, x_3 with the letters u, v, w to avoid overloaded use of indices.

Linear Transformations of Projective Points A linear transformation H from $\mathbb{P}^n$ to $\mathbb{P}^m$ can be represented as a $(m+1) \times (n+1)$, such that for $\mathbf{x} \in \mathbb{P}^n$ and $\mathbf{x}' \in \mathbb{P}^m$:

$$\mathbf{x}' = \mathsf{H}\mathbf{x} \tag{2.5}$$

If $n = m$ and the matrix H is regular, we call H a *homography.*

Properties that remain invariant under a transformation H are called projectively invariant. Examples for such properties are collinearity and incidence.

Fig. 2.2. Transfer between Euclidean and Homogeneous Coordinates: giving a Euclidean point $\boldsymbol{x} \in \mathbb{R}^n$ we can derive a projective point $\mathbf{x} \in \mathbb{P}^n$ which we represent as a homogeneous vector $\mathbf{x} \in \mathbb{R}^{n+1}$, see also equation (2.3). Given a homogeneous vector $\mathbf{x} \in \mathbb{R}^{n+1}$, we may obtain a Euclidean representation by normalization, yielding $\boldsymbol{x} \in \mathbb{R}^m$, equation (2.4). In general, the normalization is done by dividing the homogeneous vector by its homogeneous part as described in section 2.2. Note that we use the symbol **x** both for a projective point and for homogeneous vectors representing the projective points.

2.1.2 Hyperplanes

A point in projective space can be regarded as the smallest linear subspace that is non-zero. Opposed to a point, a *hyperplane* is the largest linear subspace that is not equal to the complete space. Examples for hyperplanes are lines in 2D and planes in 3D.

In general, a hyperplane $\mathbf{h}$ in $\mathbb{P}^n$ is defined by n linearly independent points $\mathbf{y}_1, \cdots, \mathbf{y}_n$: for example in $\mathbb{P}^2$, two points $\mathbf{y}_1, \mathbf{y}_2$ define a line and in $\mathbb{P}^3$ three points $\mathbf{Y}_1, \mathbf{Y}_2, \mathbf{Y}_3$ define a plane. Any additional point $\mathbf{x}$ is incident to the a hyperplane $\mathbf{h}(\mathbf{y}_1, \cdots, \mathbf{y}_n)$ if the determinant of all concatenated homogeneous vectors is zero

$$|\mathbf{y}_1\, \mathbf{y}_2\, \cdots \mathbf{y}_n\, \mathbf{x}| = 0 \tag{2.6}$$

This is a generalization of the well-known case when checking whether three 2D points are collinear BRONSTEIN *et al.* 1996:

$$\boldsymbol{y}_1, \boldsymbol{y}_2 \text{ and } \boldsymbol{x} \text{ are collinear} \quad \Leftrightarrow \quad \begin{vmatrix} \boldsymbol{y}_1 & \boldsymbol{y}_2 & \boldsymbol{x} \\ 1 & 1 & 1 \end{vmatrix} = 0 \tag{2.7}$$

which can be generalized to the to the 3D case when checking whether four points are coplanar:

$$\boldsymbol{Y}_1, \boldsymbol{Y}_2, \boldsymbol{Y}_3 \text{ and } \boldsymbol{X} \text{ are coplanar} \quad \Leftrightarrow \quad \begin{vmatrix} \boldsymbol{Y}_1 & \boldsymbol{Y}_2 & \boldsymbol{Y}_3 & \boldsymbol{X} \\ 1 & 1 & 1 & 1 \end{vmatrix} = 0 \tag{2.8}$$

(2.9)

An alternative definition of a hyperplane can be obtained by using the Laplacian expansion on the determinant in equation (2.6): if we expand by the last column, we obtain $n-1$ minors $|\mathsf{M}_{i,n}|$ that depend on the vectors $\mathbf{y}_1, \cdots \mathbf{y}_n$. With $h_i = (-1)^{i+n}|\mathsf{M}_{i,n}|$, equation (2.6) is equivalent to

$$\sum_i h_i x_i = \mathbf{h}^\mathsf{T}\mathbf{x} = \mathbf{x}^\mathsf{T}\mathbf{h} = 0 \tag{2.10}$$

Both (2.6) and its equivalent equation (2.10) is a necessary and sufficient condition to check whether a point $\mathbf{x}$ is incident to a hyperplane, $\mathbf{x} \in \mathbf{h}$.

Since the minors h_i with $i = 1, \cdots, n$ uniquely define a hyperplane, we can identify them with the coordinates of a hyperplane, defining the vector $\mathbf{h} = (h_1, \cdots, h_n)^\mathsf{T}$. The coordinates h_i are called Plücker coordinates, see also section 2.2.4. The vector $\mathbf{h}$ is a homogeneous vector as (2.10) is a homogeneous equation. As for projective points, it is assumed that it is clear from the context whether a homogeneous vector is interpreted as a projective point or a hyperplane: in the following lines in 2D are usually denoted by $\mathbf{l}$, $\mathbf{m}$ and planes in 3D are denoted by $\mathbf{A}, \mathbf{B}$ opposed to points denoted by $\mathbf{x}$, $\mathbf{y}$ resp. $\mathbf{X}, \mathbf{Y}$.

It is important to note that $\mathbf{h}$ is actually a linear form of $\mathbb{R}^{n+1}$, since each coordinate is a function of the form $\mathbb{R}^{n+1} \to \mathbb{R}$. Thus the vector $\mathbf{h}$ represents an element of the dual space $(\mathbb{R}^{n+1})^*$ or equivalently $(\mathbb{P}^n)^*$.

Given a linear transformation $\mathbf{x}' = \mathsf{H}\mathbf{x}$ for projective points as in (2.5), one may be interested in the corresponding transformation for hyperplanes. H is a linear mapping from $\mathbb{P}^n$ to $\mathbb{P}^m$, its transpose H^T is defined as the mapping from $(\mathbb{P}^m)^*$ to $(\mathbb{P}^n)^*$. With $\mathbf{h}' \in (\mathbb{P}^m)^*$ being the imaged hyperplane of $\mathbf{h} \in (\mathbb{P}^n)^*$ with respect to H, one obtains

$$\mathsf{H}^\mathsf{T}\mathbf{h}' = \mathbf{h} \tag{2.11}$$

If H is a homography, thus $n = m$ and H being regular, one can prove (2.11) as follows: given $\mathbf{x}' = \mathsf{H}\mathbf{x}$, we are looking for the corresponding transformation $\mathbf{h}' = \mathsf{J}\mathbf{h}$, such that for all $\mathbf{y} \in \mathbf{h}$ and $\mathbf{y}' \in \mathbf{h}'$: $\mathbf{y}' = \mathsf{H}\mathbf{y}$. Thus the following equation must hold

$$\mathbf{y}'^\mathsf{T}\mathbf{h}' = \mathbf{x}'^\mathsf{T}\mathsf{J}\mathbf{h} = \mathsf{x}^\mathsf{T}\mathsf{H}^\mathsf{T}\mathsf{J}\mathbf{h} = 0$$

This can be true only if $\mathsf{J} = \mathsf{H}^{-\mathsf{T}}$.

2.2 Representation of Geometric Entities

This section introduces the basic geometric entities, that will be used throughout the rest of this text. As we want to reconstruct polyhedral objects, it is sufficient to deal with geometric entities that can be modeled as linear subspaces, cf. section 1.3.2 on page 6. Therefore only points, lines and planes

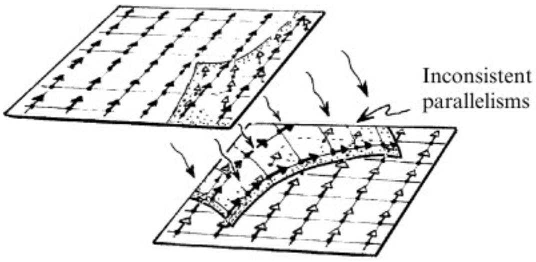
Recall from §10.3 and §12.3 that in the case of a *scalar* field Φ on a general smooth n-manifold $\mathcal{M}$, we were indeed able to provide an appropriate measure of its 'rate of change', namely the 1-form $\mathrm{d}\Phi$, where $\mathrm{d}\Phi = 0$ is the condition that Φ be constant (throughout connected regions of $\mathcal{M}$). However, this idea will not work for a general tensor quantity. It will not even work for a vector field $\boldsymbol{\xi}$. Why is this? One trouble is that in a general manifold we have no appropriate notion of $\boldsymbol{\xi}$ being constant (as we shall see in a moment), whereas any self-respecting differentiation ('gradient') operation that applies to $\boldsymbol{\xi}$ ought to have the property that its vanishing signals the constancy of $\boldsymbol{\xi}$ (as, indeed, $\mathrm{d}\Phi = 0$ signals the constancy of a scalar field Φ). More generally, we would expect that for a 'non-constant' $\boldsymbol{\xi}$, such a derivative operation ought to be measuring $\boldsymbol{\xi}$'s deviation from constancy.

Why is there a problem with this notion of vector 'constancy', on a general n-manifold $\mathcal{M}$? A constant vector field $\boldsymbol{\xi}$, in ordinary Euclidean space, should have the property that all the 'arrows' of its geometrical description are parallel to each other. Thus, some kind of notion of 'parallelism' would have to be part of $\mathcal{M}$'s structure. One might worry about this, bearing in mind the issue of Euclid's fifth postulate—the parallel postulate—that was central to the discussion of Chapter 2. Hyperbolic geometry, for example, does not admit vector fields that could unambiguously considered to be everywhere 'parallel'. In any case, a notion of 'parallelism' is not something that $\mathcal{M}$ would possess merely by virtue of its being a smooth manifold. In Fig. 14.1, the difficulty is illustrated in the case of a 2-manifold pieced together from two patches of Euclidean plane. The normal Euclidean notion of 'parallel' is not consistent from one patch to the next.

In order to gain some insights as to what kind of notion of parallelism is appropriate, it will be helpful for us first to examine the intrinsic geometry of an ordinary 2-dimensional sphere S^2. Let us choose a particular point p on S^2 (say, at the north pole, for definiteness) and a particular tangent vector $\boldsymbol{v}$



G ''' 9' 3% & ## # 2 U1 O > + ? ## # # % 1
? @ # # 1 % '

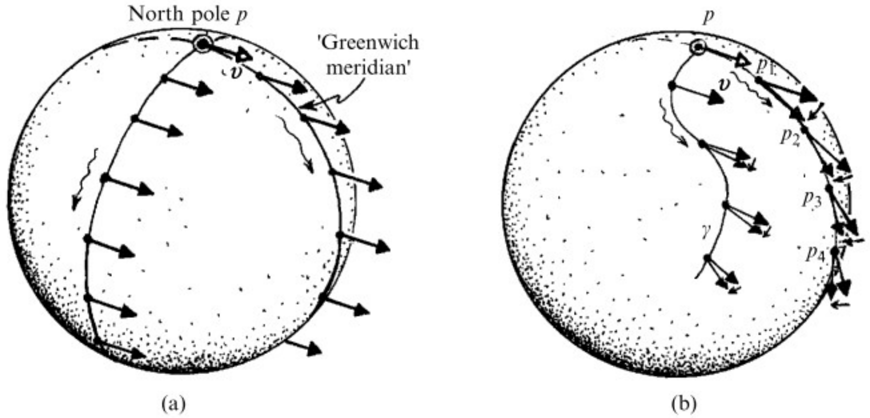


Fig. 14.2 Parallelism on the sphere S^2. Choose p at the north pole, with tangent vector $\boldsymbol{v}$ pointing along the Greenwich meridian. Which tangent vectors, at other points of S^2, are we to regard to being 'parallel' to $\boldsymbol{v}$? (a) The direct Euclidean notion of 'parallel', from the embedding of S^2 in $\mathbb{E}^3$, does not work because (except along the meridian perpendicular to the Greenwich meridian) the parallel $\boldsymbol{v}$s do not remain tangent to S^2. (b) Remedy this, moving $\boldsymbol{v}$ parallel along a given curve γ, by continually projecting back to tangency with the sphere. (Think of γ as made up of large number of tiny segments $p_0p_1, p_1p_2, p_2p_3, \ldots,$ projecting back at each stage. Then take the limit as the segments are made smaller and smaller.) This notion of *parallel transport* is indicated for the Greenwich meridian, but also for a general curve γ.

8M"' ./ - ;

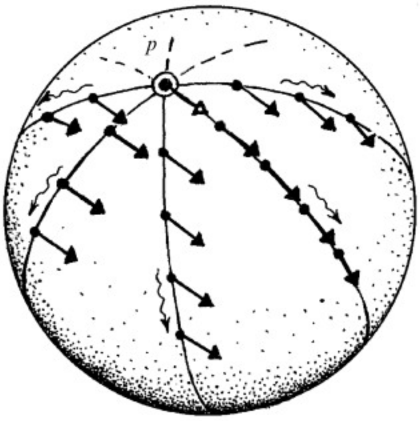

Fig. 14.3 Parallel transport of $\boldsymbol{v}$ along five different paths (all great circles).

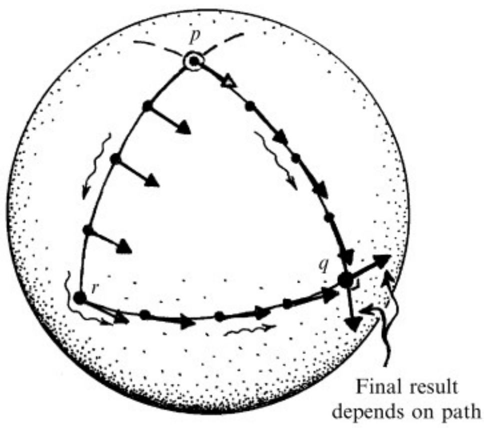

Fig. 14.4 Path dependence of parallel transport. This is illustrated using two distinct paths from p to q, one of which is a direct great-circle route, the other consisting of a pair of great-circle arcs jointed at an intermediate point r. Parallel transport along these two paths gives results at q differing by a right-angle rotation.

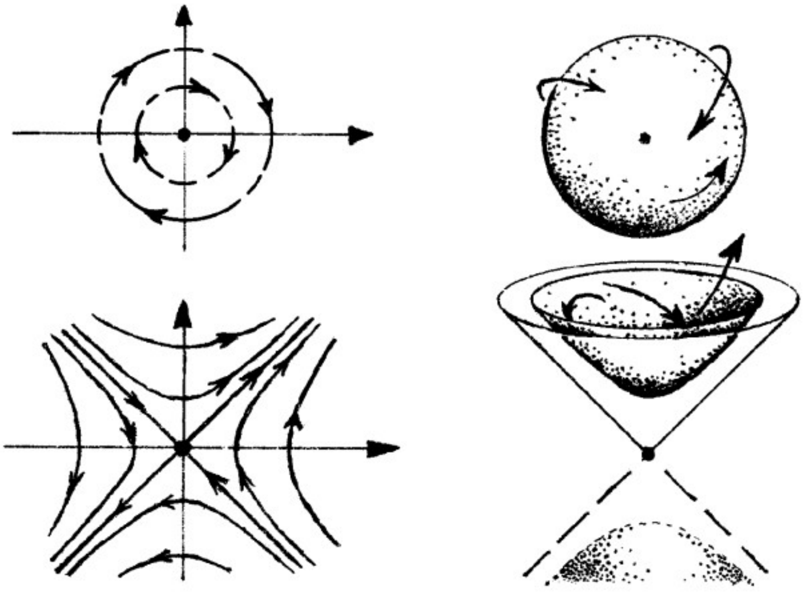
>
8M"' /.- <

How 'different' are the various groups $\mathrm{O}(p, q)$, for $p+q=n$, for fixed n? (The positive-definite and Lorentzian cases are contrasted, for $n=2$ and $n=3$, in Fig. 13.18.) They are closely related, all having the same dimension $\frac{1}{2}n(n-1)$; they are what are called *real forms* of one and the same complex group $\mathrm{O}(n, \mathbb{C})$, the *complexification* of $\mathrm{O}(n)$. This complex group is defined in the same way as $\mathrm{O}(n)$ $(=\mathrm{O}(n, \mathbb{R}))$, but where the linear transformations are allowed to be *complex*. Indeed, although I have phrased my considerations in this chapter in terms of real linear transformations, there is a parallel discussion where 'complex' replaces 'real' throughout. (Thus the coordinates x^a become complex and so do the components of our matrices.) The only essential difference, in what has been said above, arises with the concept of *signature*. There are complex linear coordinate transformations that can convert a -1 in a diagonal realization of g_{ab} into a $+1$ and *vice versa*,[13.52] so we do not now have a



(a) (b)

meaningful notion of signature. The only invariant[20] of ***g***, in the complex case, is what is called its *rank*, which is the number of non-zero terms in its diagonal realization. For a non-singular ***g***, the rank has to be maximal, i.e. n.

When is the difference between these various real forms important and when is it not? This can be a delicate question, but physicists are often rather cavalier about the distinctions, even though these can be important. The positive-definite case has the virtue that the group is compact, and much of the mathematics is easier for such situations (see §13.7). Sometimes people blithely carry over results from the compact case to the non-compact cases ($p \neq 0 \neq q$), but this is often not justified. (For example, in the compact case, one need only be concerned with representations that are finite-dimensional, but in the non-compact case additional infinite-dimensional representations arise.) On the other hand, there are other situations in which considerable insights can be obtained by ignoring the distinctions. (We may compare this with Lambert's discovery of the formula, in terms of angles, of the area of a hyperbolic triangle, given in §2.4. He obtained his formula by allowing his sphere to have an imaginary radius. This is similar to a signature change, which amounts to allowing some coordinates to have imaginary values. In §18.4, Fig. 18.9, I shall try meaningful notion of signature. The only invariant[20] of $\boldsymbol{g}$, in the complex case, is what is called its *rank*, which is the number of non-zero terms in its diagonal realization. For a non-singular $\boldsymbol{g}$, the rank has to be maximal, i.e. n.

8M"'   -   9' (: 1   "   : #

First, in order to build ourselves a parallelogram, let us consider the concept of a *geodesic*, as defined by the connection $\boldsymbol{\nabla}$. Geodesics are important to us for other reasons. They are the analogues of the straight lines of Euclidean geometry. In our example of the sphere S^2, considered above (Figs. 14.2–14.4), the geodesics are great circles on the sphere. More generally, for a curved surface in Euclidean space, the curves of minimum length (as would be taken up by a string stretched taut along the surface) are geodesics. We shall be seeing later (§17.9) that geodesics have a fundamental significance for Einstein's general relativity, representing the paths in spacetime that describe freely falling bodies. How does our

This equation actually provides the idea of Cauchy's method of characteristics for wave equations that will be discussed in a later chapter. Solving these first order ODEs in (6.67), which are called characteristics equations, gives the following characteristic lines:

$$u_1(x,y,z)=c_1 \tag{6.68}$$

$$u_2(x,y,z)=c_2 \tag{6.69}$$

Equations (6.68) and (6.69) are the characteristics of the solution of the PDE. Physically, if the PDE reflects the wave phenomenon, these characteristics lines are

La siguiente discusión presupone cierta familiaridad con las principales propiedades de los números reales. *El sistema de los números reales* fue el resultado de la búsqueda de un sistema (un conjunto abstracto con ciertas reglas) que incluyera a los racionales, pero que también proporcionara soluciones a ecuaciones polinomiales tales como $x^2 - 2 = 0$.

Históricamente, una consideración similar dio origen a la extensión de los números reales. A principios del siglo XVI, Geronimo Cardano consideró ecuaciones cuadráticas (y cúbicas) tales como $x^2 + 2x + 2 = 0$, que no son satisfechas por ningún número real x. La fórmula cuadrática $(-b \pm \sqrt{b^2 - 4ac})/2a$ da expresiones "formales" para las dos soluciones de la ecuación $ax^2 + bx + c = 0$. Pero esta fórmula puede requerir raíces cuadradas de números negativos, por ejemplo, $-1 \pm \sqrt{-1}$ para la ecuación $x^2 + 2x + 2 = 0$. Cardano notó que si estos "números complejos" son tratados como números ordinarios con la regla $\sqrt{-1} \cdot \sqrt{-1} = -1$, estos, resolvían en efecto las ecuaciones. A la importante expresión $\sqrt{-1}$ se le da ahora la ampliamente aceptada designación de $i = \sqrt{-1}$. Una convención alternativa es seguida por muchos ingenieros eléctricos, quienes prefieren el símbolo $j = \sqrt{-1}$, puesto que ellos desean reservar el símbolo i para la corriente eléctrica. Sin embargo, en el pasado se sentía que ningún significado podría realmente ser asignado a tales expresiones, que fueron entonces llamadas "imaginarias". Gradualmente, en especial como resultado del trabajo de Leonhard Euler en el siglo XVIII, estas cantidades imaginarias llegaron a desempeñar un papel importante. Por ejemplo, la fórmula de Euler $e^{i\theta} = \cos \theta + i \operatorname{sen} \theta$ reveló la existencia de una profunda relación entre los números complejos y las funciones trigonométricas. Se encontró que la regla $e^{i(\theta_1 + \theta_2)} = e^{i\theta_1} e^{i\theta_2}$ resumía las reglas para la expansión del seno y del coseno de la suma de dos ángulos de una manera sencilla, y este solo resultado indicó que algún significado debería ser atribuido a estos números "imaginarios".

Sin embargo, no fue hasta los trabajos de Casper Wessel (*circa* 1797), Jean Robert Argand (1806), Karl Friedrich Gauss (1831), Sir William R. Hamilton (1837) y otros, que se clarificó el significado de los números complejos y se comprendió que no hay nada de "imaginario" en ellos (aun cuando este término se emplea todavía.

El análisis complejo, que es el tema de este libro, fue desarrollado en el siglo XIX, principalmente por Augustin Cauchy (1789-1857). Posteriormente, su teoría se hizo más rigurosa y fue extendida por matemáticos como Peter Dirichlet (1805-1859), Karl Weierstrass (1815-1897) y Georg Friedrich Bernhard Riemann (1826-1866).

La búsqueda de un método para describir la conducción del calor influenció el desarrollo de la teoría, la cual encontró muchos usos fuera de las matemáticas. En los capítulos subsecuentes se discutirán algunas de estas aplicaciones a problemas en física e ingeniería, tales como hidrodinámica y electrostática. La teoría tiene también aplicaciones matemáticas en problemas que a primera vista no parecen involucrar números complejos. Por ejemplo, la demostración de que

$$\int_0^\infty \frac{\operatorname{sen}^2 x}{x^2}\,dx = \frac{\pi}{2}$$

o que

$$\int_0^\infty \frac{x^{\alpha-1}}{1+x}\,dx = \frac{\pi}{\operatorname{sen}(\alpha\pi)} \qquad \text{para } 0 < \alpha < 1$$

o que

$$\int_0^{2\pi} \frac{d\theta}{a + \operatorname{sen}\theta} = \frac{2\pi}{\sqrt{a^2 - 1}}$$

9.1.2 *The parallel transporter*

By definition, for a vector w at a point p of an n-dimensional manifold M, **parallel transport** assigns a vector $\|_C(w)$ at another point q that is dependent upon a specific path C in M from p to q.

To see that this dependence upon the path matches our intuition, we can consider a vector transported in what we might consider to be a "parallel" fashion along the edges of an eighth of a sphere. In this example, the sphere is embedded in $\mathbb{R}^3$ and the concept of "parallel" corresponds to incremental vectors along the path having a projection onto the original tangent plane that is parallel to the original vector.

8M"' ; - <

Extending his idea, in 1917, Einstein postulated that if the photon had to be considered a particle,[9] it ought to have a momentum $\boldsymbol{p}$ so that its kinetic energy would be $\varepsilon = pc$. But Planck's black-body theory and the interpretation of the photoelectric effect required an $\varepsilon = h\nu$ energy for the photon associated with an electromagnetic wave with frequency $\nu = c/\lambda = ck/(2\pi)$, where k is the wave vector. It is therefore clear that some kind of relationship must exist between the photon momentum $\boldsymbol{p}$ and the electromagnetic wave vector $\boldsymbol{k}$:

$$\boldsymbol{p} = \hbar \boldsymbol{k} \tag{1.11}$$

Corollary 5.4 *For any $t \in \mathbb{R}$, $|\exp(it)| = 1$.*

Proof. We have $\exp(it) = \cos t + i \sin t$. Both $\cos t$ and $\sin t$ are real if t is, and therefore $|\exp(it)|^2 = \cos^2 t + \sin^2 t = 1$. □

Remark 5.5 For real x, $\sin x$ and $\cos x$ are also real, and so the relation $\sin^2 x + \cos^2 x = 1$ shows that $|\sin x| \le 1$ and also $|\cos x| \le 1$. These inequalities do not extend to the complex case. For example, if $z = it$, with $t \in \mathbb{R}$, then $\sin z = \sin it = (\exp(-t) - \exp t)/2i$. If t is large (and positive), then $\exp t$ is large, $\exp(-t)$ is small and so $|\sin it|$ is large. A similar remark applies to $\cos z$.

5.6 The Appearance of π

We wish to discuss various properties of $\sin x$ and $\cos x$ for real x. In particular, we would like to introduce the number π.

Theorem 5.2 *If $x \in (0, 2)$, then $\sin x > 0$.*

Proof. Suppose that $0 < x \le 1$. Then

$$\begin{aligned}\cos x &= 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \dots \\ &> 1 - \frac{x^2}{2!} - \frac{x^4}{4!} - \frac{x^6}{6!} - \dots \\ &> 1 - \frac{1}{2} - \frac{1}{2^3} - \frac{1}{2^5} - \dots,\end{aligned}$$

since $\dfrac{x^2}{2!} \le \dfrac{1}{2}$, $\dfrac{x^4}{4!} \le \dfrac{1}{4.3.2} < \dfrac{1}{2^3}, \dots$ etc.,

$$= 1 - \frac{\frac{1}{2}}{(1 - \frac{1}{4})} = \tfrac{1}{3}.$$

Hence $\sin' x = \cos x > \frac{1}{3}$ on $[0, 1]$ and so (by the Mean Value Theorem), $\sin x$ is strictly increasing on $[0, 1]$. But $\sin 0 = 0$ and therefore $\sin x > 0$ for $0 < x \le 1$. It follows that

$$\sin x = 2 \sin \tfrac{x}{2} \cos \tfrac{x}{2} > 0$$

whenever $0 < x \le 2$, since, in this case, $\sin \frac{x}{2} > 0$ and $\cos \frac{x}{2} > \frac{1}{3}$. □

Corollary 5.5 *The function* $\cos x$ *is strictly decreasing on* $[0, 2]$.

Proof. We have $\cos' x = -\sin x$ which is strictly negative on $(0, 2)$, by the theorem. By the Mean Value Theorem, it follows that the function $\cos x$ is strictly decreasing on $[0, 2]$. □

Theorem 5.3 $\sin 4 < 0$.

Proof. From the definition of $\sin x$,

$$\begin{aligned} \sin 4 = 4 - \frac{4^3}{3!} + \frac{4^5}{5!} - \frac{4^7}{7!} + \frac{4^9}{9!} \\ - \frac{4^{11}}{11!}\left(1 - \frac{4^2}{12.13}\right) - \frac{4^{15}}{15!}\left(1 - \frac{4^2}{16.17}\right) \\ - \frac{4^{19}}{19!}\left(1 - \frac{4^2}{20.21}\right) - \dots \\ < 4 - \frac{4^3}{3!} + \frac{4^5}{5!} - \frac{4^7}{7!} + \frac{4^9}{9!} = -\tfrac{268}{405} \end{aligned}$$

and the result follows. □

Theorem 5.4 *There is a unique real number* π *satisfying* $0 < \pi < 4$ *such that* $\sin \pi = 0$. *Furthermore,* $\cos \frac{\pi}{2} = 0$, $\sin \frac{\pi}{2} = 1$ *and* $\cos \pi = -1$.

Proof. We have seen that $\sin x > 0$ for $x \in (0, 2)$ and so, in particular, $\sin 1 > 0$. We have also shown that $\sin 4 < 0$. Now, the map $x \mapsto \sin x$ is continuous on $\mathbb{R}$, and so, by the Intermediate Value Theorem, there is some real number, which we will denote by π, with $1 < \pi < 4$ and such that $\sin \pi = 0$.

We must now show that π is the only value in $(0, 4)$ obeying $\sin \pi = 0$. To this end, suppose that $\sin \alpha = 0$ with $0 < \alpha < 4$. Then

$$0 = \sin \alpha = 2 \sin \tfrac{\alpha}{2} \cos \tfrac{\alpha}{2}.$$

Hence either $\sin \frac{\alpha}{2} = 0$ or $\cos \frac{\alpha}{2} = 0$ (they cannot both vanish because the sum of their squares is equal to 1). But if $0 < \alpha < 4$, then $0 < \frac{\alpha}{2} < 2$ and we know that $\sin x > 0$ on $(0, 2)$, so $\sin \frac{\alpha}{2}$ cannot be zero. Hence, we must have that $\cos \frac{\alpha}{2} = 0$. In particular, $\cos \frac{\pi}{2} = 0$. However, $\cos x$ is strictly decreasing on $[0, 2]$ and so there can be at most one solution to $\cos x = 0$ in this interval. Hence $\frac{\alpha}{2} = \frac{\pi}{2}$ so that $\alpha = \pi$, and the uniqueness is established.

Next, $\sin^2 z + \cos^2 z = 1$ implies that $\sin^2 \frac{\pi}{2} = 1$, since $\cos \frac{\pi}{2} = 0$. Hence $\sin \frac{\pi}{2} = 1$ because $\sin \frac{\pi}{2} > 0$ (since $0 < \frac{\pi}{2} < 2$).

Finally, we have $\cos \pi = 2 \cos^2 \frac{\pi}{2} - 1 = -1$. □

What's going on? We have defined the trigonometric functions, out of the blue as it were, by means of power series. This approach avoids any appeal to geometry and right-angled triangles. However, having chosen this route, we must stick with it. In particular, it is necessary to get to π via these definitions rather than by drawing triangles or circles. As we have seen, this is all perfectly possible. Our view here is that the trigonometric functions are as we have defined them. Any results must be deduced as consequences of these power series definitions.

Remark 5.6 Numerical investigation yields $\pi = 3.14159\ldots$. It is known that π is irrational (in fact, transcendental). It is something of a sport (involving some fascinating numerical analysis) to calculate the value of π to a large number of decimal places and this has been done to over a million decimal places. Such programs have been used to test the computational integrity of supercomputers by checking to see whether they get these digits correct or not.

Theorem 5.5 *For any $z \in \mathbb{C}$ and $n \in \mathbb{Z}$,*

$$\begin{aligned}\sin(z + n\pi) &= (-1)^n \sin z\\ \cos(z + n\pi) &= (-1)^n \cos z.\end{aligned}$$

Proof. We use the trigonometric formulae;

$$\begin{aligned}\sin(z + \pi) &= \sin z \cos \pi + \cos z \sin \pi\\ &= -\sin z + 0,\end{aligned}$$

and

$$\begin{aligned}\cos(z + \pi) &= \cos z \cos \pi - \sin z \sin \pi\\ &= -\cos z - 0.\end{aligned}$$

For $n > 0$, the result now follows by induction. Substituting $z = w - n\pi$, the result then follows for $n < 0$. □

Remark 5.7 Particular cases of the above formulae deserve mention. If we set $z = 0$, then we see that $\sin(n\pi) = 0$ and $\cos(n\pi) = (-1)^n$, for any $n \in \mathbb{Z}$. The functions sin and cos are periodic (with period 2π). In particular, for any $x \in \mathbb{R}$ and any $n \in \mathbb{Z}$,

$$\begin{aligned}\sin(x + 2n\pi) &= \sin x \quad \text{and}\\ \cos(x + 2n\pi) &= \cos x.\end{aligned}$$

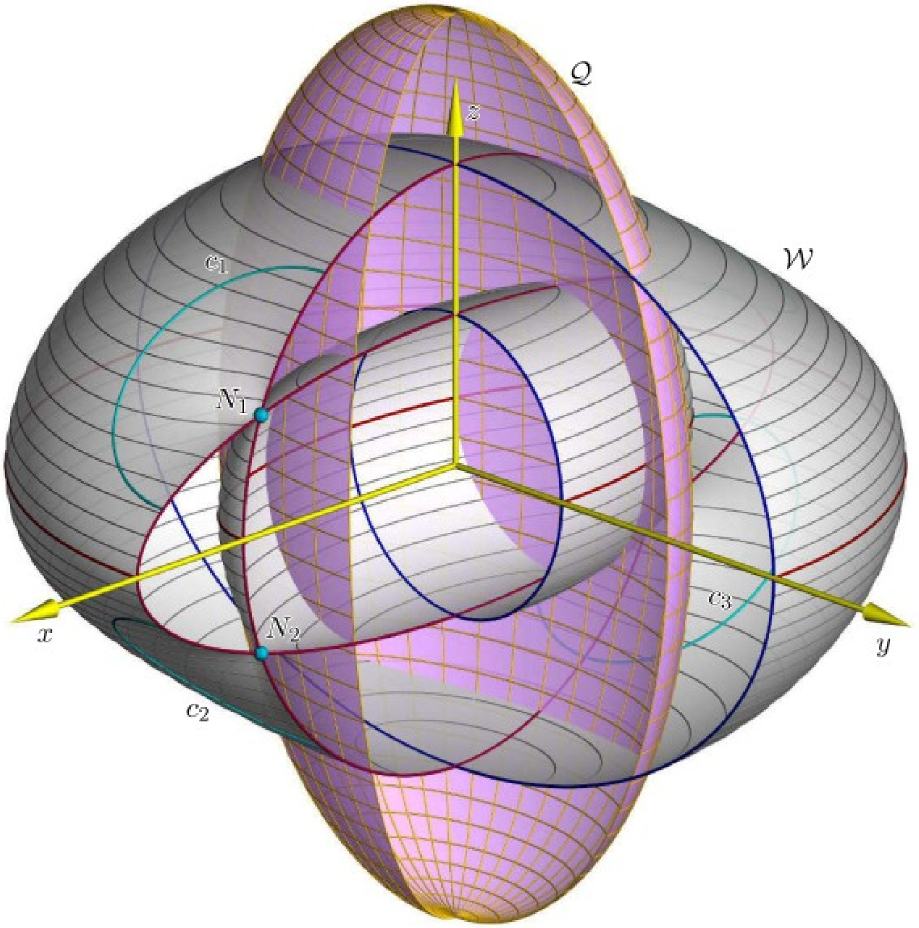

FIGURE 10.16. The quartic Fresnel wave surface $\mathcal{W}$ has four conical nodes N_1, …, N_4 corresponding to the umbilics of an ellipsoid $\mathcal{Q}$. $\mathcal{W}$ intersects its planes of symmetry along circles and ellipses (red and blue). There are four circles c_1, …, c_4 on Fresnel's surface that are the intersection of the four real double tangent planes with $\mathcal{W}$.

Painvin's complex

The tangent planes of a regular quadric $\mathcal{Q}$ form the dual quadric $\mathcal{Q}^\star$. A quadric $\mathcal{Q}$ sends two tangent planes through each line that is not tangent to $\mathcal{Q}$, and thus, a quadric is said to be of *rank* two. This notion of rank is not to be confused with the rank of a matrix, especially with the rank of the coefficient matrix of a quadric. By assumption, $\mathcal{Q}$ is regular, and

trying to test spacetime geometry by physical measurements. His/her conclusions will also be valid locally for true gravitational fields, on the basis of the PE. Assume that the observer sits at the centre of the disc, and has two identical clocks: one of them is placed at the centre, the other at some point on the periphery. The observer will see that the clock on the periphery is running slower (time dilatation from SR). Consequently, clocks at various positions in the gravitational field run faster or slower, depending on the local strength of the field. There is no definition of time that is pertinent to the whole spacetime in general. The observer will also conclude that the length of a piece of line orthogonal to the radius of the disc will be shortened (length contraction from SR). Therefore, the ratio of the circumference of the circle to its radius will be smaller than 2π, so that the Euclidean geometry of space does not hold in GR.

Geometry of curved surfaces. We have seen that in spacetime, within a limited region, we can always choose a suitable reference frame, called the local inertial frame. Taking spacetime apart into locally inertial components, we can apply the laws of SR in each such component and derive various dynamical conclusions. Reconstruction of the related global dynamical picture, based on the PE (and some additional, simple geometric assumptions), gives rise to GR.

This procedure for dissecting spacetime into locally inertial components, out of which we can reconstruct, using the PE, the global structure of spacetime containing the gravitational field, can be compared geometrically with an attempt to build a curved surface, approximately, from a lot of small, plane elements 'continuously' bound to each other (figure 1.1). A locally flat surface is a geometric analogue of locally inertial spacetime.

GR makes essential use of curved spaces (or, more accurately curved spacetimes). Since the curved, four-dimensional spacetime cannot be visualized, let us try to understand the basic features of curved spaces by considering a two-dimensional surface X_2. We shall focus our attention on those geometric properties of X_2, which could be determined by an intelligent, two-dimensional being entirely confined to live and measure in the surface, a being that does not know anything about the embedding Euclidean space E_3. Such properties determine the *intrinsic geometry* on X_2.

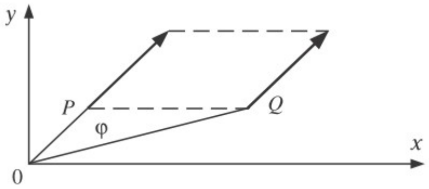

Figure 1.2. Vector components change under the parallel transport.

On a general surface we cannot set up Cartesian coordinates; the best we can do is to introduce two arbitrary families of coordinate lines and label them by $u^\alpha = (u^1, u^2)$. These curvilinear (or Gaussian) coordinates do not always have a direct geometric interpretation.

Let us now imagine a surface X_2 embedded in E_3, and consider a point P in X_2 with Cartesian coordinates (x, y, z) in E_3; since P is in X_2, these coordinates can be expressed as functions of u^α. The squared distance between two neighbouring points in X_2, $P(x, y, z)$ and $Q(x+\mathrm{d}x, y+\mathrm{d}y, z+\mathrm{d}z)$, is given by $\mathrm{d}s^2 = \mathrm{d}x^2 + \mathrm{d}y^2 + \mathrm{d}z^2$. Going over to u^α we obtain

$$\mathrm{d}s^2 = g_{\alpha\beta}\, \mathrm{d}u^\alpha\, \mathrm{d}u^\beta \tag{1.6}$$

where the set of functions $g_{\alpha\beta}(u^1, u^2)$ defines the *metric* on X_2. The metric is an essential intrinsic property of X_2, independent of its embedding in E_3. A two-dimensional continuum X_2, equipped with a squared differential distance according to (1.6), becomes the *metric space*, $G_2 = (X_2, \boldsymbol{g})$ (it is now clear that the symbol X_2 is used to denote an abstract two-dimensional continuum, disregarding all metric properties of the real surface).

Studying the motion of particles in X_2 our observer could have arrived at the idea of the tangent vector, $\boldsymbol{a} = (a^1, a^2)$. Consider, further, two tangent vectors $\boldsymbol{a}$ and $\boldsymbol{b}$, defined at neighbouring points P and Q. If we wish to compare these two vectors we have to know how one of them can be transported to the position of the other. This transport is called *parallel transport*. The continuum X_2 together with the parallel transport law, denoted by Γ, is called a *linearly connected* (or *affine*) space, $L_2 = (X_2, \Gamma)$.

The components of a vector in curvilinear coordinates are expected to change under parallel transport. This can be easily seen by considering the parallel transport of a vector in a plane, using polar coordinates (r, θ). As shown in figure 1.2, if the unit vector $\boldsymbol{a}$ at point P has components ($a^r = 1$, $a^\theta = 0$), after parallel transport from P to Q its components become ($a^r = \cos\varphi$, $a^\theta = \sin\varphi$).

A two-dimensional observer should determine the rule of parallel transport of vectors in accordance with his/her own experience. This rule is generally independent of the concept of a metric. If X_2 is equipped with a rule of

parallel transport and the independent concept of a metric, we obtain the *linearly connected metric* space $(X_2, \Gamma, \boldsymbol{g}) = (L_2, \boldsymbol{g}) = (G_2, \Gamma)$.

It is very probable that our two-dimensional observer will demand that the lengths of vectors should remain unchanged under parallel transport. After adopting this very natural property, which relates Γ and $\boldsymbol{g}$, the linearly connected metric space becomes the *Riemann–Cartan* space U_2. The usual surfaces have some additional geometric structure, and belong to the class of *Riemann* spaces V_2.

This discussion was slightly more general than strictly necessary for studying surfaces embedded in E_3, in order to emphasize that the intrinsic geometry on X_2 is defined in terms of

- the metric $\boldsymbol{g}$ and
- the rule of parallel transport Γ.

These basic concepts of the intrinsic geometry of surfaces can be extended directly to spaces with higher dimensions, although in this case we lose the intuitive geometric picture.

Any Riemann space is locally Euclidean, i.e. its metric is positive definite ($\mathrm{d}s^2 > 0$). A slight generalization of this case, that consists in admitting metrics that are pseudo-Euclidean, leads to a pseudo-Riemannian geometry or Riemannian geometry with an indefinite metric.

Relativity, covariance and Mach's ideas

Relativity and covariance. We have seen previously that inertial frames play a particularly important role in SR. Einstein considered this to be an expression of the incompleteness of SR. He wanted to generalize the relativity of inertial motions to the relativity of all motions, including accelerated ones. This idea can be formulated as the general principle of relativity:

> *General PR: The form of physical laws is the same in all reference frames.*

Equations expressing physical laws are often formulated using specific coordinates. Thus, for instance, spatial positions in an inertial laboratory L can be determined using Cartesian coordinates (x, y, z) or the coordinates obtained from these by a rotation around the z-axis for a fixed angle φ. If we allow the angle φ to change with time as $\varphi = \omega t$, new coordinates can be naturally attached to a new physical reference frame, rotating relative to L with the angular velocity ω around the z-axis. We see that coordinate transformations can be interpreted as describing transitions from one to another laboratory (the so-called active interpretation). Thus, it becomes clear that the general PR can be realized with the help of the principle of general covariance:

2.1.1 Projective Space and Homogeneous Coordinates

Generally, a projective space $\mathbb{P}^n$ is the set of one-dimensional vector subspaces of a given vector space $\mathbb{R}^{n+1}$. Each one-dimensional vector subspace represents a projective point $\mathbf{x}$ with the *projective* dimension 0.

Assuming $n = 1$, the projective space is the projective line $\mathbb{P}^1$ and is visualized in figure 2.1 (a) on the facing page: the projective points $\mathbf{x}_{1/2} \in \mathbb{P}^1$ can be identified with lines going through the origin of the vector space $\mathbb{R}^2$. Thus these lines are one-dimensional subspaces of $\mathbb{R}^2$. Note that no coordinate system but only the origin is defined here.

A definition of a projective point $\mathbf{x} \in \mathbb{P}^n$ may be given as follows:

Definition 2 (Projective point) *A projective point* $\mathbf{x} \in \mathbb{P}^n$ *of dimension* n *is an element of the quotient of* $\mathbb{R}^{n+1} \setminus \mathbf{0}$ *and the equivalence relation* $\cong$*:*

$$\mathbf{x} \cong \mathbf{y} \quad \Leftrightarrow \quad \exists \lambda \neq 0, \mathbf{x} = \lambda \mathbf{y} \tag{2.1}$$

In other words: all vectors $\lambda \mathbf{x}^h = (\lambda x_1, \ldots, \lambda x_n, \lambda)^\mathsf{T} \in \mathbb{R}^{n+1}$ $\lambda \neq 0$ are equivalent with respect to $\cong$ and define a projective point $\mathbf{x}$. In other words, a projective point $\mathbf{x} \in \mathbb{P}^n$ is defined by representing it with a $n+1$ vector $\mathbf{x}^h \in \mathbb{R}^{n+1}$, the so-called *homogeneous vector* representation. This representation is overdetermined: the equivalence relation states, that the lengths of the vectors $\mathbf{x}^h, \mathbf{y}^h \in \mathbb{R}^{n+1}$ do not matter, only their directions.

them within the Euclidean framework. Therefore we need a more general framework which enables us to deal with infinite points, this mathematical framework is known as *projective geometry.*

In this and the following chapters, we will see that projective geometry provides a simple and consistent way to represent and transform geometric entities, that are important for Euclidean polyhedral reconstruction. One drawback though is the fact that properties such as parallelity or orthogonality can not be directly used; more precisely, they are not invariant with respect to projective transformations. The study of invariance of properties with respect to certain groups of transformation may be regarded as a definition of geometry, as KLEIN 1939 mentioned in his Erlanger Programm. We will come back to the issue of invariance in section 3.3 on page 70, where we investigate possible relations between geometric entities and their invariance properties with respect to Euclidean, similar, affine and projective geometry. We will see that for our application it is possible to infer parallelity and orthogonality of lines and planes from homogeneous vectors by using the Euclidean interpretation thereof.

For a detailed and more precise introduction to projective geometry in the context of Computer Vision, see FAUGERAS AND LUONG 2001 or chapter 23 in MUNDY 1992.

2.1.1 Projective Space and Homogeneous Coordinates

Generally, a projective space $\mathbb{P}^n$ is the set of one-dimensional vector subspaces of a given vector space $\mathbb{R}^{n+1}$. Each one-dimensional vector subspace represents a projective point $\mathbf{x}$ with the *projective* dimension 0.

Assuming $n = 1$, the projective space is the projective line $\mathbb{P}^1$ and is visualized in figure 2.1 (a) on the facing page: the projective points $\mathbf{x}_{1/2} \in \mathbb{P}^1$ can be identified with lines going through the origin of the vector space $\mathbb{R}^2$. Thus these lines are one-dimensional subspaces of $\mathbb{R}^2$. Note that no coordinate system but only the origin is defined here.

A definition of a projective point $\mathbf{x} \in \mathbb{P}^n$ may be given as follows:

Definition 2 (Projective point) *A projective point* $\mathbf{x} \in \mathbb{P}^n$ *of dimension* n *is an element of the quotient of* $\mathbb{R}^{n+1} \setminus \mathbf{0}$ *and the equivalence relation* $\cong$*:*

$$\mathbf{x} \cong \mathbf{y} \quad \Leftrightarrow \quad \exists \lambda \neq 0, \mathbf{x} = \lambda \mathbf{y} \tag{2.1}$$

In other words: all vectors $\lambda \mathbf{x}^h = (\lambda x_1, \ldots, \lambda x_n, \lambda)^\mathsf{T} \in \mathbb{R}^{n+1}$ $\lambda \neq 0$ are equivalent with respect to $\cong$ and define a projective point $\mathbf{x}$. In other words, a projective point $\mathbf{x} \in \mathbb{P}^n$ is defined by representing it with a $n+1$ vector $\mathbf{x}^h \in \mathbb{R}^{n+1}$, the so-called *homogeneous vector* representation. This representation is overdetermined: the equivalence relation states, that the lengths of the vectors $\mathbf{x}^h, \mathbf{y}^h \in \mathbb{R}^{n+1}$ do not matter, only their directions.

(d)

Fig. 2.1. Different interpretations of the projective line $\mathbb{P}^1$: in (a), projective points $\mathbf{x}_1, \mathbf{x}_2$ are interpreted as lines going through the origin without defining any coordinate system. In (b), the projective points are homogeneous vectors, that are normalized to the sphere S^2. In (c) the homogeneous vectors intersect the Euclidean axis and define the points $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$ on the Euclidean axis. The role of a hyperplane $\mathbf{l}$ can be visualized by considering the projective plane $\mathbb{P}^2$ in (d): two projective points $\mathbf{x}_1$ and $\mathbf{x}_2$ define two points $\boldsymbol{x}_1, \boldsymbol{x}_2$ on the Euclidean plane $\mathbb{R}^2$. The first point $\boldsymbol{x}_1$ is incident to a line l on the Euclidean plane. The line l in turn is defined by the homogeneous vector $\mathbf{l} \in \mathbb{R}^3 \simeq \mathbb{P}^2$, which is the normal of the plane that contains the origin of $\mathbb{R}^3$ and the line on the Euclidean plane $\mathbb{R}^2$. As the first Euclidean point $\boldsymbol{x}_1$ is incident to the Euclidean line, the homogeneous vector $\mathbf{l}$ is orthogonal to the homogeneous vector $\mathbf{x}_1$, or $\mathbf{l}^\mathsf{T}\mathbf{x}_1 = 0$.

To simplify the notation, we identify projective points $\mathbf{x} \in \mathbb{P}^n$ with their (non-unique) coordinate vector representation based on $\mathbf{x}^h \in \mathbb{R}^{n+1}$, i.e. $\mathbf{x} = \mathbf{x}^h$. Therefore we are not strict with respect to mathematical notation and do *not* distinguish between projective points and its coordinate vectors as in FAUGERAS AND LUONG 2001, p. 78. HARTLEY AND ZISSERMAN 2000 take a similar approach, see p. 3f. In the following, we assume that the correct interpretation is clear from the context.

One can *normalize* a homogeneous vector $\mathbf{x}_s := \frac{\mathbf{x}}{|\mathbf{x}|}$ to avoid ambiguities, see fig.2.1(b). The index s in the homogeneous vector $\mathbf{x}_s$ indicates that the vector is normalized and thus lies on the unit sphere. We could use the normalization of a homogeneous vector with its length for an alternative

definition of the equivalence class $\cong$ for two homogeneous vectors $\mathbf{x}, \mathbf{y} \in \mathbb{R}^{n+1} \setminus \mathbf{0}$:

$$\mathbf{x} \cong \mathbf{y} \quad \Leftrightarrow \quad \left(\frac{\mathbf{x}}{|\mathbf{x}|} = \frac{\mathbf{y}}{|\mathbf{y}|} \text{ or } \frac{\mathbf{x}}{|\mathbf{x}|} = -\frac{\mathbf{y}}{|\mathbf{y}|} \right) \quad \Leftrightarrow \quad \frac{\mathbf{x}}{|\mathbf{x}|} = \pm \frac{\mathbf{y}}{|\mathbf{y}|} \tag{2.2}$$

We sometimes denote the spherical normalization by $\mathsf{N}_s(\mathbf{x}) = \frac{\mathbf{x}}{|\mathbf{x}|}$.

The definition of the equivalence class $\cong$ is ambiguous as the orientation of the normalized vectors can be positive or negative. In other words, a projective point from $\mathbb{P}^n$ has two representations on a sphere S^{n+1}. To overcome this ambiguity one may use *oriented* projective geometry, as proposed by STOLFI 1991, where every element has an intrinsic orientation. This is analytically expressed by the specialized definition, that homogeneous vectors are identical if they differ by a *positive* scale factor. But the ambiguity is not critical for our application, so we will keep the definition in equation (2.2).

The link between an original Euclidean space $\mathbb{R}^n$ and the projective space $\mathbb{P}^n$ is now quite easy: a simple mapping $\mathbb{R}^n \to \mathbb{P}^n$ of the Euclidean space to the projective space can be written as follows:

$$\boldsymbol{x} = (x_1, \ldots, x_n)^\mathsf{T} \in \mathbb{R}^n \to \mathbf{x}_e = (x_1, \ldots, x_n, 1)^\mathsf{T} \in \mathbb{P}^n \tag{2.3}$$

We will denote vectors from $\mathbb{R}^n$ with italic bold letters such as $\boldsymbol{x}, \boldsymbol{y}$, whereas homogeneous vectors from $\mathbb{P}^n \simeq \mathbb{R}^{(n+1)}$ are denoted with upright bold letters, $\mathbf{x}, \mathbf{y}$.

The index e in the homogeneous vector $\mathbf{x}_e$ denotes that we can directly extract the Euclidean information from the homogeneous vector. It is a unique member of the equivalence class defined by $\mathbf{x} \cong \mathbf{x}_e$. In figure 2.1(c) one may interpret the fixing of the last coordinate of the homogeneous vector to 1 as follows: take the line parallel to the first axis, intersecting the second axis in 1. This line represents the real axis $\mathbb{R}^1$, on which the Euclidean numbers $\boldsymbol{x}_{1/2}$ are fixed. Connecting the origin with $\boldsymbol{x}_{1/2}$ on the constructed line yield the projective points.

For the inverse direction of (2.3), any projective point $\mathbf{x} \in \mathbb{P}^n$ (except of ideal points) can be mapped to an euclidized version, see also figure 2.2:

$$\mathbf{x} = (x_1, \ldots, x_n, x_{n+1})^\mathsf{T} \in \mathbb{P}^n \to \mathbf{x}_e = 1/x_{n+1} \, (x_1, \ldots, x_n, 1)^\mathsf{T} \in \mathbb{P}^n \tag{2.4}$$

For lower dimensions, we will replace the coordinates x_1, x_2, x_3 with the letters u, v, w to avoid overloaded use of indices.

Linear Transformations of Projective Points A linear transformation H from $\mathbb{P}^n$ to $\mathbb{P}^m$ can be represented as a $(m+1) \times (n+1)$, such that for $\mathbf{x} \in \mathbb{P}^n$ and $\mathbf{x}' \in \mathbb{P}^m$:

$$\mathbf{x}' = \mathsf{H}\mathbf{x} \tag{2.5}$$

If $n = m$ and the matrix H is regular, we call H a *homography*.

Properties that remain invariant under a transformation H are called projectively invariant. Examples for such properties are collinearity and incidence.

definition of the equivalence class $\cong$ for two homogeneous vectors $\mathbf{x}, \mathbf{y} \in \mathbb{R}^{n+1} \setminus \mathbf{0}$:

$$\mathbf{x} \cong \mathbf{y} \quad \Leftrightarrow \quad \left(\frac{\mathbf{x}}{|\mathbf{x}|} = \frac{\mathbf{y}}{|\mathbf{y}|} \text{ or } \frac{\mathbf{x}}{|\mathbf{x}|} = -\frac{\mathbf{y}}{|\mathbf{y}|} \right) \quad \Leftrightarrow \quad \frac{\mathbf{x}}{|\mathbf{x}|} = \pm \frac{\mathbf{y}}{|\mathbf{y}|} \tag{2.2}$$

We sometimes denote the spherical normalization by $\mathsf{N}_s(\mathbf{x}) = \frac{\mathbf{x}}{|\mathbf{x}|}$.

The definition of the equivalence class $\cong$ is ambiguous as the orientation of the normalized vectors can be positive or negative. In other words, a projective point from $\mathbb{P}^n$ has two representations on a sphere S^{n+1}. To overcome this ambiguity one may use *oriented* projective geometry, as proposed by STOLFI 1991, where every element has an intrinsic orientation. This is analytically expressed by the specialized definition, that homogeneous vectors are identical if they differ by a *positive* scale factor. But the ambiguity is not critical for our application, so we will keep the definition in equation (2.2).

The link between an original Euclidean space $\mathbb{R}^n$ and the projective space $\mathbb{P}^n$ is now quite easy: a simple mapping $\mathbb{R}^n \to \mathbb{P}^n$ of the Euclidean space to the projective space can be written as follows:

$$\boldsymbol{x} = (x_1, \ldots, x_n)^\mathsf{T} \in \mathbb{R}^n \to \mathbf{x}_e = (x_1, \ldots, x_n, 1)^\mathsf{T} \in \mathbb{P}^n \tag{2.3}$$

We will denote vectors from $\mathbb{R}^n$ with italic bold letters such as $\boldsymbol{x}, \boldsymbol{y}$, whereas homogeneous vectors from $\mathbb{P}^n \simeq \mathbb{R}^{(n+1)}$ are denoted with upright bold letters, $\mathbf{x}$,$\mathbf{y}$.

The index e in the homogeneous vector $\mathbf{x}_e$ denotes that we can directly extract the Euclidean information from the homogeneous vector. It is a unique member of the equivalence class defined by $\mathbf{x} \cong \mathbf{x}_e$. In figure 2.1(c) one may interpret the fixing of the last coordinate of the homogeneous vector to 1 as follows: take the line parallel to the first axis, intersecting the second axis in 1. This line represents the real axis $\mathbb{R}^1$, on which the Euclidean numbers $\boldsymbol{x}_{1/2}$ are fixed. Connecting the origin with $\boldsymbol{x}_{1/2}$ on the constructed line yield the projective points.

For the inverse direction of (2.3), any projective point $\mathbf{x} \in \mathbb{P}^n$ (except of ideal points) can be mapped to an euclidized version, see also figure 2.2:

$$\mathbf{x} = (x_1, \ldots, x_n, x_{n+1})^\mathsf{T} \in \mathbb{P}^n \to \mathbf{x}_e = 1/x_{n+1} \, (x_1, \ldots, x_n, 1)^\mathsf{T} \in \mathbb{P}^n \tag{2.4}$$

For lower dimensions, we will replace the coordinates x_1, x_2, x_3 with the letters u, v, w to avoid overloaded use of indices.

Linear Transformations of Projective Points A linear transformation H from $\mathbb{P}^n$ to $\mathbb{P}^m$ can be represented as a $(m+1) \times (n+1)$, such that for $\mathbf{x} \in \mathbb{P}^n$ and $\mathbf{x}' \in \mathbb{P}^m$:

$$\mathbf{x}' = \mathsf{H}\mathbf{x} \tag{2.5}$$

If $n = m$ and the matrix H is regular, we call H a *homography*.

Properties that remain invariant under a transformation H are called projectively invariant. Examples for such properties are collinearity and incidence.

Fig. 2.2. Transfer between Euclidean and Homogeneous Coordinates: giving a Euclidean point $\boldsymbol{x} \in \mathbb{R}^n$ we can derive a projective point $\mathbf{x} \in \mathbb{P}^n$ which we represent as a homogeneous vector $\mathbf{x} \in \mathbb{R}^{n+1}$, see also equation (2.3). Given a homogeneous vector $\mathbf{x} \in \mathbb{R}^{n+1}$, we may obtain a Euclidean representation by normalization, yielding $\boldsymbol{x} \in \mathbb{R}^m$, equation (2.4). In general, the normalization is done by dividing the homogeneous vector by its homogeneous part as described in section 2.2. Note that we use the symbol $\mathbf{x}$ both for a projective point and for homogeneous vectors representing the projective points.

2.1.2 Hyperplanes

A point in projective space can be regarded as the smallest linear subspace that is non-zero. Opposed to a point, a *hyperplane* is the largest linear subspace that is not equal to the complete space. Examples for hyperplanes are lines in 2D and planes in 3D.

In general, a hyperplane $\mathbf{h}$ in $\mathbb{P}^n$ is defined by n linearly independent points $\mathbf{y}_1, \cdots, \mathbf{y}_n$: for example in $\mathbb{P}^2$, two points $\mathbf{y}_1, \mathbf{y}_2$ define a line and in $\mathbb{P}^3$ three points $\mathbf{Y}_1, \mathbf{Y}_2, \mathbf{Y}_3$ define a plane. Any additional point $\mathbf{x}$ is incident to the a hyperplane $\mathbf{h}(\mathbf{y}_1, \cdots, \mathbf{y}_n)$ if the determinant of all concatenated homogeneous vectors is zero

$$|\mathbf{y}_1\, \mathbf{y}_2\, \cdots \mathbf{y}_n\, \mathbf{x}| = 0 \tag{2.6}$$

This is a generalization of the well-known case when checking whether three 2D points are collinear BRONSTEIN *et al.* 1996:

$$\boldsymbol{y}_1, \boldsymbol{y}_2 \text{ and } \boldsymbol{x} \text{ are collinear} \quad \Leftrightarrow \quad \begin{vmatrix} \boldsymbol{y}_1 & \boldsymbol{y}_2 & \boldsymbol{x} \\ 1 & 1 & 1 \end{vmatrix} = 0 \tag{2.7}$$

which can be generalized to the to the 3D case when checking whether four points are coplanar:

$$\boldsymbol{Y}_1, \boldsymbol{Y}_2, \boldsymbol{Y}_3 \text{ and } \boldsymbol{X} \text{ are coplanar} \quad \Leftrightarrow \quad \begin{vmatrix} \boldsymbol{Y}_1 & \boldsymbol{Y}_2 & \boldsymbol{Y}_3 & \boldsymbol{X} \\ 1 & 1 & 1 & 1 \end{vmatrix} = 0 \tag{2.8}$$

(2.9)

An alternative definition of a hyperplane can be obtained by using the Laplacian expansion on the determinant in equation (2.6): if we expand by the last column, we obtain $n-1$ minors $|\mathsf{M}_{i,n}|$ that depend on the vectors $\mathbf{y}_1, \cdots \mathbf{y}_n$. With $h_i = (-1)^{i+n}|\mathsf{M}_{i,n}|$, equation (2.6) is equivalent to

$$\sum_i h_i x_i = \mathbf{h}^\mathsf{T}\mathbf{x} = \mathbf{x}^\mathsf{T}\mathbf{h} = 0 \tag{2.10}$$

Both (2.6) and its equivalent equation (2.10) is a necessary and sufficient condition to check whether a point $\mathbf{x}$ is incident to a hyperplane, $\mathbf{x} \in \mathbf{h}$.

Since the minors h_i with $i = 1, \cdots, n$ uniquely define a hyperplane, we can identify them with the coordinates of a hyperplane, defining the vector $\mathbf{h} = (h_1, \cdots, h_n)^\mathsf{T}$. The coordinates h_i are called Plücker coordinates, see also section 2.2.4. The vector $\mathbf{h}$ is a homogeneous vector as (2.10) is a homogeneous equation. As for projective points, it is assumed that it is clear from the context whether a homogeneous vector is interpreted as a projective point or a hyperplane: in the following lines in 2D are usually denoted by $\mathbf{l}$, $\mathbf{m}$ and planes in 3D are denoted by $\mathbf{A}, \mathbf{B}$ opposed to points denoted by $\mathbf{x}$, $\mathbf{y}$ resp. $\mathbf{X}, \mathbf{Y}$.

It is important to note that $\mathbf{h}$ is actually a linear form of $\mathbb{R}^{n+1}$, since each coordinate is a function of the form $\mathbb{R}^{n+1} \to \mathbb{R}$. Thus the vector $\mathbf{h}$ represents an element of the dual space $(\mathbb{R}^{n+1})^*$ or equivalently $(\mathbb{P}^n)^*$.

Given a linear transformation $\mathbf{x}' = \mathsf{H}\mathbf{x}$ for projective points as in (2.5), one may be interested in the corresponding transformation for hyperplanes. H is a linear mapping from $\mathbb{P}^n$ to $\mathbb{P}^m$, its transpose H^T is defined as the mapping from $(\mathbb{P}^m)^*$ to $(\mathbb{P}^n)^*$. With $\mathbf{h}' \in (\mathbb{P}^m)^*$ being the imaged hyperplane of $\mathbf{h} \in (\mathbb{P}^n)^*$ with respect to H, one obtains

$$\mathsf{H}^\mathsf{T}\mathbf{h}' = \mathbf{h} \tag{2.11}$$

If H is a homography, thus $n = m$ and H being regular, one can prove (2.11) as follows: given $\mathbf{x}' = \mathsf{H}\mathbf{x}$, we are looking for the corresponding transformation $\mathbf{h}' = \mathsf{J}\mathbf{h}$, such that for all $\mathbf{y} \in \mathbf{h}$ and $\mathbf{y}' \in \mathbf{h}'$: $\mathbf{y}' = \mathsf{H}\mathbf{y}$. Thus the following equation must hold

$$\mathbf{y}'^\mathsf{T}\mathbf{h}' = \mathbf{x}'^\mathsf{T}\mathsf{J}\mathbf{h} = \mathsf{x}^\mathsf{T}\mathsf{H}^\mathsf{T}\mathsf{J}\mathbf{h} = 0$$

This can be true only if $\mathsf{J} = \mathsf{H}^{-\mathsf{T}}$.

2.2 Representation of Geometric Entities

This section introduces the basic geometric entities, that will be used throughout the rest of this text. As we want to reconstruct polyhedral objects, it is sufficient to deal with geometric entities that can be modeled as linear subspaces, cf. section 1.3.2 on page 6. Therefore only points, lines and planes

2022: Feliz Ano Novo!!!

There are four fundamental forces at work in the Universe:

(20220101)

1) The strong force
2) The Weak force
3) The Electromagnetic Force
4) The Gravitational Force.

reflexo
(efeito)

The Gravitational Force é decorrência da "The Strong Force".

Se a gravidade existisse independentemente das demais forças, o Universo jamais teria sido criado pois antes do Big-Bang tudo estava reunido em um único ponto e portanto, a própria gravidade teria impedido a própria explosão do Big-Bang.

A gravidade deve ser analisada localmente e quando estendida, você terá outro valor.

A extensão da análise do fator gravitacional em relação a todo Universo gera uma curvatura ~~do~~ espaço-tempo.

O Universo se expande pois a "gravidade" age localmente em relação à cada galáxia e não em relação ao todo.

Fig. 15

the radius of (Ω_4) and the affix of its centre. To do this, note that (Ω_3) passes into (Ω_4) under the inversion with respect to the circle (Ω_1) and under the homothetic transformation $(0,\ 1/\sigma)$, where σ is the power of the point O with respect to the circle (Ω_3).

But under the homothetic transformation $(O,\ 1/\sigma)$, the centre of (Ω_3) goes into the centre of (Ω_4); hence the affix ω_4 of the centre Ω_4 of (Ω_4) is equal to

$$\omega_4 = \frac{1}{\sigma}\,\frac{\bar{d}}{\bar{c}}$$

and the radius is equal to the product of the radius $R_3 = 1$ of the circle (Ω_3) by the modulus of the homothetic ratio, that is, by $1/|\sigma|$:

$$R_4 = R_3\frac{1}{|\sigma|} = \frac{1}{|\sigma|} \quad (R_3 = 1).$$

Furthermore,

$$\sigma = O\Omega_3^2 - R_3^2 = \frac{\bar{d}}{\bar{c}}\,\frac{d}{c} - 1 = \frac{d\bar{d} - c\bar{c}}{c\bar{c}}.^{*}$$

---

[*] In the general case, under inversion with respect to the point O, we have

$$(OM)\cdot(OM') = k,$$

where $k \neq 0$ is the power of the inversion, and, hence,

$$\frac{(OM')}{(ON)} = \frac{k}{\sigma},$$

where k is the second point of intersection of the straight line OM with circle being inverted; $\sigma \neq 0$, since $|d| \neq |c|$.

so that

$$(\Omega_4) = \left(\frac{c\bar{d}}{d\bar{d} - c\bar{c}},\ \frac{c\bar{c}}{|d\bar{d} - c\bar{c}|}\right).$$

(3) The transformation

$$\frac{1}{z + \frac{d}{c}} \to \frac{\frac{bc - ad}{c^2}}{z + \frac{d}{c}}$$

consists in turning the plane through an angle of arg $\frac{bc - ad}{c^2}$ and in a homothetic transformation with centre O and ratio $\frac{|bc - ad|}{|c|^2}$. After these two transformations, the circle (Ω_4) goes into the circle (Ω_5), the affix ω_5 of whose centre is

$$\omega_5 = \omega_4 \frac{bc - ad}{c^2} = \frac{c\bar{d}}{d\bar{d} - c\bar{c}} \frac{bc - ad}{c^2} = \frac{\bar{d}}{c} \frac{bc - ad}{d\bar{d} - c\bar{c}}$$

and the radius is

$$R_5 = \left| \frac{c\bar{c}}{d\bar{d} - c\bar{c}} \cdot \frac{bc - ad}{c^2} \right| = \left| \frac{bc - ad}{d\bar{d} - c\bar{c}} \right|^{*}.$$

Thus

$$(\Omega_5) = \left(\frac{\bar{d}}{c} \frac{bc - ad}{d\bar{d} - c\bar{c}},\ \left| \frac{bc - ad}{d\bar{d} - c\bar{c}} \right| \right).$$

(4) Finally, the transformation of translation

$$\frac{\frac{bc - ad}{c^2}}{z + \frac{d}{c}} \to \frac{a}{c} + \frac{\frac{bc - ad}{c^2}}{z + \frac{d}{c}}$$

carries the circle (Ω_5) into (Ω_6) of the same radius: $R_6 = R_5$, and the affix ω_6 of the centre Ω_6 of (Ω_6) is equal to

$$\omega_6 = \frac{a}{c} + \frac{\bar{d}}{c} \frac{bc - ad}{d\bar{d} - a\bar{c}} = \frac{b\bar{d} - a\bar{c}}{d\bar{d} - c\bar{c}}.$$

---

* $\left| \frac{c\bar{c}}{c^2} \right| = \left| \frac{|c|^2}{c^2} \right| = \frac{|c|^2}{|c^2|} = \frac{|c|^2}{|c|^2} = 1.$

To summarize, then: as a result of the transformation

$$u = \frac{az+b}{cz+d}, \quad ad - bc \neq 0, \quad c \neq 0, \quad |c| \neq |d|,$$

the circle $(\Omega_1) = (0,\ 1)$ goes into the circle

$$(\Omega_6) = \left(\frac{b\bar{d} - a\bar{c}}{d\bar{d} - c\bar{c}},\quad \left|\frac{bc - ad}{d\bar{d} - c\bar{c}}\right|\right).$$

Problem 13. Suppose $\overrightarrow{BCA_1A_2}$, $\overrightarrow{CAB_1B_2}$, $\overrightarrow{ABC_1C_2}$ are squares with the same orientation and constructed on the sides BC, CA, AB of $\triangle\ ABC$, the orthocentre of which is H. Denote by $(O) = (ABC)$ the circle passing through the points A, B, C. Let P, Q, R be the respective centres of the squares $\overrightarrow{A_1B_2C'C''}$, $\overrightarrow{B_1C_2A'A''}$, $\overrightarrow{C_1A_2B'B''}$ having the same orientation as the first three squares. Denote by P_1, P_2, P_3 the orthogonal projections of point P on the sides BC, CA, AB of $\triangle ABC$, by Q_1, Q_2, Q_3 the orthogonal projections of point Q on the same sides and by R_1, R_2, R_3 the orthogonal projections of point R on the same sides BC, CA, AB of $\triangle ABC$. Prove that the sum of the *forces*

$$\overrightarrow{PP_1} + \overrightarrow{PP_2} + \overrightarrow{PP_3} + \overrightarrow{QQ_1} + \overrightarrow{QQ_2} + \overrightarrow{QQ_3} + \overrightarrow{RR_1} + \overrightarrow{RR_2} + \overrightarrow{RR_3} \quad (31)$$

is equal to the vector $\overrightarrow{OH'}$, where H' is the orthocentre of the triangle whose vertices are the feet of the altitudes of the given triangle ABC.

Prove that the straight line on which the resultant of these forces * lies passes through the endpoint of the directed line segment $4\overrightarrow{OH}$.

Now if the squares of the second triplet have an orientation opposite that of the first three squares, then the sum of the forces (31) belongs to the straight line OH'.

Set up the equations of these two straight lines and take the circle $(O) = (ABC)$ as the unit circle (Fig. 16).

Solution. 1°. Let a, b, c be the affixes of the points A, B, C. Find the affixes p, q, r of the points P, Q, R. Denoting by a_1, b_1, c_1, a_2, b_2, c_2 the affixes of the points A_1, B_1, C_1, A_2, B_2, C_2, we have

$$\left.\begin{aligned} b_2 &= c + \overrightarrow{CB_2} = c + i\overrightarrow{CA} = c + i(a - c) = ia + (1 - i)\,c, \\ a_1 &= c + \overrightarrow{CA_1} = c - i\overrightarrow{CB} = c - i\,(b - c) = (1 + i)\,c - ib. \end{aligned}\right\} \quad (32)$$

Also,

$$\begin{aligned} p &= b_2 + \frac{1}{2}\,\overrightarrow{B_2A_1} - \frac{i}{2}\,\overrightarrow{B_2A_1} = b_2 + \frac{1}{2}\,(a_1 - b_2) - \frac{i}{2}\,(a_1 - b_2) \\ &= b_2 + \frac{1}{2}\,a_1 - \frac{1}{2}\,b_2 - \frac{ia_1}{2} + \frac{ib_2}{2} = \frac{1+i}{2}\,b_2 + \frac{1-i}{2}\,a_1 \end{aligned}$$

6. Relations métriques dans le cercle.

189-A. — *Montrer que les diagonales d'un pentagone régulier se divisent en moyenne et extrême raison.* (Bacc. Ajaccio.)

(Ex. 1286.)

189-B. — *On considère un demi-cercle* AMB, *avec ses tangentes parallèles* AC, BD, *et la tangente mobile* CMD. — *Montrer que le produit* AC . BD *est constant.*

(Bacc. Toulouse, Marseille, 1911.)

I. — Les angles COD, AMB, sont égaux comme ayant leurs côtés perpendiculaires.

Le triangle rectangle COD donne :

$$MC . MD = \overline{OM}^2;$$

d'où

$$AC . BD = R^2.$$

II. — *Par l'homographie.* D'après un théorème de Chasles, la tangente mobile marque sur les tangentes fixes deux ponctuelles homographiques, ayant pour points limites les contacts A, B.

On a donc : $AC . BD = C^{te}$.

Cette constante est R^2, comme on le voit quand CD est parallèle à AB.

189-C. — *Un point* M *décrit un cercle* O, *dans lequel on a tracé deux diamètres rectangulaires* AA′, BB′. *La droite* AA′ *coupe* MB *en* P *et* MB′ *en* P′. — *Montrer que le produit* OP . OP′ *est constant.* (Bacc. Clermont, 1909.)

Il suffit de remarquer que les triangles OBP, OB′P′, sont semblables; ou que les droites BP, B′P′, sont antiparallèles par rapport à l'angle O; que les points P, P′, sont conjugués harmoniques sur AA′, etc.

On a : $OP . OP' = R^2$.

189-D. — *Par le milieu* M *de l'arc sous-tendu par une corde* EF, *on mène deux sécantes* MAD, MBC, *qui coupent la droite en* A, B, *et le cercle en* C, D. — *Quelle relation existe-t-il dans le quadrilatère* ABCD, *entre le produit des diagonales et les produits des côtés opposés?* (Bacc. Lyon.)

Ce quadrilatère est inscriptible, car l'angle C et l'angle extérieur en A ont même mesure.

On a donc la relation de Ptolémée :

$$AC . BD = AB . CD + BC . DA.$$

189-E. — *On désigne par* O *le centre du cercle circonscrit à* *un triangle* ABC, *et par* H, M, N, *les projections du sommet* A *sur les droites* BC, OB, OC. — *Montrer que l'on a :*

$$\overline{AH}^2 = BM \,.\, CN. \qquad \text{(Bacc. Besançon.)}$$

Le triangle ABC avec sa hauteur AH donnent :

$$AB \,.\, AC = 2R \,.\, AH.$$

En projetant les côtés AB, AC, sur les diamètres adjacents BOM, CON, on a :

$$\overline{AB}^2 = 2R \,.\, BM,$$

$$\overline{AC}^2 = 2R \,.\, CN.$$

Éliminant AB et AC, on obtient :

$$BM \,.\, CM = \overline{AH}^2.$$

189-F. — *D'un point* A *pris hors d'un cercle* O, *on mène une sécante mobile* AMM', *puis on décrit le cercle* OMM' *qui recoupe* OA *en un point* P. — *Montrer que le produit* PM . PM' *est constant.*

(Bacc. Rennes.)

Le point P est fixe puisque l'on a :

$$AP \,.\, AO = AM \,.\, AM' = C^{te}.$$

Soient R le rayon du cercle O, ρ celui du cercle OMM'; h, h', les distances du point P et du point O à la sécante MM', c'est-à-dire les hauteurs des triangles PMM', OMM', qui donnent :

$$PM \,.\, PM' = 2\rho h;$$

$$R^2 = 2\rho h'.$$

Par division membre à membre, on en déduit :

$$\frac{PM \,.\, PM'}{R^2} = \frac{h}{h'} = \frac{AP}{AO};$$

d'où
$$PM \,.\, PM' = R^2\left(\frac{AP}{AO}\right) = C^{te}.$$

189-G. — *On considère le cercle* O *de diamètre* AHB, *la demi-corde* HM *perpendiculaire à ce diamètre, et les milieux* A', B', *des segments* HA, HB. *Si le cercle de centre* M *et de rayon* MH *coupe le cercle* O *en* C, D, *la corde* CD *passe par le milieu* P *de* MH, *et elle est tangente aux trois cercles qui ont pour diamètres* A'B', HA, HB.

I. — 1° Le rayon OM coupe CD en son milieu E, et le quadrilatère inscriptible HPEO donne :

$$MP \,.\, MH = ME \,.\, MO = \frac{2R \,.\, ME}{2} = \frac{\overline{MC}^2}{2} = \frac{\overline{MH}^2}{2};$$

d'où
$$MP = \frac{MH}{2} = PH.$$

2° Les triangles MAB, PA'B', sont homothétiques.

La corde DC, parallèle à la tangente en M au cercle AMB, est tangente en P au cercle A'PB'.

3° La droite MB étant la bissectrice de HMT, la droite PB′ est la bissectrice de l'angle HPC.

Donc le cercle B′ est inscrit dans l'angle HPC.

De même le cercle A′ est inscrit dans l'angle HPD.

II. — *Par l'axe radical.* (Quest. 997.)

189-H. — *Dans un heptagone régulier* ABCDEFO, *on a :*

$$\frac{1}{AB}=\frac{1}{AC}+\frac{1}{AD}. \qquad \text{(Emmerich, M. 1890.)}$$

Posons : $AB=a, \quad AC=b, \quad AD=c.$

Dans le quadrilatère inscrit ABCE, on a :

$$AB=BC=a, \quad CA=CE=b, \quad EA=EB=c,$$

et le premier théorème de Ptolémée donne :

$$bc=ab+ac,$$

relation équivalente à la proposée.

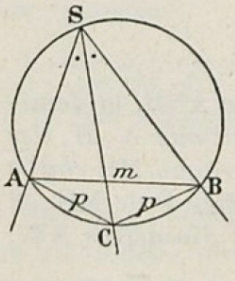
190. Théorème de Maclaurin. — *Par le sommet* S *d'un angle constant, on mène un cercle variable qui recoupe les côtés en* A, B, *et la bissectrice en* C. — *Montrer que l'on a :*

$$\frac{SA+SB}{SC}=C^{te}.$$

I. — *Triangles semblables.* (Ex. 1291.)

II. — *Calcul trigonométrique.* (Ex. 1292.)

III. — *Similitude.* Soient CD, CE, les distances du point C aux droites SA, SB.



Les triangles rectangles CAD, CBE, sont égaux puisque les cordes CA, CB, sous-tendent des arcs égaux.

On a donc: $SA+SB=2SD.$

Le triangle rectangle SDC reste semblable à lui-même, puisque l'angle $ASB=2\alpha=C^{te}$.

Donc $\dfrac{SA+SB}{SC}=2\dfrac{SD}{SC}=2\cos\alpha=C^{te}.$

IV. — *Par le théorème de Ptolémée.* Appliquons le premier théorème de Ptolémée au quadrilatère SABC. en remarquant que le triangle ABC reste semblable à lui-même, et en posant :

$$\frac{AB}{AC}=\frac{m}{p}.$$

On obtient : $$SC.m=(SA+SB)p;$$

d'où $$\frac{SA+SB}{SC}=\frac{m}{p}=C^{te}.$$

Remarque. — Si le point C est fixe, on a :

$$SC=C^{te}, \quad \text{d'où} \quad (SA+SB)=C^{te}.$$

On retrouve ainsi la question 36.

190-A. — *Dans tout quadrilatère inscriptible, les côtés* a, b, c, d, *les diagonales* m, n, *et la distance* p *des milieux des diagonales vérifient la relation :*

$$(a + c)^2 + (b + d)^2 = (m + n)^2 + 4p^2.$$

Il suffit d'additionner, membre à membre, les relations d'Euler et de Ptolémée :

$$a^2 + b^2 + c^2 + d^2 = m^2 + n^2 + 4p^2;$$

$$ac + bd = mn,$$

après avoir multiplié cette dernière par 2.

190-B. — *D'un point* O *pris sur le cercle* C *de diamètre* OCD, *on décrit un second cercle qui coupe le premier en* A *et* B. *D'un point quelconque* M *du cercle* O, *les points* A, B, D, *se projettent en* E, F, G, *sur le cercle* C. — *Montrer que* MEFG *est un parallélogramme, et que l'on a :*

$$\overline{MG}^2 = \overline{MA} \,.\, \overline{MB}. \qquad \text{(Cambier, N. A. 1878.)}$$

D'après les mesures de l'angle AOB, l'arc AB du cercle O est semblable à chacun des arcs DA, DB. Il s'ensuit que l'arc DE est égal à AE, et que l'arc EF est égal à DB.

Donc ME est parallèle à DF, et MF à DE.

Enfin les triangles MAG, MBG, sont équiangles, et donnent :

$$\frac{MG}{MA} = \frac{MB}{MG}.$$

190-C. Quadrilatère harmonique. — *D'un point* P *à un cercle, on mène les tangentes* PA, PC, *et la sécante* PDB *qui coupe* AC *en* K. — *Montrer que, dans le quadrilatère inscrit* ABCD :

1° *Les côtés adjacents sont proportionnels* (Mannheim);

2° *Les côtés opposés ont un produit constant;*

3° *Les côtés* a, b, c, d, *sont proportionnels à leurs distances* x, y, r, t, *au point* K.

I. — (Ex. 2454.)

II. — 1° Les triangles équiangles PAB, PAD, ou PCB, PCD donnent :

$$\frac{\text{PA ou PC}}{\text{PD}} = \frac{d}{a} = \frac{c}{b}.$$

2° La relation de Ptolémée :

$$ac + bd = AC \,.\, BD,$$

devient :

$$2ac = 2bd = AC \,.\, BD.$$

3° Dans tout quadrilatère inscriptible, les triangles semblables KAB, KCD, ou KAD, KBC, donnent :

$$\frac{x}{a} = \frac{z}{c}, \qquad \text{et} \qquad \frac{y}{b} = \frac{t}{d}.$$

Projetons P en X sur BA, en Y sur BC, on aura :

$$\frac{x}{y} = \frac{PX}{PY} = \frac{PA \sin BCA}{PC \sin BAC} = \frac{a}{b}.$$

Donc $$\frac{x}{a}=\frac{y}{b}=\frac{z}{c}=\frac{t}{d}.$$

III. — *Rapport anharmonique dans le cercle.* (Quest. 714-A.)

IV. — *Inversion.* (Quest. 837.)

190-D. — *D'un point* O *à un cercle on mène des sécantes* OAA′, OBB′, OCC′, ... *formant des angles adjacents égaux.* — *Montrer que tous ces angles interceptent quatre cordes dont le produit est constant.*

Il suffit de considérer deux angles adjacents AOB, BOC.

Soient R le rayon du cercle, et h, h', les distances des points B, B′, aux droites OA, OC.

On a :
$$2Rh = BA \, . \, BA' = BC \, . \, BC';$$
$$2Rh' = B'A \, . \, B'A' = B'C \, . \, B'C'.$$

Multipliant membre à membre, on obtient :
$$AB \, . \, BA' \, . \, AB' \, . \, A'B' = BC \, . \, BC' \, . \, CB' \, . \, B'C'.$$

191. Porisme d'Euclide. — *Par deux points* A, B, *symétriques par rapport au centre d'un cercle* O, *on mène, dans une direction variable, deux segments* AM, BN, *parallèles, de même sens, limités à la circonférence.* — *Démontrer que le produit* AM . BN *est constant.*

Puissance d'un point. (Ex. 1292.)

192. Porisme d'Euclide. — *Autour d'un cercle* O, *on considère la tangente au point fixe* A, *et deux tangentes parallèles, de direction variable, qui coupent la première en des points* M, N. — *Démontrer que le produit* AM . AN *est constant.*

Hauteur d'un triangle rectangle. (Ex. 1293.)

193. Porisme d'Euclide. — *Autour d'un demi-cercle, on considère deux tangentes fixes également inclinées sur le diamètre qu'elles rencontrent aux points* A, B, *et une tangente mobile qui coupe les premières aux points* M, N. — *Démontrer que le produit* AM . BN *est constant.*

Triangles équiangles. (Ex. 1296.)

194. — *Dans un cercle* O, *une corde* CD *pivote autour d'un point* L *qui est fixe sur le diamètre* AB. *La tangente en* A *rencontre* BC *au point* E *et* BD *au point* F. — *Démontrer que le produit* AE . AF *est constant.*

I. — Le quadrilatère ECDF est inscriptible, car les angles BCD, BFE, ont même mesure.

Le cercle ECDF coupe AB en des points fixes M, N; car, par rapport à ce cercle, la puissance du point L est :

$$LA . LB = C^{te},$$

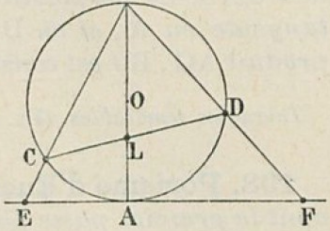
et celle du point B :

$$BD . BF = \overline{AB}^2 = C^{te}.$$

Donc $AE . AF = AM . AN = C^{te}$.

En effectuant le calcul, on trouve :

$$AE . AF = \frac{LA}{LB} \overline{BA}^2.$$



II. — (Ex. 1297.)

III. — *Par l'involution.* Les mobiles C, D, restant alignés sur un point fixe L, leurs projections E, F, à partir d'un point fixe B pris sur le cercle, décrivent une involution, ayant A pour point central.

Donc $AE . AF = C^{te}$.

195. — *On considère sur un cercle deux points fixes* A, B, *et un mobile* M.

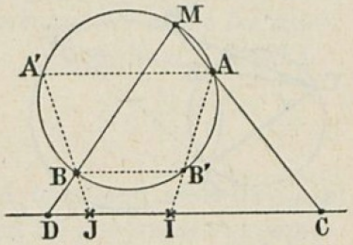
Les sécantes MA, MB, *coupent une droite fixe* XY *en des points* C, D.

Trouver sur XY *deux points fixes* I, J, *tels que le produit* IC . JD *soit constant.*

I. — (Ex. 1298.)

II. — *Homographie.* Les droites AM, BM, se correspondent homographiquement. Donc les points C, D, décrivent deux ponctuelles homographiques, dont les *points limites* I, J, répondent à la question.

Le point I est la position limite de C lorsque D s'éloigne indéfiniment. Le point J est la position limite de D, lorsque C disparaît à l'infini.



196. — *Par un point fixe* L *pris sur le prolongement du diamètre* AB *d'un cercle donné, on mène une sécante mobile* LCD, *et la droite* LM *perpendiculaire à* AB.

Les sécantes BC, BD, *coupent* LM *aux points* M *et* N. — *Démontrer que le produit* LM . LN *est constant.*

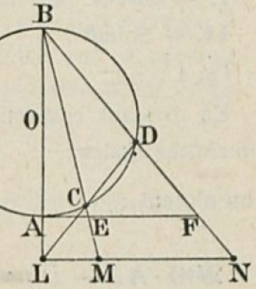
I. — (Ex. 1299.)

II. — (Quest. 194.)

La tangente en A coupe BC, BD, en des points E, F, tels que

$$AE . AF = C^{te}.$$

Cette question ne diffère pas de la question 194, le point L étant intérieur au cercle dans l'un des cas, et extérieur dans l'autre cas.



197. Porisme d'Euclide. — *On considère un mobile* M *qui décrit un demi-cercle* AMB, *et un point* P *qui reste fixe sur le diamètre* AB. *La perpendiculaire à l'extrémité de* PM *coupe en* C *la tangente en* A, *et en* D *la tangente en* B. — *Démontrer que le produit* AC . BD *est constant.*

Triangles semblables. (Ex. 1300.)

198. Porisme d'Euclide. — *On considère deux cercles* E, A, *dont le premier passe par le centre du second, et une tangente qui roule sur le second et coupe le premier en des points* M *et* N. — *Démontrer que le produit* AM . AN *est constant.*

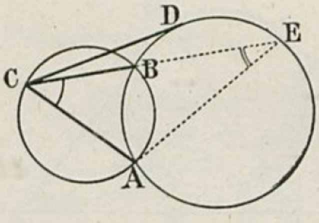
I. — *Triangles semblables.* (Ex. 1301.)

II. — Le triangle AMN est inscrit au premier cercle, de rayon R; et sa hauteur reste égale au rayon r du cercle A.

Donc $$AM \cdot AN = 2Rr.$$

199. — *Deux cercles se coupent aux points* A, B. *D'un point* C, *mobile sur le premier, on mène à l'autre la tangente* CD. —

Démontrer que l'on a : $$\frac{\overline{CD}^2}{CA \cdot CB} = C^{te}.$$



I. — (Ex. 1302.)

II. — La sécante CA recoupe le second cercle en un point E, et le triangle CBE reste semblable à lui-même, puisque ses angles sont constants.

On a donc :

$$\frac{\overline{CD}^2}{CA \cdot CB} = \frac{CA \cdot CE}{CA \cdot CB} = \frac{CE}{CB} = C^{te}.$$

200. — *Par un point* A *mobile sur une circonférence, on mène les cordes* AMB, ANC, *passant par deux points fixes* M, N, *symétriques par rapport au centre.*

Prouver que l'on a : $$\frac{AM}{MB} + \frac{AN}{NC} = C^{te}.$$

I. — *Calcul.* (Ex. 1303.)

II. — Soient : $OA = a, \quad OM = ON = b.$

On a : $$\overline{AM}^2 + \overline{AN}^2 = 2(a^2 + b^2).$$

En divisant respectivement les trois termes de cette égalité par les trois quantités égales : $AM \cdot MB = AN \cdot NC = a^2 - b^2,$

on obtient : $$\frac{AM}{MB} + \frac{AN}{NC} = \frac{2(a^2+b^2)}{a^2-b^2} = C^{te}.$$

200-A. — *D'un point* A *à un cercle* O, *on mène une sécante* *mobile* ABC. *Si les traces* B, C *se projettent sur* OA *en* B′, C′. — *Montrer que l'on a :* $\dfrac{1}{AB'} + \dfrac{1}{AC'} = C^{te}$. (Bacc. Lille.)

I. — *Similitude.* Soit M le milieu de la corde BC.
Les droites antiparallèles donnent :

$$AO \,.\, AB' = AM \,.\, AB;$$
$$AO \,.\, AC' = AM \,.\, AC.$$

Additionnant et multipliant membre à membre, on a :

$$OA(AB' + AC') = 2\overline{AM}^2;$$
$$\overline{OA}^2 \,.\, AB' \,.\, AC' = \overline{AM}^2 \,.\, AB \,.\, AC;$$

d'où, par division membre à membre :

$$\frac{AB' + AC'}{AB' \,.\, AC'} = \frac{2OA}{AB \,.\, AC} = C^{te}.$$

II. — *Polarité.* La polaire du point A coupe BC en un point mobile D, et B′C′ en un point fixe D′, tels que :

$$(AD'B'C') = (ADBC) = -1.$$

Cette relation harmonique peut s'écrire :

$$\frac{1}{AB'} + \frac{1}{AC'} = \frac{2}{AD'} = C^{te}.$$

201. — *La tangente commune extérieure à deux cercles tangents extérieurement, est moyenne proportionnelle entre les deux diamètres.* (Bacc. Nancy, 1903.)

I, II. — *Triangles semblables.* (Ex. 1305.)

III. — *Tangente intérieure.* (Ex. 1305.)

202. — *Si trois cercles tangents deux à deux sont inscrits dans un même angle, leurs rayons* r, r′, r″, *sont en progression géométrique.*

I. — *Triangles semblables.* (Ex. 1308.)

II. — *Divisions homothétiques.* Les centres O, O′, O″, et les contacts C, C′, forment deux divisions homothétiques OCO′, O′C′O″, qui donnent :

$$\frac{r}{r'} = \frac{r'}{r''}.$$

203. — *Quand une circonférence est inscrite et circonscrite à deux polygones réguliers semblables, sa longueur est moyenne proportionnelle entre la circonférence inscrite au plus petit et la circonférence circonscrite au plus grand.*

I. — *Triangles semblables.* (Ex. 1309.)

II. — *Polygones semblables.* Les rayons des polygones étant proportionnels à leurs apothèmes, on a :

$$\frac{R}{\rho} = \frac{\rho}{r}; \quad \text{d'où} \quad (2\pi\rho)^2 = (2\pi R)(2\pi r).$$

BIBLIOTHÈQUE NATIONALE IMPRIMÉS

204. — *Si la corde des contacts de deux tangentes à un cercle pivote sur un point fixe, les inverses des distances de ce point aux tangentes ont une somme constante.*

I, II. — *Calcul.* (Ex. 1312.)

205. — *Si deux cercles égaux se coupent orthogonalement au point* A, *les cordes qu'ils interceptent sur une sécante mobile autour du point* A *ont une somme de carrés constante.*

(Ex. 1313.)

205-A. — *Quand deux cercles* A, B, *sont orthogonaux, leur corde commune* MM′ *est égale à la projection de leur tangente commune* CD *sur la ligne des centres.*

Soient a, b, les rayons.

On a : $\mathrm{MM'} = \dfrac{2ab}{\mathrm{AB}}$.

La tangente a pour longueur : $\mathrm{CD} = \sqrt{2ab}$;

et pour projection : $\dfrac{\overline{\mathrm{CD}}^2}{\mathrm{AB}} = \dfrac{2ab}{\mathrm{AB}} = \mathrm{MM'}$.

206. — *Dans un cercle donné, une corde mobile* AB, *inclinée à 45° sur un diamètre* MN, *est divisée par ce diamètre en deux parties* CA, CB, *dont les carrés ont une somme constante.*

I. — (Ex. 1316.) Les projections des segments CA, CB, sur le diamètre MN, ou sur le diamètre perpendiculaire à MN, sont respectivement égales au sinus et au cosinus d'un même angle.

II. — Soient R le rayon du cercle, et d la distance du centre à la corde AB.

On a : $\mathrm{CA} = \sqrt{\mathrm{R}^2 - d^2} + d, \quad \mathrm{CB} = \sqrt{\mathrm{R}^2 - d^2} - d$;

d'où $\overline{\mathrm{CA}}^2 + \overline{\mathrm{CB}}^2 = 2\mathrm{R}^2$.

III. — Soit B′ le symétrique du point B par rapport à MN. L'angle ABB′ étant égal à 45°, la corde AB′ est le côté du carré inscrit.
Le triangle rectangle ACB′ donne :

$$\overline{\mathrm{CA}}^2 + \mathrm{CB}^2 = \overline{\mathrm{AB'}}^2 = 2\mathrm{R}^2.$$

207. — *Dans deux circonférences concentriques, les distances d'un point mobile sur l'une, aux extrémités d'un diamètre quelconque de l'autre, ont une somme de carrés constante.*

(Ex. 1317.)

208. Théorème de Faure. — *Par rapport à deux cercles orthogonaux* B, C, *tout point de la circonférence décrite sur* BC *comme diamètre, a deux puissances égales et de signes contraires.*

I. — (Ex. 1319.)

II. — (Voir quest. 729-B.)

209. — *On considère deux cercles orthogonaux* B, C, *et un point* M *mobile sur un cercle quelconque ayant pour centre le milieu* O *de* BC.

Montrer que les puissances du point M *par rapport aux cercles* B *et* C, *ont une somme constante.*

I. — (Ex. 1320.)

II. — Cette propriété subsiste quand les cercles A, B, ne sont pas orthogonaux. (Quest. 729-A.)

210. — *On considère trois cercles* A, B, O, *qui passent par les mêmes points* C, D, *et tels que le centre* O *soit le milieu de* AB.

Démontrer que les puissances de tout point du cercle O, *par rapport aux cercles* A *et* B, *ont une somme nulle.*

I. — (Ex. 1321.)

II. — (Quest. 729-B.)

211. Théorèmes d'Archimède. — *Dans tout quadrilatère orthodiagonal inscrit à un cercle donné, les diagonales se partagent en quatre segments dont les carrés ont une somme constante, égale à la somme des carrés des côtés opposés.*

(Bacc. Lyon.)

I. — (Ex. 1323.)

II. — (Ex. de Méc. 1129.)

212. — *Dans un cercle donné, si deux cordes rectangulaires pivotent sur un point fixe, leurs carrés ont une somme constante.*

I. — (Ex. 1325.)

II. — (Ex. de Méc. 1129.)

212-A. — *On considère tous les quadrilatères à diagonales rectangulaires inscrits dans un cercle donné. — Montrer que la somme des carrés des quatre côtés est constante.*

(Bacc. Dijon, 1908.)

I. — Soient a, b, c, d, les quatre côtés; $2m$, $2n$, les diagonales; M, N, P, leurs milieux et leur intersection, formant le rectangle OMPN.

Le théorème d'Euler donne :

$$a^2+b^2+c^2+d^2=4(m^2+n^2+\overline{\mathrm{MN}}^2).$$

Or on a : $m^2+n^2=(\mathrm{R}^2-\mathrm{OM})^2+(\mathrm{R}^2-\overline{\mathrm{ON}}^2)=2\mathrm{R}^2-\overline{\mathrm{MN}}^2.$

Donc $$a^2+b^2+c^2+d^2=8\mathrm{R}^2.$$

II. — *Dans un quadrilatère inscrit à diagonales rectangulaires, on peut construire un triangle rectangle ayant pour hypoténuse le diamètre du cercle circonscrit et pour côtés de l'angle droit deux côtés opposés* AB, CD, *ou* BC, DA. (Quest. 35-A.)

Traçons la corde CA′ parallèle à BD. AA′ est un diamètre. Le côté CD se reporte en BA′, et BC en DA′.

Les deux triangles AA′B, AA′D, répondent à la question.

D'après cela, on a séparément :

$$a^2+c^2=4R^2 \quad \text{et} \quad b^2+d^2=4R^2.$$

212-B. — *Par le centre* O *d'un triangle équilatéral* ABC, *on mène un axe quelconque* Ox, *sur lequel les trois sommets se projettent en* A′, B′, C′. *Montrer que la somme* $(\overline{AA'}^2+\overline{BB'}^2+\overline{CC'}^2)$ *est indépendante de la direction attribuée à* Ox. (Bacc. Dijon.)

Soient $OA=1$ et $xOA=\alpha$.

La somme en question peut s'écrire :

$$\sin^2\alpha+\sin^2\left(\alpha+\frac{2\pi}{3}\right)+\sin^2\left(\alpha+\frac{4\pi}{3}\right)=\frac{3}{2}.$$

(Ex. de Trigonométrie, nº 62.)

212-C. — *Par le centre* O *de deux cercles concentriques* α, β, *on mène un cercle* φ *qui coupe ces cercles aux points* A, A′; B, B′.

1º *Si les rayons* OA, OA′, *coupent* β *en* M, M′, *et si* OB, OB′, *coupent* α *en* N, N′, *les droites* MM′, NN′, *se confondent, et coupent le cercle* φ *aux mêmes points* C, C′.

2º *Les droites* MBF, NB′E, *recoupent le cercle* φ *au milieu* E *de l'arc* AB, *et au milieu* F *de l'arc* ABB′.

3º *Le point* E *est le centre du cercle* AMBN, *le point* F *est le centre du cercle* AMB′N′.

4º *Le point* E *est l'orthocentre du triangle* OMF, *et le point* F *est l'orthocentre de* OME.

5º *Les quadrilatères* OMEN, OMFN′, *sont inscriptibles.*

6º *Les deux couples de points* E, N; F, N′, *sont alignés sur le point* A′.

1º Si le point C est déterminé par MM′, les triangles équiangles OMC, OCA, donnent : $\overline{OC}^2=OA.OM.$

Si le point C est déterminé par NN′, les triangles équiangles ONC, OCB, donnent : $\overline{OC}^2=OB.ON.$

Le point C est le même dans les deux cas, puisqu'on a :

$$OA.OM=OB.ON.$$

D'après ces relations, *la droite* OC *est tangente en* C *à chacun des cercles* CAM *et* CBN.

2º Chacun des triangles OMB, OMB′, est isocèle. En comparant, dans le cercle φ, les mesures de leurs angles égaux, on trouve :

$$\text{arc } EA=EB \quad \text{et} \quad \text{arc } FBA=FB'.$$

3º Le milieu E de l'arc AB appartient à la médiatrice des cordes parallèles MB, AN.

4º Le milieu F de l'arc ABB′ appartient à la médiatrice des cordes parallèles MB′, AN′.

Enfin EF est la médiatrice de AM, puisqu'on a :

$$FB' = FA = FM.$$

5° Dans le cercle φ, les angles NOE, NME, ont même mesure, ainsi que les angles N'OF, N'MF.

6° La droite MM' fait des angles égaux avec les droites NE, NA', et avec les droites N'F, N'A'.

§ II. — Lieux géométriques.

212-A. — *Dans un cercle* O, *on considère deux diamètres rectangulaires* AA', BB', *et un point* M *qui se meut sur* BB' *et se projette en* M' *sur la tangente en* A. — *Lieu du point* P *où se croisent les droites* AM, A'M'.

Les droites AM', MA', se coupent en un point C.
Le point P est le barycentre de A'AC. Donc il décrit une droite parallèle à AC.

212-B. — *On considère un point fixe* A *dans le plan d'un cercle* O, *et un point* M *mobile sur ce cercle. Les deux bissectrices de l'angle* AOM *coupent* AM *en des points* P, P', *dont on demande le lieu.*

D'après la propriété des bissectrices, on a :

$$\frac{AP}{AM} = -\frac{AP'}{AM} = \frac{OA}{OA + OM} = C^{te}.$$

Donc P et P' décrivent deux cercles symétriques par rapport au point A, et homothétiques au cercle O par rapport à ce point A.

212-C. — *Dans un triangle variable* ABC, *l'angle* A *reste fixe, et le côté* BC *se déplace parallèlement à lui-même. Lieux des contacts de la droite* BC *avec les quatre cercles tritangents.*

Toutes les positions de la figure sont homothétiques par rapport au point A. Donc tous ses points décrivent des droites passant par le point A.

212-D. — *On considère deux droites fixes* Ox, Oy, *et un point* M *mobile sur* Ox. *Par ce point* M *on mène le cercle tangent en* O *à* Oy, *et le cercle inscrit dans l'angle* xOy. — *Ces deux cercles se recoupent en un point* P *dont on demande le lieu.*

Toutes les positions de la figure sont homothétiques par rapport au point O. Donc le point P décrit une droite passant par le point O.

213. — *Lieu des points* P *dont les distances à deux droites fixes* OA, OB, *sont dans un rapport donné* k. (Bacc. Dijon, 1905.)

3D Geometry

Figure 8.1.
3D objects: Guggenheim Museum in Bilbao, Spain. Designed by Frank Gehry.

This chapter introduces the essential building blocks of 3D geometry by first extending the 2D tools from Chapters 2 and 3 to 3D. But beyond that, we will also encounter some concepts that are truly 3D, i.e., those that do not have 2D counterparts. With the geometry presented in this chapter, we will be ready to create and analyze simple 3D objects, which then could be utilized to create forms such as in Figure 8.1.

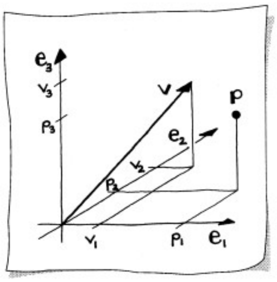
8.1 From 2D to 3D

Moving from 2D to 3D geometry requires a coordinate system with one more dimension. Sketch 8.1 illustrates the $[\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3]$-system which consists of the vectors

$$\mathbf{e}_1 = \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix}, \quad \mathbf{e}_2 = \begin{bmatrix} 0 \\ 1 \\ 0 \end{bmatrix}, \quad \text{and} \quad \mathbf{e}_3 = \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix}.$$

Thus, a *vector* in 3D is given as

$$\mathbf{v} = \begin{bmatrix} v_1 \\ v_2 \\ v_3 \end{bmatrix}. \tag{8.1}$$



Sketch 8.1.

The $[\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3]$-axes, a point, and a vector.

The three *components* of $\mathbf{v}$ indicate the displacement along each axis in the $[\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3]$-system. This is illustrated in Sketch 8.1. A 3D vector $\mathbf{v}$ is said to live in 3D space, or $\mathbb{R}^3$, that is $\mathbf{v} \in \mathbb{R}^3$. The 3D *zero vector* will be represented as

$$\mathbf{0} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix}.$$

A *point* is a reference to a *location*. Points in 3D are given as

$$\mathbf{p} = \begin{bmatrix} p_1 \\ p_2 \\ p_3 \end{bmatrix}. \tag{8.2}$$

The *coordinates* indicate the point's location in the $[\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3]$-system, as illustrated in Sketch 8.1. A point $\mathbf{p}$ is said to live in Euclidean 3D space, or $\mathbb{E}^3$, that is $\mathbf{p} \in \mathbb{E}^3$. The origin is denoted as $\mathbf{o}$.

All the rules for combining points and vectors in 2D from Section 2.2 carry over to 3D. In Section 2.5, we defined the fundamental operation for points, the *barycentric combination*, and it looks the same in 3D:

$$\mathbf{r} = (1 - t)\mathbf{p} + t\mathbf{q},$$

however now $\mathbf{p}, \mathbf{q}, \mathbf{r} \in \mathbb{E}^3$. The scalar values $(1 - t)$ and t are called the *barycentric coordinates* of $\mathbf{r}$ with respect to $\mathbf{p}$ and $\mathbf{q}$. In Section

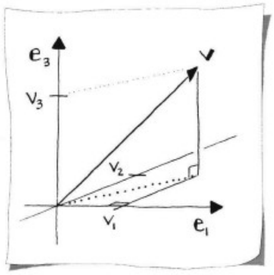
2.6 we defined the *linear combination* as a fundamental operation for vectors,

$$\mathbf{u} = r\mathbf{v} + s\mathbf{w},$$

where $\mathbf{v}, \mathbf{w}, \mathbf{u} \in \mathbb{R}^3$ and r, s are scalars. Both of these operations provide the tools to create new geometry in terms of existing geometry. Importantly, they ensure coordinate independent operations.

Sketch 8.2 illustrates a 3D vector $\mathbf{v}$ along with its components. Notice the two right triangles. Applying the *Pythagorean theorem* twice, the *length* or *Euclidean norm* of $\mathbf{v}$, denoted as $\|\mathbf{v}\|$, is

$$\|\mathbf{v}\| = \sqrt{v_1^2 + v_2^2 + v_3^2}. \tag{8.3}$$



Sketch 8.2.
Length of a 3D vector.

The length or magnitude of a 3D vector can be interpreted as distance, speed, or force.

Scaling a vector by an amount k yields $\|k\mathbf{v}\| = |k|\|\mathbf{v}\|$. Also, a *normalized vector* has unit length, $\|\mathbf{v}\| = 1$.

Example 8.1

We will get some practice working with 3D vectors. The first task is to normalize the vector

$$\mathbf{v} = \begin{bmatrix} 1 \\ 2 \\ 3 \end{bmatrix}.$$

First calculate the length of $\mathbf{v}$ as $\|\mathbf{v}\| = \sqrt{1^2 + 2^2 + 3^2} = \sqrt{14}$, then the normalized vector $\mathbf{w}$ is

$$\mathbf{w} = \frac{\mathbf{v}}{\|\mathbf{v}\|} = \frac{1}{\sqrt{14}} \begin{bmatrix} 1 \\ 2 \\ 3 \end{bmatrix} \approx \begin{bmatrix} 0.27 \\ 0.53 \\ 0.80 \end{bmatrix}.$$

Check for yourself that $\|\mathbf{w}\| = 1$.

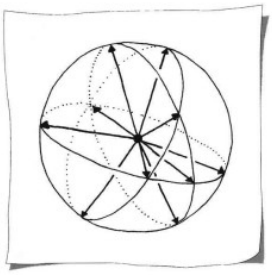
Scale $\mathbf{v}$ by $k = 2$:

$$2\mathbf{v} = \begin{bmatrix} 2 \\ 4 \\ 6 \end{bmatrix}.$$

Now calculate $\|2\mathbf{v}\| = \sqrt{2^2 + 4^2 + 6^2} = 2\sqrt{14}$. Thus we verified that $\|2\mathbf{v}\| = 2\|\mathbf{v}\|$.

◇□◆

There are infinitely many 3D unit vectors. In Sketch 8.3 a few of these are drawn emanating from the origin. The sketch is a sphere of radius one.



Sketch 8.3.
All 3D unit vectors define a sphere.

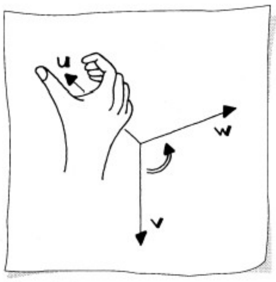
In Section 2.7, we derived the dot product for 2D vectors. That development is easy to apply to 3D vectors: the *dot product* of two 3D vectors, $\mathbf{v}$ and $\mathbf{w}$, becomes

$$\mathbf{v} \cdot \mathbf{w} = v_1 w_1 + v_2 w_2 + v_3 w_3.$$

The *cosine* of the angle θ between the two vectors can be determined as

$$\cos\theta = \frac{\mathbf{v} \cdot \mathbf{w}}{\|\mathbf{v}\|\|\mathbf{w}\|}. \tag{8.4}$$

8.2 Cross Product



Sketch 8.4.
Characteristics of the cross product.

The dot product is a type of multiplication for two vectors which reveals geometric information, namely the angle between them. However, this does not reveal information about their orientation in relation to $\mathbb{R}^3$. Two vectors define a plane. It would be useful to have yet another vector in order to create a 3D coordinate system that is *embedded* in the $[\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3]$-system. This is the purpose of another form of vector multiplication called the *cross product.*

In other words, the cross product of $\mathbf{v}$ and $\mathbf{w}$, written as

$$\mathbf{u} = \mathbf{v} \wedge \mathbf{w},$$

produces the vector $\mathbf{u}$ which satisfies the following:

1. The vector $\mathbf{u}$ is perpendicular to $\mathbf{v}$ and $\mathbf{w}$, that is
$$\mathbf{u} \cdot \mathbf{v} = 0 \quad \text{and} \quad \mathbf{u} \cdot \mathbf{w} = 0.$$
2. The orientation of the vector $\mathbf{u}$ follows the *right-hand rule.* This means that if you curl the fingers of your right hand from $\mathbf{v}$ to $\mathbf{w}$, your thumb will point in the direction of $\mathbf{u}$. See Sketch 8.4.
3. The magnitude of $\mathbf{u}$ is the area of the parallelogram defined by $\mathbf{v}$ and $\mathbf{w}$.

Because the cross product produces a vector, it is also called a *vector product.*

Synthesis of Planar Stiffness

J. M. Selig(✉)

School of Engineering, London South Bank University, London, U.K.
`seligjm@lsbu.ac.uk`

Abstract. In this work the problem of designing systems of springs to achieve a desired stiffness matrix is considered. Only planar configurations are studied. After a brief section outlining the theory of the stiffness of planar systems the planar stiffness matrix of three typical design elements are found, simple springs, beams and pairs of stretched springs. A final section shows how arbitrary stiffness matrices can be achieved using three simple springs or two stretched spring pairs.

Keywords: Stiffness matrix · Springs · Beams

1 Introduction

The synthesis of stiff or compliant systems is an important area of mechanism theory and robotics. There are many previous works in this area, see for example, [3–5]. Most of these concentrate on the problem of synthesising spatial stiffness matrices using so-called simple springs. These simple springs have zero natural length and are un-stretched. In this work the simpler problem of synthesising planar stiffnesses is considered. Using simple springs gives a mathematically interesting problem related to the secant varieties of a certain Veronese variety. More practical are simple beams and pairs of stretched springs, these are also considered.

2 Planar Rigid-Body Geometry

Here the basic geometric entities of points and lines are introduced and the action of the group of rigid-body displacement on these elements is described. As usual, given a coordinate frame, points can be represented as vectors,

$$\boldsymbol{p} = \begin{pmatrix} p_x \\ p_y \end{pmatrix},$$

where p_x and p_y are the coordinates of the points in the fixed coordinate frame. It is often be more convenient to represent points using extended vectors,

$$\tilde{p} = \begin{pmatrix} \boldsymbol{p} \\ 1 \end{pmatrix} = \begin{pmatrix} p_x \\ p_y \\ 1 \end{pmatrix}.$$

An advantage of this representation is that it extends easily to projective space $\mathbb{P}^2$. This space has homogeneous coordinates, $(x : y : w)$ and two sets of these homogeneous coordinates represent the same point in $\mathbb{P}^2$ if they are of the form $(x : y : w)$ and $(\lambda x : \lambda y : \lambda w)$ for some non-zero number λ. Thinking of points in the plane as points in the projective plane does however, introduce some extra points. The points with third homogeneous coordinate $w = 0$ do not correspond to any points in the plane. They are usually referred to as points at infinity. In the projective plane these ideal points constitute a line.

The group $SE(2)$ acts by the familiar homogeneous representation on the extended points,

$$\begin{pmatrix} \boldsymbol{p} \\ 1 \end{pmatrix} \longmapsto \begin{pmatrix} R & \boldsymbol{t} \\ 0 & 1 \end{pmatrix} \begin{pmatrix} \boldsymbol{p} \\ 1 \end{pmatrix}$$

where, as usual,

$$R = \begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{pmatrix} \quad \text{and} \quad \boldsymbol{t} = \begin{pmatrix} t_x \\ t_y \end{pmatrix}$$

are respectively the rotation matrix and translation vector of the displacement.

In 2 dimensions lines are dual elements to points. The equation for a point to lie on a line is given by,

$$n_x p_x + n_y p_y = d$$

where d is the perpendicular distance from the line to the origin of coordinates and $\boldsymbol{n} = (n_x, n_y)^T$ is the unit normal vector to the line. If lines are represented by 3-vectors of the form,

$$\ell = \begin{pmatrix} \boldsymbol{n} \\ -d \end{pmatrix} = \begin{pmatrix} n_x \\ n_y \\ -d \end{pmatrix},$$

then the relation above can be represented by the pairing,

$$\ell^T \tilde{p} = 0.$$

That is, the point $\tilde{p}$ lies on the line ℓ if and only if $\ell^T \tilde{p} = 0$.

Again, it is often useful to think of these as homogeneous coordinates of a $\mathbb{P}^2$. Notice that ℓ and $\lambda\ell$ give the same line if λ is non-zero, although now $\lambda\boldsymbol{n}$ is no longer a unit vector and λd is not the perpendicular distance from the origin to the line. Thinking of lines as elements of a $\mathbb{P}^2$ means that the "line at infinity" must be included. This is the line with homogeneous coordinates $\ell_\infty = (0, 0, 1)^T$, on which the points at infinity $\tilde{p} = (x, y, 0)^T$, lie.

Thinking of lines as dual to points means that it is easy to see that lines transform under the inverse-transpose representation of the group. That is the dual representation of the group,

$$\begin{pmatrix} \boldsymbol{n} \\ -d \end{pmatrix} \longmapsto \begin{pmatrix} R & 0 \\ -\boldsymbol{t}^T R & 1 \end{pmatrix} \begin{pmatrix} \boldsymbol{n} \\ -d \end{pmatrix}$$

Since,

$$\begin{pmatrix} R & \boldsymbol{t} \\ 0 & 1 \end{pmatrix}^{-T} = \begin{pmatrix} R & 0 \\ -\boldsymbol{t}^T R & 1 \end{pmatrix}.$$

Twists are elements of the Lie algebra of the group, $SE(2)$ here. They can be thought of as infinitesimal rigid displacements. The Lie algebra of $SE(2)$ can be found from first principles or simply by abridging the results for the spatial case $SE(3)$, see [8]. So a general twist in the plane can be written as a 3-component vector,

$$\mathbf{s} = \begin{pmatrix} \omega \\ \boldsymbol{v} \end{pmatrix} = \begin{pmatrix} \omega_z \\ v_x \\ v_y \end{pmatrix}$$

where $\boldsymbol{v}$ is the linear velocity of a point instantaneously coincident with the origin and ω_z is the angular velocity of the body or lamina in this case. Under a rigid displacement these transform according to yet another representation of the group,

$$\begin{pmatrix} \omega \\ \boldsymbol{v} \end{pmatrix} \longmapsto \begin{pmatrix} 1 & 0 \\ J\boldsymbol{t} & R \end{pmatrix} \begin{pmatrix} \omega \\ \boldsymbol{v} \end{pmatrix}, \quad \text{where} \quad J = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$$

Again, this can be found by computing the adjoint representation for $SE(2)$ or by looking at the adjoint representation of $SE(3)$ which is more widely known.

In the plane almost all twists are infinitesimal rotations about some point in the plane. So it is possible to associate points and twists. The mapping from twists to points is given by,

$$\mathbf{s} \longmapsto \widetilde{L}\mathbf{s} = \begin{pmatrix} J\boldsymbol{v} \\ \omega \end{pmatrix} = \tilde{p}, \quad \text{where} \quad \widetilde{L} = \begin{pmatrix} 0 & J \\ 1 & 0 \end{pmatrix} = \begin{pmatrix} 0 & 0 & 1 \\ 0 & -1 & 0 \\ 1 & 0 & 0 \end{pmatrix}.$$

These matrices satisfy $J^T = J^{-1} = -J$ and $\widetilde{L}^{-1} = \widetilde{L}$.

Notice that, here points in the plane are represented by points in the projective space $\mathbb{P}^2$. Hence the centre of rotation of the twist $\mathbf{s}$ is given by the point $\boldsymbol{c} = (c_x,\, c_y)^T$ where,

$$c_x = v_y/\omega, \quad \text{and} \quad c_y = -v_x/\omega.$$

This shows that, when $\omega = 0$ and the motion is an instantaneous translation, there is no finite centre of rotation. The extension of the map to the projective space $\mathbb{P}^2$ maps infinitesimal translations to points at infinity.

In 3 dimensions the combination of the torque and force acting on a rigid body is called a wrench. Wrenches are dual to twists, in 2-dimensions the abridged version of the wrench will be another 3-component vector this time with the form,

$$\mathbf{w} = \begin{pmatrix} \tau \\ \boldsymbol{f} \end{pmatrix} = \begin{pmatrix} \tau_z \\ f_x \\ f_y \end{pmatrix},$$

where τ_z is the torque, and f_x and f_y the components of the force acting on the lamina. The duality is given by the pairing,

$$\mathbf{w}^T\mathbf{s} = \tau_z\omega_z + f_x v_x + f_y v_y$$

which gives the power, a scalar.

The effect of a rigid displacement on a wrench can be found from the duality. The dual representation is the inverse transpose of the representation for the twists, so given by,

$$\begin{pmatrix} 1 & 0 \\ J\boldsymbol{t} & R \end{pmatrix}^{-T} = \begin{pmatrix} 1 & 0 \\ -R^T J\boldsymbol{t} & R^T \end{pmatrix}^{T} = \begin{pmatrix} 1 & \boldsymbol{t}^T JR \\ 0 & R \end{pmatrix}.$$

The action of a rigid displacement on a wrench is thus,

$$\begin{pmatrix} \tau \\ \boldsymbol{f} \end{pmatrix} \longmapsto \begin{pmatrix} 1 & \boldsymbol{t}^T JR \\ 0 & R \end{pmatrix} \begin{pmatrix} \tau \\ \boldsymbol{f} \end{pmatrix}$$

The line of action of the force gives a natural association between wrenches and lines. The line of action of a wrench $\mathbf{w}$ is given by the map,

$$\mathbf{w} \longmapsto \widetilde{L}^T\mathbf{w} = \begin{pmatrix} J\boldsymbol{f} \\ \tau \end{pmatrix} = \ell.$$

Again this map is defined on projective space, non-zero constants multiplying every coordinate are irrelevant. The line associated with a pure torque is the line at infinity.

Notice that if a screw and a wrench are dual, that is if $\mathbf{w}^T\mathbf{s} = 0$, then the point associated with the twist lies on the line associated to the wrench,

$$\ell^T\tilde{p} = \mathbf{w}^T\widetilde{L}\widetilde{L}\mathbf{s} = \mathbf{w}^T\mathbf{s} = 0,$$

since, $\widetilde{L}^2 = I$. This means that if the lamina is instantaneously rotating about a point on the axis of the applied force then no work is being done on the lamina.

3 Stiffness Matrices

Consider a lamina attached to a number of springs in the plane. Alternatively the lamina could be subject to some conservative force field. Stationary points of the potential energy correspond to equilibria of the lamina. At such an equilibrium configuration the Hessian matrix of the potential is the stiffness matrix of the configuration, see [6]. The Hessian is the matrix of second derivatives at the configuration and this gives an extended form of Hooke's law,

$$\mathbf{w} = K\mathbf{s}$$

where $\mathbf{w}$ is the wrench applied to the lamina, $\mathbf{s}$ is the resulting infinitesimal twist and K the stiffness matrix. The stiffness matrix is a symmetric matrix and from physical considerations is also positive definite.

In the plane, all non-singular stiffness matrices are diagonalisable. This is not the same as saying that any 3×3 symmetric matrix is diagonalisable because we want the stiffness matrix to be diagonalisable by rigid-body displacements, not by arbitrary non-singular matrices or even orthogonal matrices. So we need to know how the group $SE(2)$ acts on stiffness matrices. Since a stiffness matrix K, transforms a twist into a wrench the expression, $\mathbf{s}_1^T K \mathbf{s}_2$ is a scalar, so if the compliant element and the screws all undergo a rigid displacement or we just change the coordinates we are working in, this quantity must remain constant. This implies that under a rigid displacement the stiffness matrix K will transform according to,

$$K \longmapsto \begin{pmatrix} 1 & 0 \\ J\boldsymbol{t} & R \end{pmatrix}^{-T} K \begin{pmatrix} 1 & 0 \\ J\boldsymbol{t} & R \end{pmatrix}^{-1} = \begin{pmatrix} 1 & \boldsymbol{t}^T J R \\ 0 & R \end{pmatrix} K \begin{pmatrix} 1 & 0 \\ -R^T J\boldsymbol{t} & R^T \end{pmatrix}$$

Writing the stiffness matrix in partitioned form,

$$K = \begin{pmatrix} q & \boldsymbol{k}^T \\ \boldsymbol{k} & \Upsilon \end{pmatrix},$$

a pure translation of $\boldsymbol{t}$ will give,

$$K' = \begin{pmatrix} 1 & \boldsymbol{t}^T J \\ 0 & I \end{pmatrix} \begin{pmatrix} q & \boldsymbol{k}^T \\ \boldsymbol{k} & \Upsilon \end{pmatrix} \begin{pmatrix} 1 & 0 \\ -J\boldsymbol{t} & I \end{pmatrix} = \begin{pmatrix} q' & \boldsymbol{k}^T + \boldsymbol{t}^T J \Upsilon \\ \boldsymbol{k} - \Upsilon J \boldsymbol{t} & \Upsilon \end{pmatrix},$$

where $q' = q - \boldsymbol{k}^T J\boldsymbol{t} + \boldsymbol{t}^T J \boldsymbol{k} - \boldsymbol{t}^T J \Upsilon J \boldsymbol{t}$. Choosing $\boldsymbol{t} = -J\Upsilon^{-1}\boldsymbol{k}$, the stiffness matrix becomes,

$$K' = \begin{pmatrix} q' & \mathbf{0}^T \\ \mathbf{0} & \Upsilon \end{pmatrix}.$$

Notice that, with this choice for $\boldsymbol{t}$ we get $q' = q - \boldsymbol{k}^T \Upsilon^{-1} \boldsymbol{k}$. Now we can use standard theory to diagonalise this symmetric 2×2 matrix Υ, with a rotation. This result is well known, but seems to be difficult to find in the literature. When the stiffness matrix is in diagonal form we will assume the diagonal entries are k_1^2, k_2^2 and k_3^2.

Next we turn to the invariants of the stiffness matrix K. That is we seek functions of the entries of K which are invariant with respect to a rigid change in coordinates or rigid displacement. We can expect these to be symmetric polynomials in the diagonal elements of diagonalisation of K. The determinant of K is clearly an invariant since it is an invariant under the group $SL(3)$ it must also be an invariant under the subgroup $SE(2)$. The determinant of the diagonal stiffness matrix is just the product of the stiffnesses, $\det(K) = k_1^2 k_2^2 k_3^2$. Notice that after a translation the bottom right 2×2 block of K is unchanged. A rotation will change this block to,

$$\Upsilon \longmapsto R \Upsilon R^T$$

So rotational invariants of this block will be invariant under all of $SE(2)$. The invariants in question are $\det(\Upsilon) = k_2^2 k_3^2$ and $\mathrm{Tr}(\Upsilon) = k_2^2 + k_3^2$.

Next, a few examples will be considered, the first of these is a simple spring. This is an idealised component but the following two examples are a little more practical.

The simple spring is an idealisation of real springs, simple springs can be thought of as un-stretched springs with zero natural length. These elements are determined by lines in the plane. Given a line $\ell = (n_x,\, n_y,\, -d)^T$, the spring will only generate a wrench in the direction of the line, $\mathbf{w} = k\widetilde{L}\ell$, where k is a constant The wrench produced by the simple spring is only in response to a small motion in the direction of the line, that is $\mathbf{w}^T\mathbf{s} \neq 0$ when $\mathbf{s}$ is a translation in the direction of ℓ but is zero for the orthogonal direction and infinitesimal rotations. This means that we can write the stiffness matrix as,

$$K = \mathbf{w}\mathbf{w}^T = k^2\widetilde{L}\ell\ell^T\widetilde{L} = k^2 \begin{pmatrix} d^2 & dn_y & -dn_x \\ dn_y & n_y^2 & -n_xn_y \\ -dn_x & -n_xn_y & n_x^2 \end{pmatrix},$$

where k^2 is knows as the stiffness constant of the spring. Usually this is stated the other way around—the wrench produces a small motion of the spring.

If we think of lines ℓ as points in a projective plane $\mathbb{P}^2$ and stiffness matrices as points in a projective space $\mathbb{P}^5$ then the above is clearly a Veronese embedding. Hence the space of all possible simple springs is the degree 4, Veronese surface, see [2].

Next we consider simple beams. Again, here we can just restrict the stiffness matrix of the 3D beam, see [7]. The stiffness matrix of the slender planar beam aligned with the x-axis is thus,

$$K = \begin{pmatrix} \frac{EI_y}{l} & 0 & 0 \\ 0 & \frac{EA}{l} & 0 \\ 0 & 0 & \frac{12EI_y}{l^3} \end{pmatrix},$$

where l is the length of the beam, E is its Young's modulus, A its cross-sectional area and I_y the second moment of area. Note that, the stiffness matrix shown here is expressed in a coordinate frame whose origin is located at the centre of the beam and with the x-axis directed along the beam.

The space of these simple beams is a little more complicated than the simple springs. First we need to decide what to hold constant. For example, we could imagine that the beams that we have available are all made of the same material and have the same cross-section and length l. If this is the case then the space of all beams or rather the stiffness matrices of these beams is just the stiffness matrices which can be generated by rigid displacements of the diagonal stiffness matrix above. From the previous section it is clear that the diagonalisation of an arbitrary stiffness matrix is unique. Hence, the space of simple beams must be an embedding of the group manifold of $SE(2)$. This is well known to be isomorphic to the real projective space $\mathbb{P}^3$ with a single line deleted, see [1].

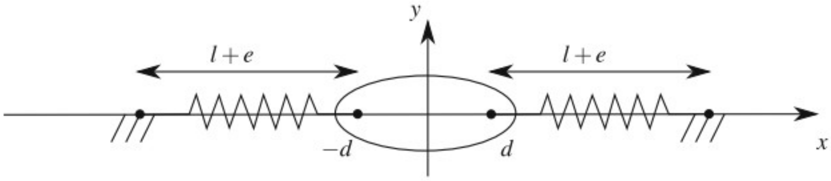

Fig. 1. A pair of stretched springs.

We can find several homogeneous equations satisfied by the stiffness matrices of simple beams. All that is needed is to find relations between the invariants of the matrices. These can be evaluated on the diagonal matrix given above,

$$\begin{aligned}\det(K) &= \frac{12\,AE^3I_y^2}{l^5},\\ \det(\Upsilon) &= \frac{12\,AE^2I_y}{l^4},\\ \mathrm{Tr}(\Upsilon) &= \left(\frac{EA}{l}+\frac{12EI_y}{l^3}\right) = \frac{E}{l^3}(Al^2+12I_y).\end{aligned}$$

These invariants are of degree $3, 2$ and 1 respectively, in the elements of the stiffness matrix. So we can write a quadratic equation,

$$12\,AI_yl^2\mathrm{Tr}(\Upsilon)^2 - (Al^2+12I_y)^2\det(\Upsilon) = 0,$$

and a couple of cubic equations,

$$12\,AI_yl^4\mathrm{Tr}(\Upsilon)^3 - (Al^2+12I_y)^3\det(K) = 0$$

and

$$I_yl^2\mathrm{Tr}(\Upsilon)\det(\Upsilon) - (Al^2+12I_y)\det(K) = 0$$

and finally a degree 6 equation,

$$12\,A\det(K)^2 - l^2I_y\det(\Upsilon)^3 = 0.$$

Presumably these four equations do not give a complete intersection in $\mathbb{P}^5$ but rather define a 3-dimensional rational variety.

If we assume that the simple beams can have different lengths then the space of all simple beams will be 4-dimensional. The equations defining this variety can be found by eliminating l from the equations. Notice that the final degree 6 equation can be rearranged to isolate l^2 and the other three equations only contain l^2 or powers of l^2.

The final example here are stretched spring pairs. Consider the system of springs shown in Fig. 1. The springs have natural length l but in the equilibrium position illustrated are extended by an amount e. The springs are attached to the body at points a distance $2d$ apart. The stiffness matrix of this arrangement can be found from the results in [6],

$$K = 2\lambda e \begin{pmatrix} d(1+\frac{d}{l+e}) & 0 & 0 \\ 0 & \frac{1}{e} & 0 \\ 0 & 0 & \frac{1}{l+e} \end{pmatrix},$$

where λ is the stiffness constant of the springs. It is, of course, possible to find homogeneous equations for the space of all stretched spring pairs using the same method we saw for the space of beams above.

4 Synthesis

Given a stiffness matrix, perhaps the specification of how one part of a machine needs to move with respect to another part, how can we select springs or beams to realise the given stiffness matrix? Unfortunately standard decomposition theorems of symmetric matrices don't apply here. The standard theory is based on eigenvalues and eigenvectors, these only make sense if the matrix represents a linear map from a space to itself or a map between Euclidean spaces. The matrix K here is a map from twist space to wrench space, neither of these spaces is Euclidean.

It is important to note that if these systems of springs are combined in parallel the stiffness matrix of the result is simply the sum of the stiffness matrices of the component systems. Care must be taken however, to ensure that the stiffness matrices are expressed in the same coordinate system before they are added.

At the end of Sect. 3 it was observed that the space of simple springs determine a Veronese surface in the $\mathbb{P}^5$ of all stiffness matrices. This is a two dimensional variety with degree $2^2 = 4$, [2]. By varying the modulus of stiffness of the springs we can produce all possible stiffness matrices lying on the line joining the stiffness matrices of the two simple springs. This is a chord or secant line to the surface. The closure of all such secant lines forms the secant variety to the surface. It is well known that the secant variety to the Veronese surface is a cubic hypersurface in $\mathbb{P}^5$ given by vanishing of a 3×3 determinant. Simple counting of dimensions would suggest that the secant variety to a surface should be 5-dimensional, however for the Veronese surface it is only 4-dimensional. This means that three simple springs will be needed to synthesise a general 2-D stiffness matrix. For singular stiffness matrices only one or two simple springs will be required.

Let K be an arbitrary stiffness matrix, as we saw in Sect. 3, there will be a rigid change of coordinates $M = \begin{pmatrix} 1 & 0 \\ J\boldsymbol{t} & R \end{pmatrix}$, which diagonalises K

$$M^T K M = \begin{pmatrix} k_1^2 & 0 & 0 \\ 0 & k_2^2 & 0 \\ 0 & 0 & k_3^2 \end{pmatrix}.$$

In Sect. 3 diagonalisation was effected using a displacement, a coordinate transformation just uses the inverse transformation.

Now consider the following three lines,

$$\ell_1 = \begin{pmatrix} 1 \\ 0 \\ -1/\sqrt{2} \end{pmatrix}, \quad \ell_2 = \begin{pmatrix} -1/2 \\ \sqrt{3}/2 \\ -1/\sqrt{2} \end{pmatrix}, \quad \ell_3 = \begin{pmatrix} -1/2 \\ -\sqrt{3}/2 \\ -1/\sqrt{2} \end{pmatrix}.$$

These are the edges of an equilateral triangle with the origin as centre. The corresponding wrenches are,

$$\mathbf{w}_1 = \frac{k_1\sqrt{3}}{\sqrt{2}} \begin{pmatrix} -1/\sqrt{2} \\ 0 \\ 1 \end{pmatrix}, \quad \mathbf{w}_2 = \frac{k_1\sqrt{3}}{\sqrt{2}} \begin{pmatrix} -1/\sqrt{2} \\ -\sqrt{3}/2 \\ -1/2 \end{pmatrix}, \quad \mathbf{w}_3 = \frac{k_1\sqrt{3}}{\sqrt{2}} \begin{pmatrix} -1/\sqrt{2} \\ \sqrt{3}/2 \\ -1/2 \end{pmatrix}.$$

Notice that all these springs have stiffness constant $k_1\sqrt{3}/\sqrt{2}$. A straightforward computation confirms that,

$$\mathbf{w}_1\mathbf{w}_1^T + \mathbf{w}_2\mathbf{w}_2^T + \mathbf{w}_3\mathbf{w}_3^T = k_1^2 \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

So we can write

$$M^T K M = \Lambda U(\mathbf{w}_1\mathbf{w}_1^T + \mathbf{w}_2\mathbf{w}_2^T + \mathbf{w}_3\mathbf{w}_3^T)U^T\Lambda$$

where $\Lambda = \begin{pmatrix} 1 & 0 & 0 \\ 0 & k_2/k_1 & 0 \\ 0 & 0 & k_3/k_1 \end{pmatrix}$ and U is an arbitrary 3×3 orthogonal matrix, an element of $O(3)$. Now writing,

$$\mathbf{v}_i = M^{-T}\Lambda U\mathbf{w}_i, \qquad i = 1,\, 2,\, 3$$

we get the decomposition,

$$K = \mathbf{v}_1\mathbf{v}_1^T + \mathbf{v}_2\mathbf{v}_2^T + \mathbf{v}_3\mathbf{v}_3^T.$$

Moreover, this gives all possible such decompositions for a non-singular stiffness matrix K, different choices are given by different orthogonal matrices U.

In terms of simple springs this means that we can decompose a stiffness matrix K into a system of three simple springs placed along the lines,

$$\ell_i' = \widetilde{L}\mathbf{v}_i, \qquad i = 1,\, 2,\, 3,$$

Next we consider stretched spring pairs. For a general stiffness matrix in 2D we need at least two stretched string pairs. As above, we can assume that the stiffness matrix has been diagonalised by some rigid-body displacement M, so that we can write,

$$K = \begin{pmatrix} k_1^2 & 0 & 0 \\ 0 & k_2^2 & 0 \\ 0 & 0 & k_3^2 \end{pmatrix}.$$

Assuming that we cannot change the stiffness of the material that the springs are made from means that we cannot use the secant variety to the space of spring pairs to synthesise the stiffness matrix. A possible strategy is to combine pairs with diagonal stiffness matrices. For example, suppose we rotate the pair by a quarter turn, such a pair can have a different extension e_2 and separation d_2 to the original pair e_1 and d_1. The stiffness matrix of such a perpendicular arrangement of pairs will give a stiffness matrix,

$$K = 2\lambda e_1 \begin{pmatrix} d_1(1+\frac{d_1}{l+e_1}) & 0 & 0 \\ 0 & \frac{1}{e_1} & 0 \\ 0 & 0 & \frac{1}{l+e_1} \end{pmatrix} + 2\lambda e_2 \begin{pmatrix} d_2(1+\frac{d_2}{l+e_2}) & 0 & 0 \\ 0 & \frac{1}{l+e_2} & 0 \\ 0 & 0 & \frac{1}{e_2} \end{pmatrix}.$$

Comparing this with the target stiffness gives 3 equations,

$$\begin{aligned} k_1^2 &= 2\lambda\left(e_1d_1 + e_2d_2 + \frac{e_1d_1^2}{l+e_1} + \frac{e_2d_2^2}{l+e_2}\right), \\ k_2^2 &= 2\lambda\left(1 + \frac{e_2}{l+e_2}\right), \\ k_3^2 &= 2\lambda\left(1 + \frac{e_1}{l+e_1}\right). \end{aligned}$$

The last two of these equations are easily solved,

$$e_1 = \left(\frac{k_3^2 - 2\lambda}{4\lambda - k_3^2}\right) l \quad \text{and} \quad e_2 = \left(\frac{k_2^2 - 2\lambda}{4\lambda - k_2^2}\right) l.$$

These result give limits on the stiffnesses that can be synthesised with such springs, if the extension is to be positive then we must have, $2\lambda < k_2^2 < 4\lambda$ and the same for k_3^2.

The first of the equations above would give many solutions for d_1 and d_2, so it seems reasonable to set $d_1 = d_2 = d$. This gives a quadratic equation for d,

$$\left(\frac{e_1}{l+e_1} + \frac{e_2}{l+e_2}\right) d^2 + (e_1 + e_2)d - \frac{k_1^2}{2\lambda} = 0.$$

From the pattern of sign changes in the coefficients, this has one positive real solution for d, and this will give a stable equilibrium for the system.

An alternative solution might be to use a couple of identical spring pairs but move them relative to each other. Suppose we have two identical diagonal stiffness matrices and we subject them to either equal but opposite translations or equal but opposite rotations. The composite will be a diagonal stiffness matrix. For example, if we rotate the stiffness matrices of two stretched string pairs by θ and compare the combined system with the desired diagonal stiffness we get the following three equations,

$$k_1^2 = 4\lambda\left(ed + \frac{ed^2}{l+e}\right),$$
$$k_2^2 = 4\lambda\left(\cos^2\theta + \frac{e}{l+e}\sin^2\theta\right),$$
$$k_3^2 = 4\lambda\left(\sin^2\theta + \frac{e}{l+e}\cos^2\theta\right).$$

Adding the last two equations eliminates the angle so that we can solve for the extension,

$$e = \left(\frac{k_2^2 + k_3^2 - 4\lambda}{8\lambda - k_2^2 - k_3^2}\right) l.$$

Again, this gives limits on the stiffnesses which can be synthesised using this method with positive extensions e. Subtracting the last two equations gives a linear equation for $\cos(2\theta)$,

$$\cos(2\theta) = \frac{k_2^2 - k_3^2}{8\lambda - k_2^2 - k_3^2},$$

since $l + e = (4\lambda l)/(8\lambda - k_2^2 - k_3^2)$. Finally d can be found as the unique positive real solution to the quadratic equation in d given by the first equation above.

5 Conclusions

Similar techniques to those outlined above could be used to synthesis a desired stiffness from simple beams. We could also consider other compliant design elements. It was possible to find all possible designs using three simple springs, it would be useful to find all possible solutions for pairs of stretched springs and other stiffness elements.

It would also be useful to extend these ideas to 3 dimensional stiffness. However, in 3D a general stiffness matrix cannot necessarily be diagonalised with a rigid-body displacement. This makes the general problem of the synthesis of stiffness in 3D much more difficult.

For small values of θ we can make the approximation that:

$$\theta_{\text{radians}} = h/f,$$

where θ is measured in radians (see Figure 1.2 for an explanation of radian measure).

Expressing θ in arcseconds:

$$\theta_{\text{arcsec}} = 206\,265 \times h/f$$

From which:

$$\theta_{\text{arcsec}}/h = 206\,265/f$$

Now, θ_{arcsec}/h is the *image scale* – the linear distance in the focal plane that corresponds to a given angular distance in the sky/distant object.

$$\therefore \textbf{ Image scale} = \mathbf{206\,265/}\boldsymbol{f}$$

If the focal length of the lens is measured in millimetres, then the image scale is in arcseconds per millimetre. For example, suppose that the diameter of the Moon subtends an angle of 2000 arcseconds. If the lens has a focal length of 1000 mm then the image scale in its focal plane is, to 3 significant figures, 206 arcseconds per millimetre. The focused image of the Moon will, in this case, be just under 10 mm across.

The image scale in the focal plane actually varies with the distance from the optical axis, though only by a negligible amount for small values of θ.

Aperture, focal ratio and light grasp

The *aperture* (diameter), focal length and *focal ratio* of our hypothetical lens are related by:

$$\text{Focal ratio} = \text{focal length/aperture},$$

the aperture and the focal length being expressed in the same units.

The light collected by the lens is proportional to its area, and is thus proportional to the square of its aperture:

$$\text{Light grasp} \propto (\text{aperture})^2$$

Diffraction and resolution

It is an oversimplification to say that a lens, even a perfect one, will form a truly point image of a point object. In practice the image will consist of a

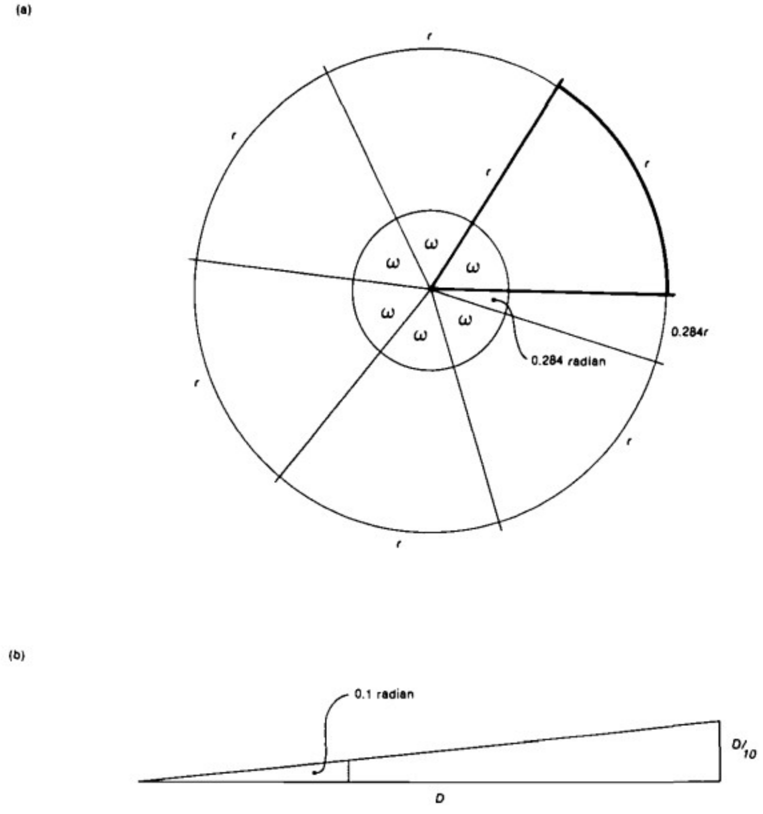

Figure 1.2. Radian measure. Consider a circle of radius r. If an arc of length equal to r is drawn along the circumference, the angle that the arc subtends from the centre of the circle is defined to be 1 radian. This is illustrated in (a) by the boldly outlined sector. In this diagram the angle ω is equal to 1 radian. Since the circumference of a circle is equal to 2π (6.284) times its radius, it follows that there are 2π radians in 360°. Hence:

$$\begin{aligned} 1\ \mathit{radian} &= 360°/2\pi = 57°.29578 \\ &= 206\,265\ \mathit{arcseconds}. \end{aligned}$$

In general, if the arc length is l and the radius of the arc is R, then the angle, θ, is given by:

$$\begin{aligned} \theta\ (\text{in radians}) &= l/R, \\ \text{or } \theta\ (\text{in arcseconds}) &= 206\,265\ l/R \end{aligned}$$

Diagram (b) shows the concept of the radian applied to smaller angles. In this case the angle subtended by a length $D/10$ (notice that the distiction between a straight line and an arc can be ignored for small angles) from a distance D is equal to 0.1 radian.

diffraction pattern, an effect caused by the wave nature of the light passing through the restricted aperture of the lens.

The diffraction pattern that our hypothetical lens might form of a star is represented, at a very large scale, in Figure 1.3. It consists of a central bright disc, the *Airy disc*, surrounded by concentric rings of decreasing brightness. The diffraction pattern of a star produced by a perfect lens has 84 per cent of the light energy contained in the Airy disc. The remainder of the light energy is shared amongst the more diffuse rings.

The diameter of the diffraction pattern is inversely proportional to the diameter of the lens producing it. Hence **larger** apertures produce **smaller** diffraction patterns. This effect is of crucial importance when the lens is used to image fine details. For instance, consider the case of two close stars being imaged by a lens of given aperture. The size of the aperture sets the sizes of the diffraction pattern images of each star. If the stars are too close together their diffraction patterns will merge and the stars will appear as one. In order to resolve the two stars as separate a lens of larger aperture must be used. Figure 1.4 (a), (b) and (c) illustrates the cases of two stars which are not resolved as separate, just resolved, and easily resolved, respectively.

The relationship between the limiting resolution of a lens and its aperture is expressed mathematically by the equation:

$$R = 206\,265 \times \frac{1.22\lambda}{d}$$

where R is the minimum angular separation of a pair of stars in order to be just resolved, measured in arcseconds; λ is the wavelength of the light being imaged and d is the diameter of the lens. Both λ and d are measured in the same units, for instance both in metres, or both in centimetres, etc.

You should notice that the resolution of the lens is wavelength dependent. The wavelength of light to which the eye is most sensitive is taken as 5.5×10^{-7}m (This corresponds to the yellow-green part of the spectrum). A perfect lens of 0.1m aperture should then be able to resolve two stars separated by 1.4 arcseconds when used visually.

Another formula for resolving power at visual wavelengths is that derived empirically by Dawes:

$$R = 4.56/D,$$

where R is the minimum resolvable separation of two stars in arcseconds, as before, and D is the aperture expressed in inches (1 inch = 25.4 mm). Dawes' formula predicts a minimum separation for resolution about 20 per

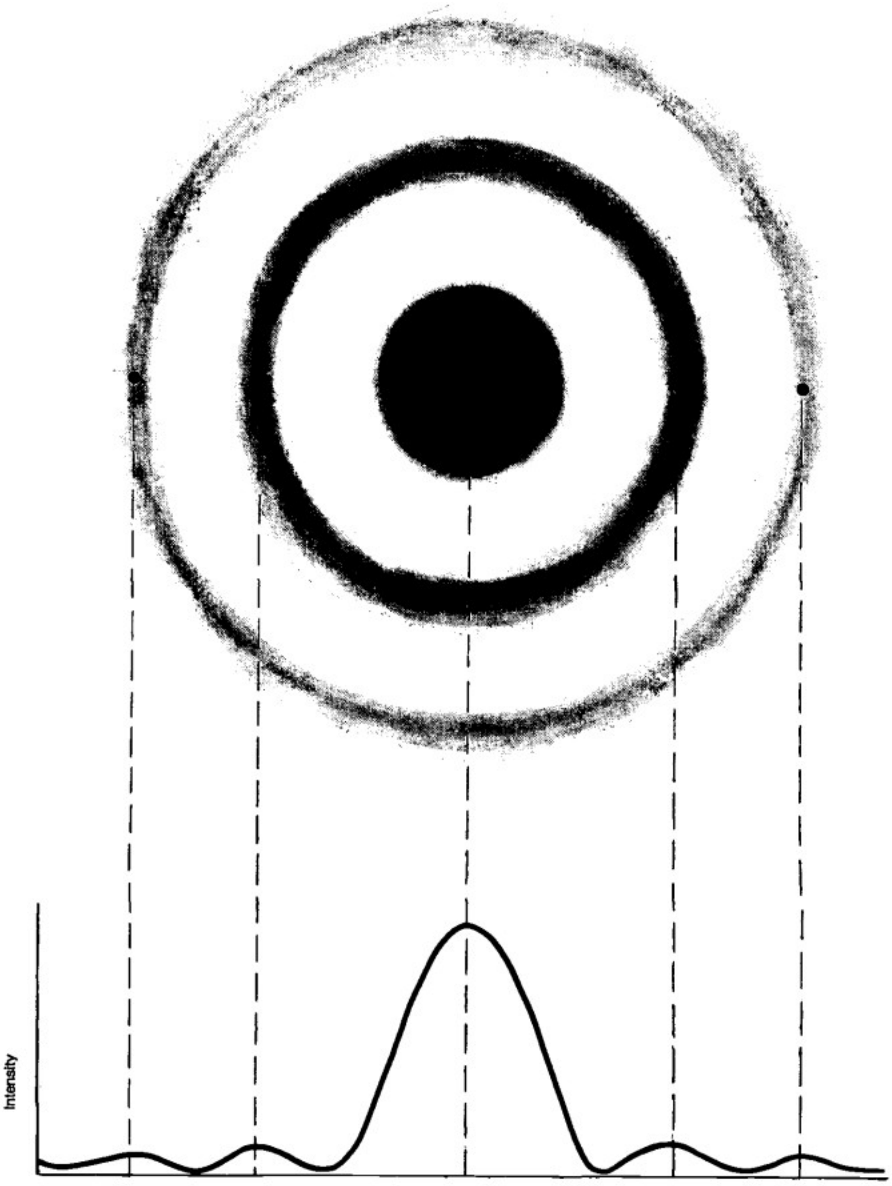

Figure 1.3. A representation of the diffraction pattern of a point source as seen through a limited aperture. The graph below illustrates the variation of the intensity of the light across the diameter of the diffraction pattern.

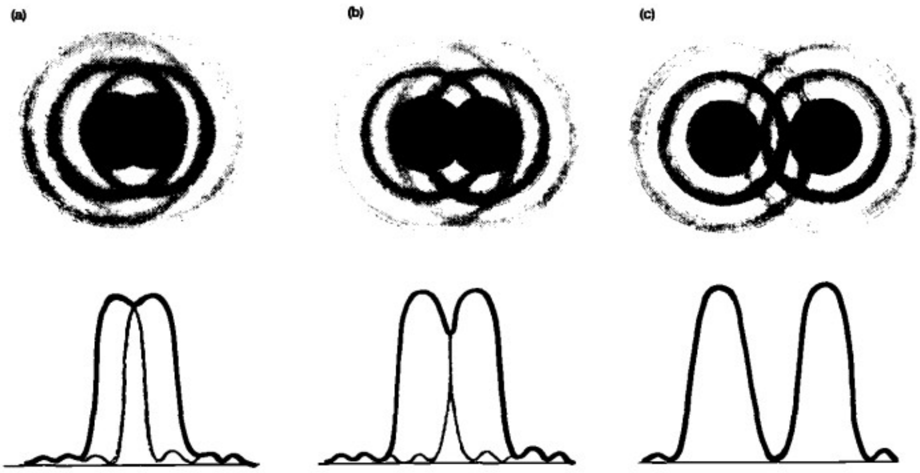

Figure 1.4. The overlapping diffraction patterns produced by two stars as seen through a given aperture. In (a) the stars are too close together to be resolved as separate. In (b) the stars are just resolvable and in (c) the stars are easily resolved.

cent closer than that of the mathematically derived formula but double star observers have found it to be more accurate in practice. Strictly, Dawes' formula applies to a pair of double stars of the sixth magnitude. Brighter stars, and those of unequal brightness, are less easily resolved.

The image of an extended object (anything which does not appear as a point), such as the surface of the Moon or a planet, can be thought of as a series of overlapping diffraction patterns. Here, too, the smaller diffraction patterns produced by larger apertures enable finer detail to be resolved. The situation has been compared to viewing a mosaic made of tiles. The finest details that can be seen in the mosaic are the size of the individual tiles. Making the mosaic from smaller tiles allows finer details to be represented.

The simple refractor

Figure 1.5(a) illustrates the optical principles of the simple refractor. Here the object glass and eyepiece are each represented as single lenses. The single-arrowed light rays originate from the top of some distant object and the double-arrowed light rays originate from the bottom of it. The object glass forms an inverted image of the object at position *I*. This is the object glass' focal plane.

When in normal adjustment, the eyepiece's focal plane is also made to

Chapter 10

PARALLEL POSTULATES

> [Euclid's Fifth Postulate] ought to be struck from the postulates altogether. For it is a theorem — one that invites many questions ... — and requires for its demonstration a number of definitions as well as theorems. ... it lacks the special character of a postulate.
>
> — Proclus (Greek, 410–485) [**AT**: Proclus], p. 151

PARALLEL LINES ON THE PLANE ARE SPECIAL

Up to this point we have not had to assume anything about parallel (non-intersecting) lines. No version of a parallel postulate has been necessary, on the plane, on a sphere, or on a hyperbolic plane. We defined the concrete notion of parallel transport and proved in Problem **8.2** that, on the plane (and hyperbolic planes), parallel transported lines do not intersect. Now in this chapter we will look at three important properties on the plane that require further assumptions and that will be needed in later chapters. If you are willing to assume these three statements, you may skip this chapter, but we urge you to finish reading through at least the next page.

> *If two lines on the plane are parallel transports of each other along some transversal, then they are parallel transports along any transversal.* (Contained in Problem **10.1**)

> *On the plane, the sum of the interior angles of a triangle is always* 180°. (Contained in Problem **7.3b** or Problem **10.2**)

On the plane, non-intersecting lines are parallel transports along all transversals. (Contained in Problem **10.3d**)

We have already seen that none of these properties is true on a sphere or a hyperbolic plane. Thus all three need for their proofs some property of the plane that does not hold on spheres and hyperbolic planes. The various properties that permit proofs of these three statements are collectively termed the ***Parallel Postulates***.

Only the three statements above are needed from this chapter for the rest of the book. Therefore, it is possible to omit this chapter and assume one of the above three statements and then prove the others. However, parallel postulates have a historical importance and a central position in many geometry textbooks and in many expositions about non-Euclidean geometries. The problems in this chapter are an attempt to help people unravel and enhance their understanding of parallel postulates. Comparing situations on the plane with situations on a sphere and on a hyperbolic plane is a powerful tool for unearthing our hidden assumptions and misconceptions about the notion of "parallel" on the plane.

As we discussed already in Chapter 8, because we have so many (often unconscious) connotations and assumptions attached to the word "parallel," we find it best to avoid using the term "parallel" as much as possible in this discussion. Instead we will use terms such as "parallel transport," "non-intersecting," and "equidistant," which make explicit the meaning that is intended.

PROBLEM 10.1 PARALLEL TRANSPORT ON THE PLANE

Show that if l_1 and l_2 are lines on the plane such that they are parallel transports along a transversal l, then they are parallel transports along any transversal. Prove this using any assumptions you find necessary. Make as few assumptions as you can, and make them as simple as possible. ***Be sure to state your assumptions clearly.***

What part of your proof does not work on a sphere or on a hyperbolic plane?

SUGGESTIONS

This problem is by no means as trivial as it at first may appear. In order to prove this theorem, you will have to assume something — there are many possible assumptions, so use your imagination. But at the same time, try not to assume any more than is necessary. If you are having trouble deciding what to assume, try to solve the problem in a way that seems natural to you and then see what develops while making explicit any assumptions you are using.

On spheres and hyperbolic planes, try the same construction and proof you used for the plane. What happens? You should find that your proof does not work on these surfaces. So what is it about your proof (on a sphere and hyperbolic plane) that creates difficulties?

Problem **10.1** emphasizes the differences between parallelism on the plane and parallelism on spheres and hyperbolic planes. On the plane, non-intersecting lines exist, and one can "parallel transport" everywhere. Yet, as was seen in Problems **8.2** and **8.3**, on spheres and hyperbolic planes two lines are cut at congruent angles if and only if the transversal line goes through the center of symmetry formed by the two lines. That is, on spheres and hyperbolic planes two lines are parallel transports only when they can be parallel transported through the center of symmetry formed by them. Be sure to draw a picture locating the center of symmetry and the transversal. On spheres and hyperbolic planes it is impossible to slide the transversal along two parallel transported lines while keeping both angles constant (something you *can* do on the plane). In Figures 10.1, the line r' is a parallel transport of line r along line l, but it is not a parallel transport of r along l'.

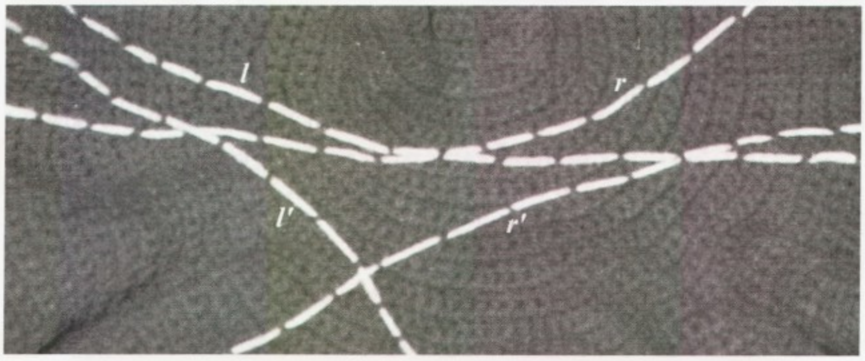

Figure 10.1a Parallel transport on a hyperbolic plane along l but not along l'

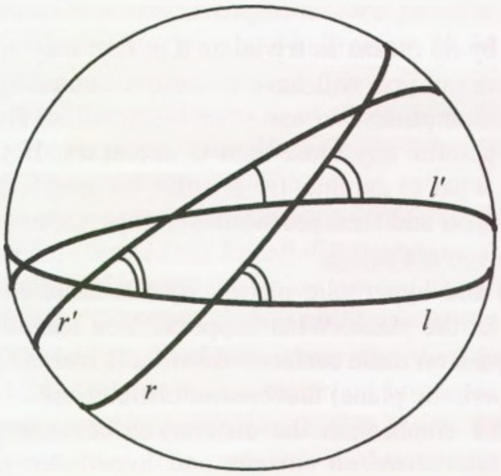

Figure 10.1b Parallel transport on a sphere along *l*, but not along *l'*

Pause, explore, and write out your ideas before reading further.

We will now divide parallel postulates into three groups: those involving mostly parallel transport, those involving mostly equidistance, and those involving mostly intersecting or non-intersecting lines. This division is useful even though it is rough and unlikely to fit every conceivable parallel postulate. *Which of these three groups is the most appropriate for your assumption from Problem* **10.1**? We will call the assumption you made in Problem **10.1** "*your parallel postulate.*"

PROBLEM 10.2 PARALLEL POSTULATES NOT INVOLVING (NON-)INTERSECTING LINES

Commonly used postulates of this sort are

H = 0: *The holonomy of triangles is zero.*

A = 180: *The sum of the angles of a triangle is equal to 180°.*

> **PT!**: *If two lines are parallel transports (PT) along one line then they are PT along ALL transversals.*

Note that these are false on spheres and on hyperbolic planes. The last two properties (**A = 180** and **PT!**) will be needed crucially in almost all the remaining chapters (and you may have already used one of them in Problem **9.4**). These properties are needed to study (on the plane) parallelograms, rectangles, and similar triangles (Chapters 12 and 13), circles and inversion (Chapters 15 and 16), projections of spheres and hyperbolic planes onto the Euclidean plane (Chapters 14 and 17), Euclidean manifolds (Chapters 18 and 24), solutions to quadratic and cubic equations (Chapter 19), trigonometry (Chapter 20), and polyhedra in 3-space (Chapter 23). It is these properties and their uses that we most often associate with consequences of the parallel postulates.

In Problem **7.3b** we proved **A = 180** on the plane, so we can

a. *Ask what assumption about the plane was used in proving* **7.3b**.

b. *Use* **A = 180** *to prove* **PT!**.

Look first at transversals that intersect the line along which the two lines are parallel transports.

c. *Using* **PT!** (Problem **10.1**), *prove* **A = 180** *without using results from Chapter 7.*

Start by parallel transporting one side of the triangle.

d. *Show that, on the plane,* **H = 0 ⇔ A = 180 ⇔ PT!**. *If your postulate from* **10.1** *is in this group, then show that it is also equivalent to the others.*

This is usually accomplished most efficiently by proving **H = 0 ⇒ A = 180 ⇒ PT! ⇒** Your Postulate **⇒ H = 0**, or in any other order.

e. *Prove that, on the plane, two parallel transported lines are equidistant.*

Look for rectangles or parallelograms.

EQUIDISTANT CURVES ON SPHERES AND HYPERBOLIC PLANES

The latitude circles on the earth are sometimes called "parallels of latitude." They are parallel in the sense that they are everywhere equidistant as are concentric circles on the plane. In general, transversals do not cut equidistant circles at congruent angles. However, there is one important case where transversals do cut the circles at congruent angles. Let l and l' be latitude circles the same distance from the equator on opposite sides of it. See Figure 10.2. Then every point on the equator is a center of half-turn symmetry for these pair of latitudes. Thus, as in Problems **8.3** and **10.1**, every transversal cuts these latitude circles in congruent angles, even though these latitude circles are not geodesics. In the first section of Chapter 2 we noted that Euclid, in his *Phenomena,* discussed such equidistant circles.

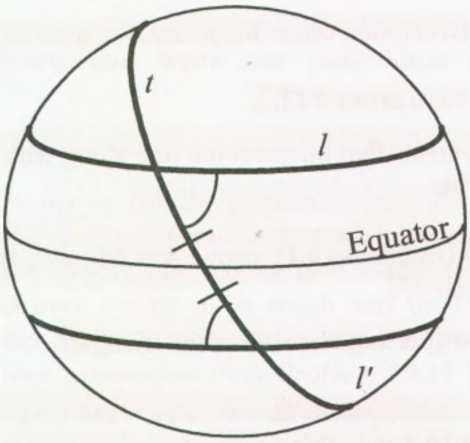

Figure 10.2 Special equidistant circles

The same ideas work on a hyperbolic plane: If g is a geodesic and l and l' are the (two) curves (not geodesics) that are a distance d from g, then l and l' are equidistant from each other and every transversal cuts them at congruent angles. This follows from the fact that g has half-turn symmetry at every point.

PROBLEM 10.3 PARALLEL POSTULATES INVOLVING (NON-)INTERSECTING LINES

One of Euclid's assumptions constitutes ***Euclid's Fifth (or Parallel) Postulate (EFP)***, which says

> **EFP:** *If a straight line intersecting two straight lines makes the interior angles on the same side less than two right angles, then the two lines (if extended indefinitely) will meet on that side on which are the angles less than two right angles.*

For a picture of EFP, see Figure 10.3.

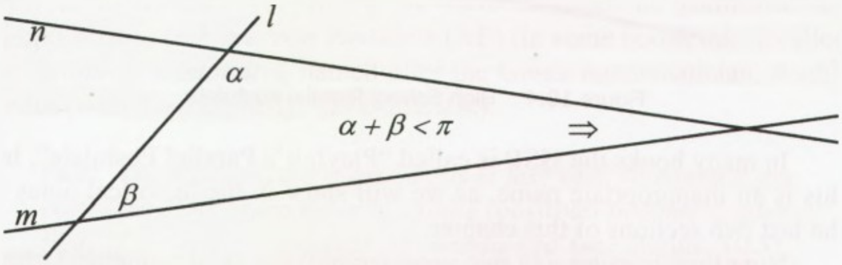

Figure 10.3 Euclid's Parallel Postulate

You probably did not assume EFP in your proof of Problem **10.1**. You are in good company — many mathematicians, including Euclid, have tried to avoid using it as much as possible. However, we will explore EFP because, historically, it is important, and because it has some very interesting properties, as you will see in Problem **10.3**. On a sphere, all straight lines intersect twice, which means that EFP is trivially true on a sphere. But in Problem **10.4**, you will show that EFP is also true in a stronger sense on spheres. You will also be able to prove that EFP is false on a hyperbolic plane.

Thus, EFP does not have to be assumed on a sphere — it can be proved! However, in most high school geometry textbooks, EFP is replaced by another postulate, claimed to be equivalent to EFP. This postulate we will call the ***High School Parallel Postulate*** (***HSP***), and it can be expressed in the following way:

> **HSP:** *For every line **l** and every point **P** not on **l**, there is a unique line **l'** that passes through **P** and does not intersect (is parallel to) **l**.*

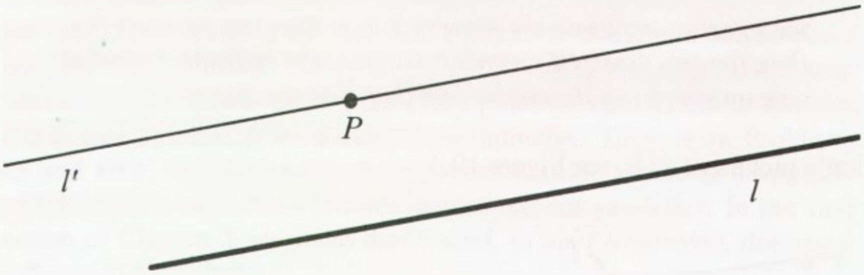

Figure 10.4 High School Parallel Postulate

In many books the **HSP** is called "Playfair's Parallel Postulate", but this is an inappropriate name, as we will show in the historical notes in the last two sections of this chapter.

Note that, because any two great circles on a sphere intersect, there are *no* lines l' that are parallel to l in the "not intersecting" sense. Therefore, **HSP** is not true on spheres. On the other hand, if we change "parallel" to "parallel transport" then *every* great circle through P is a parallel transport of l along *some* transversal. What happens on a hyperbolic plane? In Problem **10.3**, you will explore the relationships among **EFP**, **HSP**, and your postulate from Problem **10.1**. In Problem **10.4** we will explore these postulates on spheres and hyperbolic planes.

a. *Show that, on the plane,* **EFP** *and* **HSP** *are equivalent. If your postulate from* **10.1** *is in this group, is it equivalent to the others? Why or why not?*

To show that **EFP** and **HSP** are equivalent on the plane, you need to show that you can prove **EFP** if you assume **HSP** and vice versa. If the three postulates are equivalent, then you can prove the equivalence by showing that

$$\textbf{EFP} \Rightarrow \textbf{HSP} \Rightarrow \text{Your Postulate} \Rightarrow \textbf{EFP}$$

or in any other order. It will probably help you to draw lots of pictures of what is going on. Also, remember that we proved in Problem **8.2** (without using any parallel postulate) that parallel (non-intersecting) lines exist. Note that **HSP** is not true on a sphere but **EFP** is true, so your proof that **EFP** implies **HSP** on the plane must use some property of the plane that does not hold on a sphere. Look for it.

b. *Prove that either* **EFP** *or* **HSP** *can be used to prove* (*without using* **10.1** *or* **7.3b**) *one of* **H = 0**, **A = 180**, or **PT!**. (It does not matter which. *Why*?)

So, are all these postulates equivalent to each other on the plane? The answer is almost, but not quite! In order for **A = 180** (or **H = 0** or **PT!**) to imply **EFP** (or **HSP**), we have to make an additional assumption, the ***Archimedean Postulate*** (**AP**) (in some books this is called the *Axiom of Continuity*), named after the Greek mathematician, Archimedes (who lived in Sicily, 287?–212 B.C.):

> ***AP**: *On a line, if the segment AB is less than* (contained in) *the segment AC, then there is a finite* (positive) *integer, n, such that, if we put n copies of AB end-to-end* (see Figure 10.5), *then the* n^{th} *copy will contain the point C.*

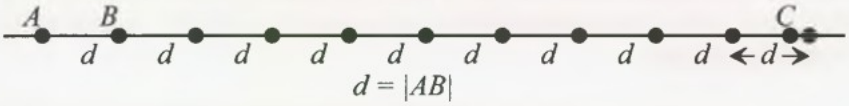

Figure 10.5 The Archimedean Postulate

The Archimedean Postulate can also be interpreted to rule out the existence of infinitesimal lengths. The reason these postulates are "almost but not quite" equivalent to each other on the plane is that, though **AP** is needed, it is assumed by most people to be true on the plane, spheres, and hyperbolic planes. But this is the first time we have needed this assumption in this book.

***c.** *Show that, on the plane,* **AP** *and* **A = 180** *imply* **EFP**.

Look at the situation of **EFP**, which we redraw in Figure 10.6. Pick a sequence of equally spaced points *A*, *A'*, *A''*,... on *n* (on the side of the angle α). Next, parallel transport l along m to lines l', l'',... that intersect n at the points A', A'',... . And parallel transport m along l to m', m'',..., which also intersect n at the points A', A'',... . Look for congruent angles and congruent triangles. Use **AP** to argue that n and m will eventually intersect.

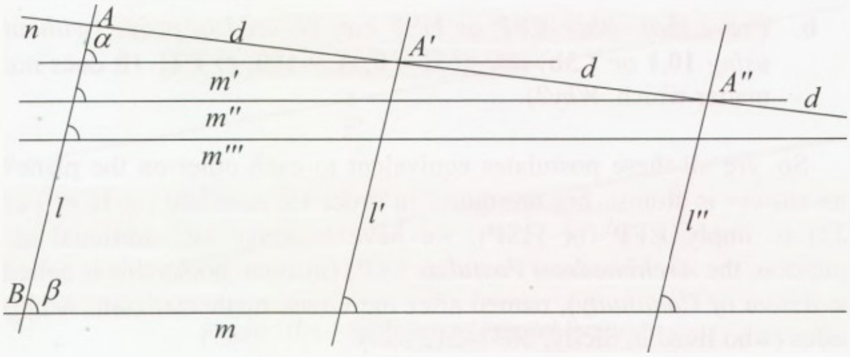

Figure 10.6 **AP** and **A = 180** imply **EFP**

Clearly, this proof feels different from the others proofs in this chapter. And, as already pointed out, most of the applications in this book of parallel postulates only need **A = 180** and **PT!**. So is it possible for us not to bother with **EFP** and **HSP**? Or are they needed? Yes, we need them, but only in a few places, such as in Problem **11.3**, where what we need to know is

d. Prove using **EFP**: *On the plane, non-intersecting lines are parallel transports along every transversal.*

Compare with **EFP**.

PROBLEM 10.4 EFP AND HSP ON SPHERE AND HYPERBOLIC PLANE

a. *Show that **EFP** is true on a sphere in a strong sense; that is, if lines **l** and **l′** are cut by a transversal **t** such that the sum of the interior angles $\boldsymbol{\alpha} + \boldsymbol{\beta}$ on one side is less than two right angles, then not only do **l** and **l′** intersect, but they also intersect closest* *to **t** on the side of α and β. You will have to determine an appropriate meaning for "closest."*

To help visualize the postulates, draw these "parallels" on an actual sphere. There are really two parts in this proof — first, you must come up with a definition of "closest," and then prove that **EFP** is true for this definition. The two parts may come about simultaneously as you come up with a proof. This problem is closely related to Euclid's Exterior Angle Theorem but can also be proved without using **EEAT**. One case that you should look at specifically is pictured in Figure 10.7. It is not necessarily obvious how to define the "closest" intersection.

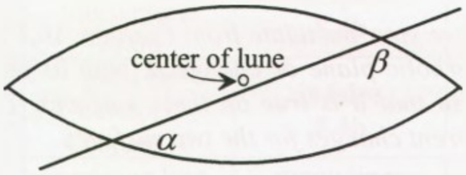

Figure 10.7 Is **EFP** true on a sphere?

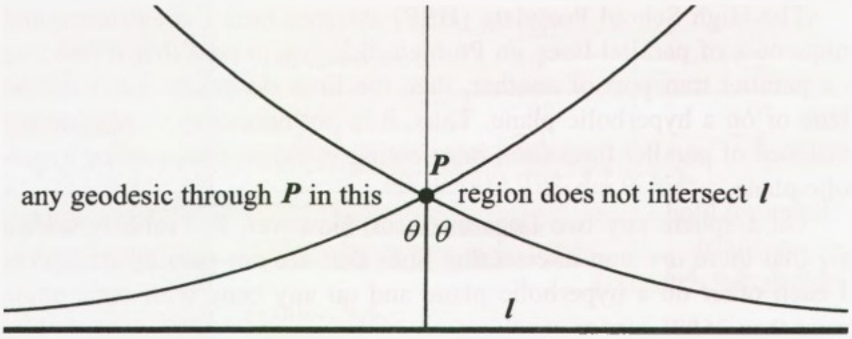
b. *On a hyperbolic plane let **l** be a geodesic and let **P** be a point not on **l**; then show that there is an angle θ with the property that any line **l′** passing through **P** is parallel to* (not intersecting) ***l** if the line **l′** does not form an angle less than θ with the line from **P** that is perpendicular to **l*** (Figure 10.8).



P
any geodesic through P in this
region does not intersect l
θ
θ
l

Figure 10.8 Multiple parallels on a hyperbolic plane

Look at a variable line through P that does intersect l and then look at what happens as you move the intersection point out to infinity.

> **c.** *Using the notion of parallel transport, change the High School Postulate so that the changed postulate is true on both spheres and hyperbolic planes. Make as few alterations as possible and keep some form of uniqueness.*

Try to limit your alterations so that the new postulate preserves the spirit of the old one. You can draw ideas from any of the previous problems to obtain suitable modifications. Prove that your modified versions of the postulate are true on spheres and hyperbolic planes.

> **d.** *Either prove your postulate from Problem* **10.1** *on a sphere and on a hyperbolic plane or change it, with as few alterations as possible, so that it is true on these surfaces. You may need to make different changes for the two surfaces.*

In Problem **10.1** you should have decided whether or not your postulate is true on spheres or on hyperbolic spaces.

COMPARISONS OF PLANE, SPHERES, AND HYPERBOLIC PLANES

Figure 10.9 is an attempt to represent the relationships among parallel transport, non-intersecting lines, **EFP**, and **HSP**. Can you fit your postulate into the diagram?

The High School Postulate (**HSP**) assumes both the existence and uniqueness of parallel lines. In Problem **8.2**, you proved that if one line is a parallel transport of another, then the lines do not intersect on the plane or on a hyperbolic plane. Thus, it is not necessary to assume the existence of parallel lines (non-intersecting lines) on the plane or hyperbolic plane.

On a sphere any two lines intersect. However, in Problem **8.4** we saw that there *are* non-intersecting lines that are not parallel transports of each other on a hyperbolic plane and on any cone with cone angle larger than 360°.

	Euclidean	**Hyperbolic**	**Spherical**
Parallel transported lines	do not intersect and are equidistant **8.2 & 10.2**	diverge in both directions **8.2 & 8.3**	always intersect **2.1**
Parallel transported lines	are parallel transports along all transversals **10.1**	are parallel transports along any transversal that passes through the center of symmetry of the lines **8.3**	
Non-intersecting lines	are parallel transports along all transversals **10.3d**	sometimes are not parallel transports **8.4b**	do not exist **2.1**
Euclid's 5th Postulate	must be assumed Chapter 10	is false **8.4b**	is provable in a strong sense **10.4a**
High School Parallel Postulate	a unique line through a point not intersecting a given line **10.3**	many lines through a point not intersecting a given line **10.4b**	no non-intersecting lines **2.1**
Your postulate from **10.1**			
Two points determine	a unique line and line segment **6.1d**		at least two line segments **6.1d**
Sum of the angles of a triangle	= 180° **7.3b & 10.2**	< 180° **7.1**	> 180° **7.2**
Holonomy	= 0° **10.2**	< 0° **7.4**	> 0° **7.4**
VAT & ITT	are always true, **3.2 & 6.2**		
SAS, ASA, and SSS	hold for all triangles **6.4, 6.5, & 9.1**		hold for small triangles **6.4, 6.5, & 9.1**
AAA	is false, **9.4**, similar triangles	is true, **9.4**, no similar triangles	

Figure 10.9 Comparisons of the three geometries

PARALLEL POSTULATES WITHIN THE BUILDING STRUCTURES STRAND

The problem of parallels puzzled Greek geometers (see the quote at the beginning of this chapter). The prevailing belief was that it surely follows from the straightness of lines that lines like n and m in Figure 10.10 *had* to intersect, and so Euclid's Fifth Postulate would turn out to be unnecessary.

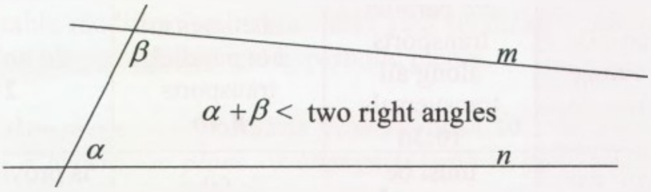


Figure 10.10 Surely these intersect!

During and since the Greek era, there have been attempts to derive the postulate from the rest of elementary geometry; attempts to reformulate the postulate or the definition of parallels into something less objectionable; and descriptions of what geometry would be like if the postulate was in some way denied. Part of these attempts was to study what geometric properties could be proved without using a parallel postulate, but with the other postulates (properties) of the plane. The results of these studies became known as ***absolute geometry***. Both the plane and a hyperbolic plane are examples of absolute geometry. Included in absolute geometry are all the results about the plane and hyperbolic planes that we have discussed in Chapters 1, 3, 5, 6, 8, and 9 (except AAA, Problem **9.4**). In general, absolute geometry includes everything that is true of both the plane and hyperbolic planes.

Claudius Ptolemy (Greek, 100–178) implicitly used what we now call Playfair's Postulate (**PP**) to prove **EFP**. This is reported to us by Proclus (Greek, 410–485) [**AT:** Proclus], who explicitly states **PP**.

> **PP**. *Two straight lines that intersect one another cannot be both parallel to the same straight line.*

Or, in another common wording,

PP. *Given a straight line and a point not on the line, there is at most one straight line through the point that does not intersect the given line.*

Playfair's Parallel Postulate got its current name from the Scottish mathematician John Playfair (1748–1819), who brought out successful editions of Euclid's *Elements* in the years following 1795. After 1800 many commentators referred to Playfair's postulate (**PP**) as the best statement of Euclid's postulate, so it became a tradition in many geometry books to use **PP** instead of **EFP**. The reader can see easily that both **PP** and **EFP** assert the uniqueness of parallel lines and neither asserts the existence of parallel lines. **HSP** seems to have been first stated by Hilbert in the first edition of his *Grundlagen der Geometrie* (but not in the later editions, where he used **PP**) and in [**EG**: Hilbert]. But later, apparently starting in the 1960s, many (but not all) textbooks (including earlier editions of this book!) started calling **HSP** by the name "Playfair's Postulate". In absolute geometry **HSP** is equivalent to **PP** and **EFP** (as you showed in **10.3a**), and because absolute geometry was the focus of many investigations, the statement "**HSP** is equivalent to **EFP**" was made and is still being repeated in many textbooks and expository writings about geometry even when the context is not absolute geometry. As you showed in **10.4a**, **EFP** is true on spheres and so is **PP**, and so they cannot be equivalent to **HSP**, which is clearly false on the sphere.

During the 9th through 12th centuries, parallel postulates were explored by mathematicians in the Islamic world. al-Hasan ibn al-Haytham (Persian, 965–1040) proved **EFP** by assuming, *A quadrilateral with three right angles must have all right angles.* Quadrilaterals with three right angles are known later in Western literature as Lambert quadrilaterals after Johann Lambert (German–Swiss, 1728–1777), who studied them and also was the first to extensively investigate hyperbolic trigonometric functions. The Persian poet and geometer Omar Khayyam (1048–1131) wrote a book that in translation is entitled *Discussion of Difficulties in Euclid* [**AT:** Khayyam 1958]. Khayyam introduces a new postulate (which he attributes to Aristotle, though it has not been found among the surviving works of Aristotle), which says *Two straight lines that start to converge continue to converge.* In his work on parallel lines he studied the Khayyam quadrilaterals (later in the West to be called Saccheri quadrilaterals), which are discussed here in Chapter 12. Nassir al-Din Al-Tusi (Khorasan, 1201–1274) furthered the study of parallel postulates and is credited (though some say it may have been his son) with first proving that **A = 180** *is equivalent to* **EFP**, our **10.3bc**. Al-Tusi's works were the first Islamic mathematical works to be discovered in the Western Renaissance and were published in Rome in 1594.

The assumption *parallel lines are equidistant* (see our **10.2d**) was discussed in various forms by Aristotle (Greek, 383–322 B.C.), Posidonius (Greek, 135–51 B.C.), Proclus, ibn Sina (Uzbek, 980–1037), Omar Khayyam, and Saccheri (Italian, 1667–1733).

John Wallis (English, 1616–1703) proved that **EFP** followed from the assumption *To every triangle, there exists a similar triangle of arbitrary magnitude*. (See our **9.4**.) The works, already mentioned, of Wallis, Saccheri, Lambert in the 17th and 18th centuries were continued by the French school into the early 19th century by Joseph Fourier (French, 1768–1830), who concluded that geometry was a physical science and could not be established a priori, and Adrien-Marie Legendre (1752–1833), who proved that *in absolute geometry the sum of the interior angles of a triangle is always less than or equal to 180°.*

The breakthrough in the study of parallel postulates came in the 19th century when, apparently independently, János Bolyai (Hungarian, 1802–1860), and N. I. Lobachevsky (Russian, 1792–1856) finally developed hyperbolic geometry as an absolute geometry that did not satisfy **EFP**. See Chapters 5 and 17 for more discussions of hyperbolic geometry. These discoveries of hyperbolic geometry showed that the quest for a proof of **EFP** from within absolute geometry is impossible.

For details of the relevant histories, see [**HI**: Gray], [**DG**: McCleary], [**HI**: Rosenfeld], and the Heath's editorial notes in [**AT**: Euclid, *Elements*].

NON-EUCLIDEAN GEOMETRIES WITHIN THE HISTORICAL STRANDS

Building Structures Strand. Because of this long history of investigation into parallel postulates within the Building Structures Strand, many books misleadingly call hyperbolic geometry "*the* non-Euclidean geometry." As pointed out in the introduction to Chapter 2, spherical geometry has been studied since ancient times within the Navigation/Stargazing Strand, but it did not fit into absolute geometry and thus was (and still is) left out of many discussions of non-Euclidean geometry, especially those that take place in the context of the Building Structures Strand. In those discussions that do include spherical geometry, hyperbolic geometry is usually called ***Lobachevskian geometry*** or ***Lobachevskian/Bolyai geometry***, and spherical geometry is usually called ***Riemannian geometry***. Bernhard Riemann (German, 1826–1866) pioneered an intrinsic and analytic view for surfaces and space and suggested that the intrinsic geometry of the sphere could be thought of as a non-Euclidean geometry. He also introduced an intrinsic analytic view of the sphere that became known as the ***Riemann sphere***. The Riemann sphere is usually studied in a course on complex analysis. The use of the term "Riemannian geometry" to denote the non-Euclidean geometry of the sphere leads to confusions since "Riemannian geometry" more commonly refers to the part of differential geometry that gives intrinsic analytic descriptions of the local geometry of general surfaces and 3-space.

Art/Pattern Strand. In this strand, artists' experimentations with perspective in art led to the mathematical theory of *projective geometry* that developed initially independently of both spherical and hyperbolic geometries. Then in the last part of the 19th century, projective geometry was used to provide a unified treatment of the three geometries. It was within this development that Felix Klein introduced the names ***double elliptic geometry*** (for the geometry of the sphere), ***elliptic geometry*** (for the geometry of the sphere with antipodal points identified — this the same as the real projective plane, **RP**^{2}, discussed in Problem **18.3**), ***parabolic geometry*** (for Euclidean geometry), and ***hyperbolic geometry*** (for the Bolyai/Lobachevsky geometry). In Chapter 11, we will discuss Klein's development of various geometries in terms of their isometries. A geometric connection between spherical and projective geometry can be seen in the image onto the plane of the sphere (with antipodal points identified) under gnomic projection. (See Problems **14.2** and **20.6**.)

For a fuller discussion of spherical and hyperbolic geometry in this strand, see [**HI**: Kline], Chapter 38, and [**HI**: Katz], Section 17.3.

In Kline we also find a statement (page 913) that represented the view of some mathematicians:

> By the early 1870s several basic non-Euclidean geometries, the hyperbolic, and the two elliptic geometries, had been introduced and intensively studied. The fundamental question which had yet to be answered in order to make these geometries legitimate branches of mathematics was whether they were consistent.

So for those who believe that the only "legitimate" branches of mathematics are those that have been included in some rigorous formal system, then non-Euclidean geometries did not became a part of mathematics until the late 1800s.

Navigation/Stargazing Strand. In the introduction to Chapter 2 we saw that spherical geometry has been studied within this strand for more than 2000 years, and in this study were developed (spherical) coordinate systems and trigonometric functions. We hope that the reader agrees that this was (and still is) legitimate mathematics.

For more readings (and references) on this history of spherical geometry within the Navigation/Stargazing Strand, see [**HI**: Katz], Chapter 4, and [**HI**: Rosenfeld], Chapter 1. Into the 19th century, spherical geometry occurred almost entirely in the Navigation/Stargazing Strand and was used by Brahe and Kepler in studying the motion of stars and planets and by navigators and surveyors. The popular book (which is also available online) *Spherical Trigonometry: For the use of colleges and schools* (1886) [**SP**: Todhunter] contains several discussions of the use of spherical geometry in surveying and was used in British schools before hyperbolic geometry was widely known in the British Isles. On the continent, C. F. Gauss (1777–1855) was using spherical geometry in various large-scale surveying projects before the advent of hyperbolic geometry. Within this context, Gauss initiated (and Riemann expanded) the analytic study of surfaces that led to what we now call differential geometry. Gauss introduced *Gaussian curvature*, which was discussed in Chapter 7. Within this theory of surfaces, spherical geometry is described locally as the geometry of surfaces with constant positive (Gaussian) curvature and hyperbolic geometry is described locally as the geometry of surfaces with constant negative curvature. As we discussed in Chapter 5, there are no analytic surfaces in 3-space with the complete hyperbolic geometry, but the pseudosphere (Problem **5.3**) locally has hyperbolic geometry. Because of this, in the Navigation/Stargazing strand, hyperbolic geometry is called by some authors ***pseudosphere geometry***.

Chapter 11

ISOMETRIES AND PATTERNS

> What geometrician or arithmetician could fail to take pleasure in the symmetries, correspondences and principles of order observed in visible things?
>
> — Plotinus, *The Enneads*, II.9.16 [**AT:** Plotinus]

> [Geometry is] the study of the properties of a space which are invariant under a given group of transformations.
>
> F. Klein, *Erlangen Program*

> Life forms illogical patterns. It is haphazard and full of beauties which I try to catch as they fly by, for who knows whether any of them will ever return? — Margot Fonteyn

Recall that in Chapter 1 we gave the following:

> **DEFINITION.** An ***isometry*** is a transformation that preserves distances and angle measures.

In this chapter we will show (for the plane, spheres, and hyperbolic planes) that every isometry is the composition (product) of (not more than three) reflections, and we will determine all the different types of isometries. This finishes the study of reflections and rotations we started in Problem **5.4**. We will note the differences between the kinds of isometries that appear in the three geometries.

Then we will study patterns in these three spaces. Along the way we will look at some group theory through its origins, that is, geometrically.

This material originated primarily within the Art/Pattern Strand.

13
Symmetry groups

13.1 Groups of transformations

SPACES that are symmetrical have a fundamental importance in modern physics. Why is this? It might be thought that completely exact symmetry is something that could arise only exceptionally, or perhaps just as some convenient approximation. Although a symmetrical object, such as a square or a sphere, has a precise existence as an idealized ('Platonic'; see §1.3) mathematical structure, any *physical* realization of such a thing would ordinarily be regarded as merely some kind of approximate representation of this Platonic ideal, therefore possessing no actual symmetry that can be regarded as exact. Yet, remarkably, according to the highly successful physical theories of the 20th century, all physical interactions (including gravity) act in accordance with an idea which, strictly speaking, depends crucially upon certain physical structures possessing a symmetry that, at a fundamental level of description, is indeed necessarily exact!

What is this idea? It is a concept that has come to be known as a 'gauge connection'. That name, as it stands, conveys little. But the idea is an important one, enabling us to find a subtle ('twisted') notion of differentiation that applies to general entities on a manifold (entities that are indeed more general than just those—the *p*-forms—which are subject to exterior differentiation, as described in Chapter 12). These matters will be the subject of the two chapters following this one; but as a prerequisite, we must first explore the basic notion of a *symmetry group*. This notion also has many other important areas of application in physics, chemistry, and crystallography, and also within many different areas of mathematics itself.

Let us take a simple example. What are the symmetries of a *square*? The question has two different answers depending upon whether or not we allow symmetries which reverse the orientation of the square (i.e. for which the square is turned over). Let us first consider the case in which these orientation-reversing symmetries are not allowed. Then the square's symmetries are generated from a single rotation through a right angle in the square's plane, repeated various numbers of times. For convenience, we can represent these motions in terms of complex numbers, as we did in

Chapter 5. We may, if we choose, think of the vertices of the square as occupying the points 1, i, -1, $-$ i in the complex plane (Fig. 13.1a), and our basic rotation represented by multiplication by i (i.e. by 'i×'). The various *powers* of i represent all our rotations, there being four distinct ones in all:

$$\mathrm{i}^0 = 1, \quad \mathrm{i}^1 = \mathrm{i}, \quad \mathrm{i}^2 = -1, \quad \mathrm{i}^3 = -\mathrm{i}$$

(Fig. 13.1b). The fourth power $\mathrm{i}^4 = 1$ gets us back to the beginning, so we have no more elements. The product of any two of these four elements is again one of them.

These four elements provide us with a simple example of a *group*. This consists of a set of elements and a law of 'multiplication' defined between pairs of them (denoted by juxtaposition of symbols) for which the *associative* multiplication law holds

$$a(bc) = (ab)c,$$

where there is an *identity* element 1 satisfying

$$1a = a1 = a,$$

and where each element a has an *inverse* a^{-1}, such that[13.1]

$$a^{-1}a = aa^{-1} = 1.$$

The symmetry operations which take an object (not necessarily a square) into itself always satisfy these laws, called the *group axioms*.

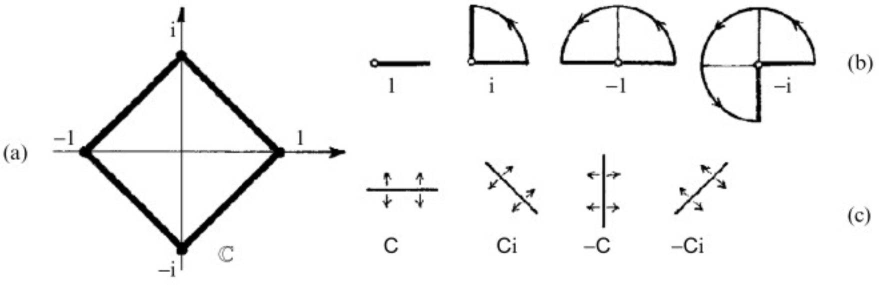

Fig. 13.1 Symmetry of a square. (a) We may represent the square's vertices by the points 1, i, $-$ 1, $-$ i in the complex plane ℂ. (b) The group of non-reflective symmetries are represented, in ℂ, as multiplication by $1 = \mathrm{i}^0$, $\mathrm{i} = \mathrm{i}^1$, $-1 = \mathrm{i}^2$, $-\mathrm{i} = \mathrm{i}^3$, respectively. (c) The reflective symmetries are given, in C, by C (complex conjugation), Ci, $-$ C, and $-$ Ci.

[13.1] Show that if we just assume $1a = a$ and $a^{-1}a = 1$ for all a, together with associativity $a(bc) = (ab)c$, then $a1 = a$ and $aa^{-1} = 1$ can be *deduced*. (*Hint*: Of course a is not the only element asserted to have an inverse.) Show why, on the other hand, $a1 = a$, $a^{-1}a = 1$, and $a(bc) = (ab)c$ are insufficient.

Recall the conventions recommended in Chapter 11, where we think of b acting first and a afterwards, in the product ab. We can regard these as operations as being performed upon some object appearing to the right. Thus, we could consider the motion, b, expressing a symmetry of an object $\boldsymbol{\Phi}$, as $\boldsymbol{\Phi} \mapsto b(\boldsymbol{\Phi})$, which we follow up by another such motion a, giving $b(\boldsymbol{\Phi}) \mapsto a(b(\boldsymbol{\Phi}))$. This results in the combined action $\boldsymbol{\Phi} \mapsto a(b(\boldsymbol{\Phi}))$, which we simply write $\boldsymbol{\Phi} \mapsto ab(\boldsymbol{\Phi})$, corresponding to the motion ab. The identity operation leaves the object alone (clearly always a symmetry) and the inverse is just the reverse operation of a given symmetry, moving the object back to where it came from.

In our particular example of non-reflective rotations of the square, we have the additional *commutative* property

$$ab = ba.$$

Groups that are commutative in this sense are called *Abelian*, after the tragically short-lived Norwegian mathematician Niels Henrik Abel.[1] Clearly any group that can be represented simply by the multiplication of complex numbers must be Abelian (since the multiplication of individual complex numbers always commutes). We saw other examples of this at the end of Chapter 5 when we considered the general case of a finite *cyclic* group $\mathbb{Z}_n$, generated by a single nth root of unity.[13.2]

Now let us allow the orientation-reversing *reflections* of our square. We can still use the above representation of the square in terms of complex numbers, but we shall need a new operation, which I denote by C, namely *complex conjugation*. (This flips the square over, about a horizontal line; see §10.1, Fig. 10.1.) We now find (see Fig. 13.1c) the 'multiplication laws'[13.3]

$$\mathsf{C}\mathrm{i} = (-\mathrm{i})\mathsf{C}, \quad \mathsf{C}(-1) = (-1)\mathsf{C}, \quad \mathsf{C}(-\mathrm{i}) = \mathrm{i}\mathsf{C}, \quad \mathsf{CC} = 1$$

(where[2] I shall henceforth write $(-\mathrm{i})\mathsf{C}$ as $-\mathrm{i}\mathsf{C}$, etc.). In fact, we can obtain the multiplication laws for the entire group just from the basic relations[13.4]

$$\mathrm{i}^4 = 1, \quad \mathsf{C}^2 = 1, \quad \mathsf{C}\mathrm{i} = \mathrm{i}^3\mathsf{C},$$

the group being non-Abelian, as is manifested in the last equation. The total number of of distinct elements in a group is called its *order*. The order of this particular group is 8.

Now let us consider another simple example, namely the group of rotational symmetries of an ordinary sphere. As before, we can first consider the

---

[13.2] Explain why any vector space is an Abelian group—called an *additive* Abelian group—where the group 'multiplication' operation is the 'addition' operation of the vector space.

[13.3] Verify these relations (bearing in mind that $\mathsf{C}\mathrm{i}$ stands for 'the operation $\mathrm{i}\times$, followed by the operation C, etc.). (*Hint*: You can check the relations by just confirming their effects on 1 and i. Why?)

[13.4] Show this.

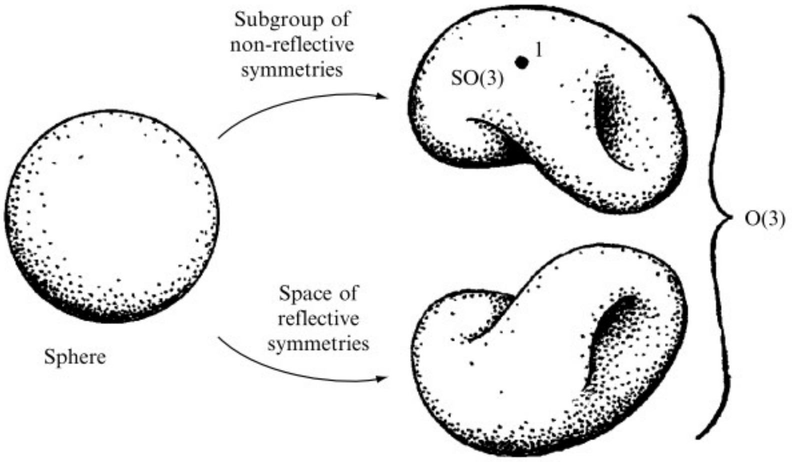

Fig. 13.2 Rotational symmetry of a sphere. The entire symmetry group, O(3), is a disconnected 3-manifold, consisting of two pieces. The component containing the identity element 1 is the (normal) subgroup SO(3) of non-reflective symmetries of the sphere. The remaining component is the 3-manifold of reflective symmetries.

case where reflections are excluded. This time, our symmetry group will have an infinite number of elements, because we can rotate through any angle about any axis direction in 3-space. The symmetry group actually constitutes a 3-dimensional space, namely the 3-manifold denoted by $\mathcal{R}$ in Chapter 12. Let me now give this group (3-manifold) its official name. It is called[3] SO(3), the non-reflective orthogonal group in 3 dimensions. If we now include the reflections, then we get a whole new set of symmetries—another 3-manifold's worth—which are disconnected from the first, namely those which involve a reversal of the orientation of the sphere. The entire family of group elements again constitutes a 3-manifold, but now it is a disconnected 3-manifold, consisting of two separate connected pieces (see Fig. 13.2). This entire group space is called O(3).

These two examples illustrate two of the most important categories of groups, the finite groups and the continuous groups (or *Lie* groups; see §13.6).[4] Although there is a great difference between these two types of group, there are many of the important properties of groups that are common to both.

13.2 Subgroups and simple groups

Of particular significance is the notion of a *subgroup* of a group. To exhibit a subgroup, we select some collection of elements within the group which themselves form a group, using the same multiplication and inversion operations as in the whole group. Subgroups are important in many modern theories of particle physics. It tends to be assumed that there is some fundamental symmetry of Nature that relates different kinds of particles to one another and also relates different particle interactions to one another. Yet one may not see this full group acting as a symmetry in any manifest way, finding, instead, that this symmetry is 'broken' down to some subgroup of the original group where the *subgroup* plays a manifest role as a symmetry. Thus, it is important to know what the possible subgroups of a putative 'fundamental' symmetry group actually are, in order that those symmetries that are indeed manifest in Nature might be able to be thought about as subgroups of this putative group. I shall be addressing questions of this kind in §§25.5–8, §26.11, and §28.1.

Let us examine some particular cases of subgroups, for the examples that we have been considering. The *non-reflective* symmetries of the square constitute a 4-element subgroup $\{1, \mathrm{i}, -1, -\mathrm{i}\}$ of the entire 8-element group of symmetries of the square. Likewise, the non-reflective rotation group SO(3) constitutes a subgroup of the entire group O(3). Another subgroup of the symmetries of the square consists of the four elements $\{1, -1, \mathsf{C}, -\mathsf{C}\}$; yet another has just the two elements $\{1, -1\}$.[13.5] Moreover there is always the 'trivial' subgroup consisting of the identity alone $\{1\}$ (and the whole group itself is, equally trivially, always a subgroup).

All the various subgroups that I have just described have a special property of particular importance. They are examples of what are called *normal* subgroups. The significance of a normal subgroup is that, in an appropriate sense, the action of any element of the whole group leaves a normal subgroup alone or, more technically, we say that each element of the whole group *commutes* with the normal subgroup. Let me be more explicit. Call the whole group $\mathcal{G}$ and the subgroup $\mathcal{S}$. If I select any particular element g of the group $\mathcal{G}$, then I can denote by $\mathcal{S}g$ the set consisting of all elements of $\mathcal{S}$ each individually multiplied by g on the right (what is called *postmultiplied* by g). Thus, in the case of the particular subgroup $\mathcal{S} = \{1, -1, \mathsf{C}, -\mathsf{C}\}$, of the symmetry group of the square, if we choose $g = \mathrm{i}$, then we obtain $\mathcal{S}\mathrm{i} = \{\mathrm{i}, -\mathrm{i}, \mathsf{C}\mathrm{i}, -\mathsf{C}\mathrm{i}\}$. Likewise, the notation $g\mathcal{S}$ will denote the set consisting of all elements of $\mathcal{S}$, each individually multiplied by g on the left (*premultiplied* by g). Thus, in our example, we now have $\mathrm{i}\mathcal{S} = \{\mathrm{i}, -\mathrm{i}, \mathrm{i}\mathsf{C}, -\mathrm{i}\mathsf{C}\}$. The condition for $\mathcal{S}$ to be a normal subgroup of $\mathcal{G}$ is that these two sets are the same, i.e.

$$\mathcal{S}g = g\mathcal{S}, \quad \text{for all } g \text{ in } \mathcal{S}.$$

In our particular example, we see that this is indeed the case (since $\mathsf{C}\mathrm{i} = -\mathrm{i}\mathsf{C}$ and $-\mathsf{C}\mathrm{i} = \mathrm{i}\mathsf{C}$), where we must bear in mind that the collection

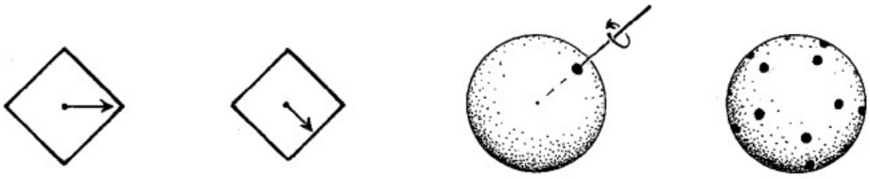
---

[13.5] Verify that all these in this paragraph are subgroups (and bear in mind Note 13.4).

of things inside the curly brackets is to be taken as an *unordered* set (so that it does not matter that the elements $-\mathrm{i}\mathsf{C}$ and $\mathrm{i}\mathsf{C}$ appear in reverse order in the collection of elements, when $\mathcal{S}\mathrm{i}$ and $\mathrm{i}\mathcal{S}$ are written out explicitly).

We can exhibit a *non*-normal subgroup of the group of symmetries of the square, as the subgroup of two elements $\{1, \mathsf{C}\}$. It is non-normal because $\{1, \mathsf{C}\}\mathrm{i} = \{\mathrm{i}, \mathsf{C}\mathrm{i}\}$ whereas $\mathrm{i}\{1, \mathsf{C}\} = \{\mathrm{i}, -\mathsf{C}\mathrm{i}\}$. Note that this subgroup arises as the new (reduced) symmetry group if we mark our square with a horizontal arrow pointing off to the right (see Fig. 13.3a). We can obtain another non-normal subgroup, namely $\{1, \mathsf{C}\mathrm{i}\}$ if we mark it, instead, with an arrow pointing diagonally down to the right (Fig. 13.3b).[13.6] In the case of O(3), there happens to be only one non-trivial normal subgroup,[13.7] namely SO(3), but there are many non-normal subgroups. Non-normal examples are obtained if we select some appropriate finite set of points on the sphere, and ask for the symmetries of the sphere with these points marked. If we mark just a single point, then the subgroup consists of rotations of the sphere about the axis joining the origin to this point (Fig. 13.3c). Alternatively, we could, for example, mark points that are the vertices of a regular polyhedron. Then the subgroup is finite, and consists of the symmetry group of that particular polyhedron (Fig. 13.3d).

One reason that normal subgroups are important is that, if a group $\mathcal{G}$ possesses a non-trivial normal subgroup, then we can break $\mathcal{G}$ down, in a sense, into smaller groups. Suppose that $\mathcal{S}$ is a normal subgroup of $\mathcal{G}$. Then the distinct sets $\mathcal{S}g$, where g runs through all the elements of $\mathcal{G}$, turn



(a) (b) (c) (d)

Fig. 13.3 (a) Marking the square of Fig. 13.1 with an arrow pointing to the right, reduces its symmetry group to a non-normal subgroup $\{1,\mathsf{C}\}$. (b) Marking it with an arrow pointing diagonally down to the right yields a different non-normal subgroup $\{1,\mathsf{C}\mathrm{i}\}$. (c) Marking the sphere of Fig. 13.2 with a single point reduces its symmetry to a (non-normal) O(2) subgroup of O(3): rotations about the axis joining the origin to this point. (d) If the sphere is marked with the vertices of a regular polyhedron (here a dodecahedron), its group of symmetries is a finite (non-normal) subgroup of O(3).

[13.6] Check these assertions, and find two more non-normal subgroups, showing that there are no further ones.

[13.7] Show this. (*Hint*: which *sets* of rotations can be rotation-invariant?)

out themselves to form a group. Note that for a given set $\mathcal{S}g$, the choice of g is generally not unique; we can have $\mathcal{S}g_1 = \mathcal{S}g_2$, for different elements g_1, g_2 of $\mathcal{G}$. The sets of the form $\mathcal{S}g$, for *any* subgroup $\mathcal{S}$, are called *cosets* of $\mathcal{G}$; but when $\mathcal{G}$ is normal, the cosets form a group. The reason for this is that if we have two such cosets $\mathcal{S}g$ and $\mathcal{S}h$ (g and h being elements of $\mathcal{G}$) then we can define the 'product' of $\mathcal{S}g$ with $\mathcal{S}h$ to be

$$(\mathcal{S}g)\,(\mathcal{S}h) = \mathcal{S}(gh),$$

and we find that all the group axioms are satisfied, provided that $\mathcal{S}$ is normal, essentially because the right-hand side is well defined, independently of which g and h were chosen in the representation of the cosets on the left-hand side of this equation.[13.8] The resulting group defined in this way is called the *factor group* of $\mathcal{G}$ by its normal subgroup $\mathcal{S}$. The factor group of $\mathcal{G}$ by $\mathcal{S}$ is written $\mathcal{G}/\mathcal{S}$. We can still write $\mathcal{G}/\mathcal{S}$ for the factor *space* (not a group) of distinct cosets $\mathcal{S}g$ even when $\mathcal{S}$ is not normal.[13.9]

Groups that possess no non-trivial normal subgroups at all are called *simple groups*. The group SO(3) is an example of a simple group. Simple groups are, in a clear sense, the basic building blocks of group theory. It is thus an important achievement of the 19th and 20th centuries in mathematics that all the finite simple groups and all the continuous simple groups are now known. In the continuous case (i.e. for Lie groups), this was a mathematical landmark, started by the highly influential German mathematician Wilhelm Killing (1847–1923), whose basic papers appeared in 1888–1890, and was essentially completed, in 1894, in one of the most important of mathematical papers ever written,[5] by the superb geometer and algebraist Élie Cartan (whom we have already encountered in Chapter 12, and whom we shall meet again in Chapter 17). This classification has continued to play a fundamental role in many areas of mathematics and physics, to the present day. It turns out that there are four families, known as A_m, B_m, C_m, D_m(for $m = 1, 2, 3, \ldots$), of respective dimension $m(m+2)$, $m(2m+1)$, $m(2m+1)$, $m(2m-1)$, called the *classical groups* (see end of §13.10) and five *exceptional groups* known as E_6, E_7, E_8, F_4, G_2, of respective dimension 78, 133, 248, 52, 14.

The classification of the finite simple groups is a more recent (and even more difficult) achievement, carried out over a great many years during the 20th century by a considerable number of mathematicians (with the aid of computers in more recent cases), being completed only in 1982.[6] Again there are some systematic families and a finite collection of *exceptional*

[13.8] Verify this and show that the axioms fail if $\mathcal{S}$ is not normal.

[13.9] Explain why the number of elements in $\mathcal{G}/\mathcal{S}$, for any finite subgroup $\mathcal{S}$ of $\mathcal{G}$, is the order of $\mathcal{G}$ divided by the order of $\mathcal{S}$.

finite simple groups. The largest of these exceptional groups is referred to as the *monster*, which is of order

$$= 808017424794512875886459904961710757005754368000000000.$$
$$= 2^{46} \times 3^{20} \times 5^{9} \times 7^{6} \times 11^{2} \times 13^{3} \times 17 \times 19 \times 23 \times 29 \times 31 \times 41 \times 47 \times 59 \times 71.$$

Exceptional groups appear to have a particular appeal for many modern theoretical physicists. The group E_8 features importantly in string theory (§31.12), while various people have expressed a hope that the huge but finite monster may feature in some future theory.[7]

The classification of the simple groups may be regarded as a major step towards the classification of groups generally since, as indicated above, general groups may be regarded as being built up out of simple groups (together with Abelian ones). In fact, this is not really the whole story because there is further information in how one simple group can build upon another. I do not propose to enter into the details of this matter here, but it is worth just mentioning the simplest way that this can happen. If $\mathcal{G}$ and $\mathcal{H}$ are any two groups, then they can be combined together to form what is called the *product group* $\mathcal{G} \times \mathcal{H}$, whose elements are simply *pairs* (g, h), where g belongs to $\mathcal{G}$ and h belongs to $\mathcal{H}$, the rule of group multiplication between elements (g_1, h_1) and (g_2, h_2), of $\mathcal{G} \times \mathcal{H}$, being defined as

$$(g_1, h_1)\,(g_2, h_2) = (g_1 g_2,\, h_1 h_2),$$

and it is very easy to verify that the group axioms are satisfied. Many of the groups that feature in particle physics are in fact product groups of simple groups (or elementary modifications of such).[13.10]

13.3 Linear transformations and matrices

In the general study of groups, there is a particular class of symmetry groups that have been found to play a central role. These are the groups of symmetries of vector spaces. The symmetries of a vector space are expressed by the *linear transformations* preserving the vector-space structure.

Recall from §11.1 and §12.3 that, in a vector space V, we have, defining its structure, a notion of addition of vectors and multiplication of vectors by numbers. We may take note of the fact that the geometrical picture of addition is obtained by use of the parallelogram law, while multiplication by a number is visualized as scaling the vector up (or down) by that number (Fig. 13.4). Here we are picturing it as a *real* number, but complex vector spaces are also allowed (and are particularly important in many

---

[13.10] Verify that $\mathcal{G} \times \mathcal{H}$ is a group, for any two groups $\mathcal{G}$ and $\mathcal{H}$, and that we can identify the factor group $(\mathcal{G} \times \mathcal{H})/\mathcal{G}$ with $\mathcal{H}$.

fingerprints on the particles and forces that emerge *after* this period, and which we can observe today at more modest energies and temperatures. To date, no GUT has yielded empirical fingerprints that are consistent with what we observe.

What does the fledgling universe contain? This is really hard to say. Most cosmological models assume that the early universe behaves much like a hot uniform gas, without being specific about the nature of the gas. If there are particles of some kind, then we can safely assume that they are massless and highly energetic, and bear scant resemblance to any particle with which we are familiar today.

The universe continues to expand and cool, to a temperature of about 10^{27} kelvin. About 10^{-35} seconds after the big bang we hit another phase transition, as the strong nuclear force condenses and separates from the residual 'electro-weak' force.

But this time, something is different.

COSMIC INFLATION: 10^{-35} TO 10^{-32} SECONDS

When the ice melts in the pan, the symmetry increases and the water molecules are freed from their prison in the crystal lattice. A considerable amount of energy in the form of heat is required to complete this phase transition. This heat is used to free the water molecules from their restraints, but it does not change the temperature during the transition (which remains fixed at the freezing point of water: 0°C, or 273 kelvin). Such a phase transition is said to be *endothermic*—it requires an input of thermal energy to make it happen.

Conversely, when liquid water freezes to form ice, this energy or 'latent heat' is released and the transition is said to be *exothermic*—there is an output of thermal energy. This heat is released in a short burst as the ice forms. When we make ice in the refrigerator we don't normally notice this, but it can be easily measured using a calorimeter.

In my kitchen experiment, I allow the hot steam to condense to liquid before popping the pan into my freezer, where the liquid will condense further to form ice. This is a conventional freezer, which will cool the liquid in its own good time. But let's now suppose that the water in the pan is ultra-pure, and the inside of the pan is ultra-smooth. This greatly reduces the number of possible sites at which the first ice crystals can nucleate. If I now cool the pan very rapidly, I find that I can reduce the temperature of the liquid well below its freezing point, to almost −50°C (223 kelvin), in fact, without forming any ice. This is *supercooling*.

In supercooled water, the latent heat is not immediately released. It remains latent.

In 1979, young American postdoctoral researcher Alan Guth and his colleague Henry Tye were trying to resolve some of the puzzles of early big bang cosmology. They asked themselves what might happen if, instead of undergoing a smooth phase transition at the end of the Grand Unification Epoch, the universe had instead persisted in its grand unified phase at temperatures several orders of magnitude *below* the transition temperature.

This did indeed resolve their problem. But when Guth went on to explore the wider effects of the onset of supercooling, he found much more than he had initially bargained for. He found that the latent heat of the supercooled universe is stored in the vacuum, in spacetime itself. Remember, vacuum energy does much the same job as Einstein's cosmological term, forcing the rate of expansion of spacetime to increase. Shovelling a very large amount of energy into spacetime results in a short burst of extraordinary exponential expansion, doubling the size of the universe every 10^{-34} of a second. One hundred such doublings would have increased the size of the universe by a factor of 10^{30}.

'I do not remember ever trying to invent a name for this extraordinary phenomenon of exponential expansion,' Guth later wrote, 'but my diary shows that by the end of December [1979] I had begun to call it *inflation*.'[10]

Is this really the way it happened? Theories of cosmic inflation are based on the assumed properties of GUTs and, as there is no generally accepted grand unified theory, then the status of inflation remains rather questionable. But there are some features of the observable universe that are quite handily explained if we assume that something like inflation actually did happen.

Friedmann had shown in 1924 that different assumptions about the density of mass-energy would give rise to different kinds of universe. In a closed universe, spacetime would have a positive curvature, like the surface of a sphere. Parallel lines will cross and the angles of a triangle will add up to more than 180°. In an open universe, spacetime would have a negative curvature, looking something like a saddle. Parallel lines would again cross and the angles of a triangle would add up to less than 180°.

It would seem that we live in a universe in which there is a very fine balance between the density of mass-energy and the rate of expansion, such that spacetime is flat (Figure 5). This is why we learn Euclidean geometry in school.

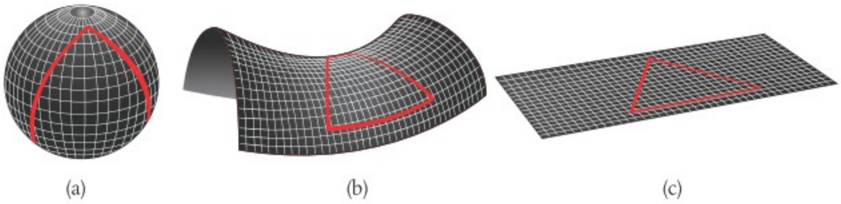

FIGURE 5 The different model universes that Friedmann identified in solutions to Einstein's gravitational field equations produce differently curved spacetimes. The 'closed' universe has a positively curved spacetime as shown in (a). The 'open' universe has a saddle-shaped negatively curved spacetime, (b). A universe with a finely tuned balance between the rate of expansion and the amount of mass-energy it contains will exhibit a flat spacetime, (c).

But why should our universe exhibit such a balance? Scientists get rather uncomfortable when confronted with evidence of such fine-tuning, especially when they can't explain it using physical mechanisms.

This is where inflation comes to the rescue. It really makes no difference precisely how much energy the early universe contained, or whether this was equal to the critical density required to produce a flat spacetime. It doesn't matter what the initial rate of expansion was. It doesn't even matter if inflation is applied to the whole of the early universe or just one small bubble of spacetime within this. No matter what the shape of spacetime prior to inflation, when inflation was done, *flat* spacetime was the only possible result.

Think of it this way. The skin of a deflated balloon may be wrinkled like a prune, curving this way and that. Pump it up and the wrinkles are quickly flattened out. The visible universe may be flat because it comes from a tiny bit of grand-unified universe blown up out of all proportion by inflation.

Inflation theory has many critics, and some have argued that there are ways of arriving at a flat spacetime that do not require inflation, or fine-tuning for that matter. Nevertheless, for the time being at least, it remains an important component of the broadly accepted theory describing the evolution of the universe.

REHEATING

Inflation is thought to have ceased around 10^{-32} seconds after the big bang. The temperature is now several orders of magnitude below the transition temperature.

2022: Feliz Ano Novo!!!

There are four fundamental forces at work in the Universe:

(20220101)

1) The strong force
2) The Weak force
3) The Electromagnetic Force
4) The Gravitational Force.

reflexo
(efeito)

The Gravitational Force é decorrência da "The Strong Force".

Se a gravidade existisse independentemente das demais forças, o Universo jamais teria sido criado pois antes do Big-Bang tudo estava reunido em um único ponto e portanto, a própria gravidade teria impedido a própria explosão do Big-Bang.

A gravidade deve ser analisada localmente e quando estendida, você terá outro valor.

A extensão da análise do fator gravitacional em relação a todo Universo gera uma curvatura ~~do~~ espaço-tempo.

O Universo se expande pois a "gravidade" age localmente em relação à cada galáxia e não em relação ao todo.

or 2, we see by Theorem 20.5 that if c is constructible, then $[Q(c) : Q] = 2^k$ for some nonnegative integer k.

We now dispatch the problems that plagued the Greeks. Consider doubling the cube of volume 1. The enlarged cube would have an edge of length $\sqrt[3]{2}$. But $[Q(\sqrt[3]{2}) : Q] = 3$, so such a cube cannot be constructed.

Next consider the possibility of trisecting a 60° angle. If it were possible to trisect an angle of 60°, then cos 20° would be constructible. (See Figure 22.1.) In particular, $[Q(\cos 20^\circ) : Q] = 2^k$ for some k. Now, using the trigonometric identity $\cos 3\theta = 4\cos^3\theta - 3\cos\theta$, with $\theta = 20^\circ$, we see that $1/2 = 4\cos^3 20^\circ - 3\cos 20^\circ$, so that cos 20° is a zero of $8x^3 - 6x - 1$. But, since $8x^3 - 6x - 1$ is irreducible over Q (see Exercise 13), we must also have $[Q(\cos 20^\circ) : Q] = 3$. This contradiction shows that trisecting a 60° angle is impossible.

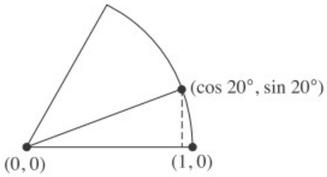

Figure 22.1 Sixty-degree angle.

The remaining problems are relegated to the reader as Exercises 14, 15, and 17.

Angle-Trisectors and Circle-Squarers

Down through the centuries, hundreds of people have claimed to have achieved one or more of the impossible constructions. In 1775, the Paris Academy, so overwhelmed with these claims, passed a resolution to no longer examine these claims or claims of machines purported to exhibit perpetual motion. Although it has been more than 100 years since the last of the constructions was shown to be impossible, there continues to be a steady parade of people who claim to have done one or more of them. Most of these people have heard that this is impossible but have refused to believe it. One person insisted that he could trisect any angle with a straightedge alone. Another found his trisection in 1973 after 12,000 hours of work. One got his from God. In 1971, a person with a Ph.D. in mathematics asserted that he had a valid trisection method. Many people have claimed the hat trick: trisecting the angle, doubling the cube, and squaring the circle. Two men who did this in 1961 succeeded in having their accomplishment noted in the *Congressional Record.* Occasionally, newspapers and magazines have run stories about "doing the impossible," often giving the impression that the construction may be valid. Many angle-trisectors and circle-squarers have had their work published at their own expense and distributed to colleges and universities. One had his printed in four languages!

Although he never claimed to have squared the circle, the incomparable Renaissance multifaceted genius Leonardo da Vinci made 169 attempts over many years at squaring the circle.

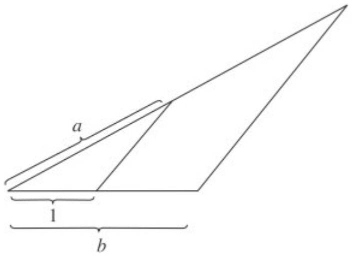
Exercises

Only prove to me that it is impossible, and I will set about it this very evening.

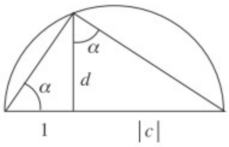
Spoken by a member of the audience after De Morgan gave a lecture on the impossibility of squaring the circle.

1. If a and b are constructible numbers and $a \geq b > 0$, give a geometric proof that $a + b$ and $a - b$ are constructible.

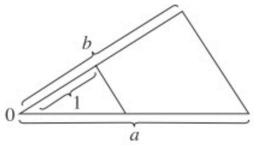
2. If a and b are constructible, give a geometric proof that ab is constructible. (*Hint:* Consider the following figure. Notice that all segments in the figure can be made with an unmarked straightedge and a compass.)



3. Prove that if c is a constructible number, then so is $\sqrt{|c|}$. (*Hint:* Consider the following semicircle with diameter $1 + |c|$.) (This exercise is referred to in Chapter 31.)



4. If a and b ($b \neq 0$) are constructible numbers, give a geometric proof that a/b is constructible. (*Hint:* Consider the following figure.)



5. Prove that $\sin\theta$ is constructible if and only if $\cos\theta$ is constructible.

6. Prove that an angle θ measured in degrees is constructible if and only if $\sin\ \theta$ is constructible.

7. Prove that $\cos 2\theta$ is constructible if and only if $\cos\theta$ is constructible.

8. Prove that 30° is a constructible angle.

9. Prove that a 45° angle can be trisected with an unmarked straightedge and a compass.

10. Prove that a 40° angle is not constructible.

11. Show that the point of intersection of two lines in the plane of a field F lies in the plane of F.

12. Show that the points of intersection of a circle in the plane of a field F and a line in the plane of F are points in the plane of F or in the plane of $F(\sqrt{\alpha})$, where $\alpha \in F$ and α is positive. Give an example of a circle and a line in the plane of Q whose points of intersection are not in the plane of Q.

13. Prove that $8x^3 - 6x - 1$ is irreducible over Q.

14. Use the fact that $8\cos^3(2\pi/7) + 4\cos^2(2\pi/7) - 4\cos(2\pi/7) - 1 = 0$ to prove that a regular seven-sided polygon is not constructible with an unmarked straightedge and a compass.

15. Show that a regular 9-gon cannot be constructed with an unmarked straightedge and a compass.

16. Show that if a regular n-gon is constructible, then so is a regular $2n$-gon.

17. (Squaring the Circle) Show that it is impossible to construct, with an unmarked straightedge and a compass, a square whose area equals that of a circle of radius 1. You may use the fact that π is transcendental over Q.

18. Use the fact that $4\cos^2(2\pi/5) + 2\cos(2\pi/5) - 1 = 0$ to prove that a regular pentagon is constructible.

19. Can the cube be "tripled"?

20. Can the cube be "quadrupled"?

21. Can the circle be "cubed"?

22. If a, b, and c are constructible, show that the real roots of $ax^2 + bx + c$ are constructible.

26 Symmetry Groups

Physicists have exalted symmetry to the position of *the* central concept in their attempts to organize and explain an otherwise bewildering and complex universe.

Mario Livio, *The Equation That Could Not Be Solved*

I'm not good at math, but I do know that the universe is formed with mathematical principles whether I understand them or not, and I am going to let that guide me.

Bob Dylan, *Chronicles, Volume One*

Isometries

In the early chapters of this book, we briefly discussed symmetry groups. In this chapter and the next, we examine this fundamentally important concept in some detail. It is convenient to begin such a discussion with the definition of an isometry (from the Greek *isometros*, meaning "equal measure") in $\mathbf{R}^n$.

Definition Isometry
An *isometry* of n-dimensional space $\mathbf{R}^n$ is a function from $\mathbf{R}^n$ onto $\mathbf{R}^n$ that preserves distance.

In other words, a function T from $\mathbf{R}^n$ onto $\mathbf{R}^n$ is an isometry if, for every pair of points p and q in $\mathbf{R}^n$, the distance from $T(p)$ to $T(q)$ is the same as the distance from p to q. With this definition, we may now make precise the definition of the symmetry group of an n-dimensional figure.

Definition Symmetry Group of a Figure in $\mathbf{R}^n$
Let F be a set of points in $\mathbf{R}^n$. The *symmetry group of F* in $\mathbf{R}^n$ is the set of all isometries of $\mathbf{R}^n$ that carry F onto itself. The group operation is function composition.

It is important to realize that the symmetry group of an object depends not only on the object, but also on the space in which we view it. For example, the symmetry group of a line segment in $\mathbf{R}^1$ has order 2, the symmetry group of a line segment considered as a set of points in $\mathbf{R}^2$ has order 4, and the symmetry group of a line segment viewed as a set of points in $\mathbf{R}^3$ has infinite order (see Exercise 9).

Although we have formulated our definitions for all finite dimensions, our chief interest will be the two-dimensional case. It has been known since 1831 that every isometry of $\mathbf{R}^2$ is one of four types: rotation, reflection, translation, and glide-reflection. Rotation about a point in a plane needs no explanation. A *reflection across a line* L is that transformation that leaves every point of L fixed and takes every point Q, not on L, to the point Q' so that L is the perpendicular bisector of the line segment from Q to Q' (see Figure 26.1). The line L is called the *axis of reflection.* In an xy-coordinate plane, the transformation $(x, y) \to (x, -y)$ is a reflection across the x-axis, whereas $(x, y) \to (y, x)$ is a reflection across the line $y = x$. Some authors call an axis of reflective symmetry L a *mirror* because L acts like a two-sided mirror; that is, the image of a point Q in a mirror placed on the line L is, in fact, the image of Q under the reflection across the line L. Reflections are called *opposite* isometries because they reverse orientation. For example, the reflected image of a clockwise spiral is a counterclockwise spiral. Similarly, the reflected image of a right hand is a left hand. (See Figure 26.1.)

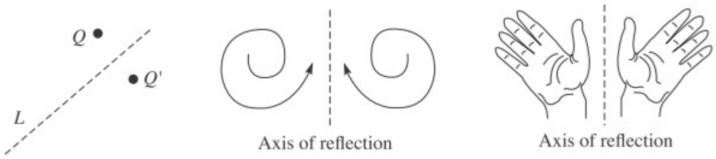

Figure 26.1 Reflected images.

A *translation* is simply a function that carries all points the same distance in the same direction. For example, if p and q are points in a plane and T is a translation, then the two directed line segments joining p to $T(p)$ and q to $T(q)$ have the same length and direction. A *glide-reflection* is the product of a translation and a reflection across the line containing the translation line segment. This line is called the *glide-axis.* In Figure 26.2, the arrow gives the direction and length of the translation, and is contained in the axis of reflection. A glide-reflection is also an opposite isometry. Successive footprints in wet sand are related by a glide-reflection.

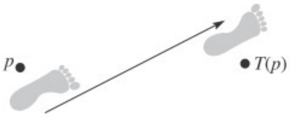

Figure 26.2 Glide-reflection

Classification of Finite Plane Symmetry Groups

Our first goal in this chapter is to classify all finite plane symmetry groups. As we have seen in earlier chapters, the dihedral group D_n is the plane symmetry group of a regular n-gon. (For convenience, call D_2 the plane symmetry group of a nonsquare rectangle and D_1 the plane symmetry group of the letter "V." In particular, $D_2 \approx Z_2 \oplus Z_2$ and $D_1 \approx Z_2$.) The cyclic groups Z_n are easily seen to be plane symmetry groups also. Figure 26.3 is an illustration of an organism whose plane symmetry group consists of four rotations and is isomorphic to Z_4. The surprising fact is that the cyclic groups and dihedral groups are the only finite plane symmetry groups. The famous mathematician Hermann Weyl attributes the following theorem to Leonardo da Vinci (1452–1519).

and V.A. Kopstik, Copyright 1974 Plenum Publishing Co.

Figure 26.3 Aurelia insulinda, an organism whose plane symmetry group is Z_4.

Theorem 26.1 Finite Symmetry Groups in the Plane

The only finite plane symmetry groups are Z_n and D_n.

PROOF Let G be a finite plane symmetry group of some figure. We first observe that G cannot contain a translation or a glide-reflection, because in either case G would be infinite. Now observing that the composition of two reflections preserves orientation, we know that such a composition is a translation or rotation. When the two reflections have parallel axes of reflection, there is no fixed point so the composition is a translation. Thus, every two reflections in G have reflection axes that intersect in some point. We claim that all reflections intersect in the same point. Suppose that f and f' are two distinct reflections in G. Then because ff' preserves orientation, we know that ff' is a rotation. We use the fact from geometry that a finite group of rotations must have a common center, say P. This means that any two reflections must intersect at point P. So, we have shown that all the elements of G have the common fixed point P.

For convenience, let us denote a rotation about P of σ degrees by R_σ. Now, among all rotations in G, let β be the smallest positive angle of rotation. (Such an angle exists, since G is finite and R_{360} belongs to G.) We claim that every rotation in G is some power of R_β. To see this, suppose that R_σ is in G. We may assume $0° < \sigma \leq 360°$. Then, $\beta \leq \sigma$ and there is some integer t such that $t\beta \leq \sigma < (t+1)\beta$. But, then $R_{\sigma - t\beta} = R_\sigma(R_\beta)^{-t}$ is in G and $0 \leq \sigma - t\beta < \beta$. Since β represents the smallest positive angle of rotation among the elements of G, we must have $\sigma - t\beta = 0$, and therefore, $R_\sigma = (R_\beta)^t$. This verifies the claim.

For convenience, let us say that $|R_\beta| = n$. Now, if G has no reflections, we have proved that $G = \langle R_\beta \rangle \approx Z_n$. If G has at least one reflection, say f, then

$$f, fR_\beta, f(R_\beta)^2, \ldots, f(R_\beta)^{n-1}$$

are also reflections. Furthermore, this is the entire set of reflections of G. For if g is any reflection in G, then fg is a rotation, and so $fg = (R_\beta)^k$ for some k. Thus, $g = f^{-1}(R_\beta)^k = f(R_\beta)^k$. So

$$G = \{R_0, R_\beta, (R_\beta)^2, \ldots, (R_\beta)^{n-1}, f, fR_\beta, f(R_\beta)^2, \ldots, f(R_\beta)^{n-1}\},$$

and G is generated by the pair of reflections f and fR_β. Hence, by our characterization of the dihedral groups (Theorem 25.5), G is the dihedral group D_n. ▮

Classification of Finite Groups of Rotations in $\mathbf{R}^3$

One might think that the set of all possible finite symmetry groups in three dimensions would be much more diverse than is the case for two dimensions. Surprisingly, this is not the case. For example, moving to three dimensions introduces only three new groups of rotations. This observation was first made by the physicist and mineralogist Auguste Bravais in 1849, in his study of possible structures of crystals.

▮ Theorem 26.2 Finite Groups of Rotations in $\mathbf{R}^3$

Up to isomorphism, the finite groups of rotations in R^3 are Z_n, D_n, A_4, S_4, and A_5.

Theorem 26.2, together with the Orbit-Stabilizer Theorem (Theorem 7.4), makes easy work of determining the group of rotations of an object in $\mathbf{R}^3$.

▮ EXAMPLE 8 We determine the group G of rotations of the cuboctahedron in Figure 26.4, which is composed of six congruent squares and eight congruent equilateral triangles. We begin by singling out any one of the squares. Obviously, there are four rotations that map this square to itself, and the designated square can be rotated to the location of any of the other five. So, by the Orbit-Stabilizer Theorem (Theorem 7.4), the rotation group has order $4 \cdot 6 = 24$. By Theorem 26.2, G is one of Z_{24}, D_{12}, and S_4. But each of the first two groups has exactly two elements of order 4, whereas G has more than two. So, G is isomorphic to S_4. ▮

The group of rotations of a tetrahedron (the *tetrahedral group*) is isomorphic to A_4; the group of rotations of a cube or an octahedron (the *octahedral group*) is isomorphic to S_4; the group of rotations of a dodecahedron or an icosahedron (the *icosahedral group*) is isomorphic to A_5. These five solids are illustrated in Figure 26.5.

Exercises

> Perhaps the most valuable result of all education is the ability to make yourself do the thing you have to do, when it ought to be done, whether you like it or not .
>
> Thomas Henry Huxley, "Technical Education"

1. Show that an isometry of $\mathbf{R}^n$ is one-to-one.

2. Show that the translations of $\mathbf{R}^n$ form a group.

3. Exhibit a plane figure whose plane symmetry group is Z_5.

4. Show that the group of rotations in $\mathbf{R}^3$ of a 3-prism (i.e., a prism with equilateral ends, as in the following figure) is isomorphic to D_3.

5. What is the order of the (entire) symmetry group in $\mathbf{R}^3$ of a 3-prism?

6. What is the order of the symmetry group in $\mathbf{R}^3$ of a 4-prism (a box with square ends that is not a cube)?

7. What is the order of the symmetry group in $\mathbf{R}^3$ of an n-prism?

8. Show that the symmetry group in $\mathbf{R}^3$ of a box of dimensions $2'' \times 3'' \times 4''$ is isomorphic to $Z_2 \oplus Z_2 \oplus Z_2$.

9. Describe the symmetry group of a line segment viewed as
a. a subset of $\mathbf{R}^1$.
b. a subset of $\mathbf{R}^2$.
c. a subset of $\mathbf{R}^3$.
(This exercise is referred to in this chapter.)

10. (From the "Ask Marilyn" column in *Parade Magazine*, December 11, 1994.)[1] The letters of the alphabet can be sorted into the following categories:
a. FGJLNPQRSZ
b. BCDEK
c. AMTUVWY
d. HIOX
What defines the categories?

11. Exactly how many elements of order 4 does the group in Example 1 have?

12. Why is inversion [that is, $\phi(x, y) = (-x, -y)$,] not listed as one of the four kinds of isometries in R^2?

13. Explain why inversion through a point in $\mathbf{R}^3$ cannot be realized by a rotation in $\mathbf{R}^3$.

14. Reflection across a line L in $\mathbf{R}^3$ is the isometry that takes each point Q to the point Q' with the property that L is a perpendicular bisector of the line segment joining Q and Q'. Describe a rotation that has this same effect.

---

15. In $\mathbf{R}^2$, a rotation fixes a point; in $\mathbf{R}^3$, a rotation fixes a line. In $\mathbf{R}^4$, what does a rotation fix? Generalize these observations to $\mathbf{R}^n$.

16. Show that an isometry of a plane preserves angles.

17. Show that an isometry of a plane is completely determined by the image of three noncollinear points.

18. Suppose that an isometry of a plane leaves three noncollinear points fixed. Which isometry is it?

19. Suppose that an isometry of a plane fixes exactly one point. What type of isometry must it be?

20. Suppose that A and B are rotations of 180° about the points a and b, respectively. What is A followed by B? How is the composite motion related to the points a and b?

27 Symmetry and Counting

Let us pause to slake our thirst one last time at symmetry's bubbling spring.

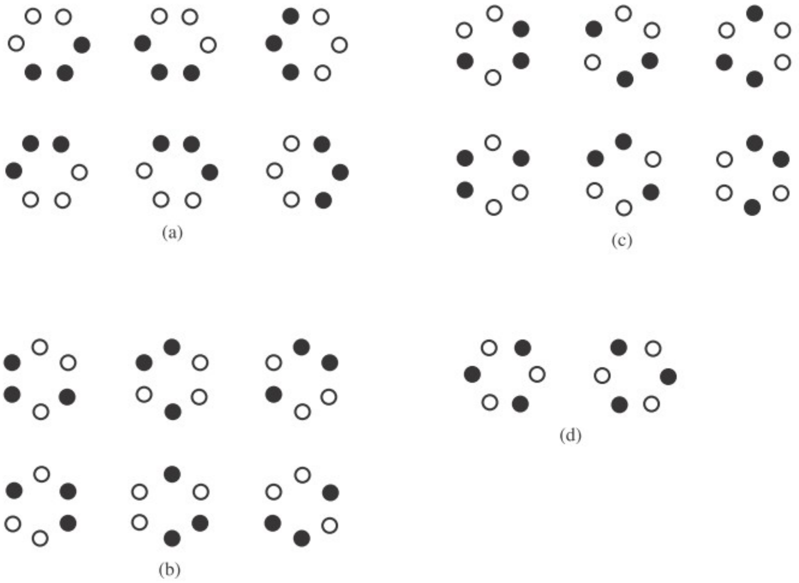
Timothy Ferris, *Coming of Age in the Milky Way*

Whenever you can, count.

Francis Galton, (1822–1911)

Motivation

Permutation groups naturally arise in many situations involving symmetric designs or arrangements. Consider, for example, the task of coloring the six vertices of a regular hexagon so that three are black and three are white. Figure 27.1 shows the $\binom{6}{3} = 20$ possibilities. However, if these designs appeared on one side of hexagonal ceramic tiles, it would be nonsensical to count the designs shown in Figure 27.1(a) as different, since all six designs shown there can be obtained from one of them by rotating. (A manufacturer would make only one of the six.) In this case, we say that the designs in Figure 27.1(a) are *equivalent* under the group of rotations of the hexagon. Similarly, the designs in Figure 27.1(b) are equivalent under the group of rotations, as are the designs in Figure 27.1(c) and those in Figure 27.1(d). And, since no design from Figure 27.1(a)–(d) can be obtained from a design in a different part by rotation, we see that the designs within each part of the figure are equivalent to each other but nonequivalent to any design in another part of the figure. However, the designs in Figure 27.1(b) and (c) are equivalent under the dihedral group D_6, since the designs in Figure 27.1(b) can be reflected to yield the designs in Figure 27.1(c). For example, for purposes of arranging three black beads and three white beads to form a necklace, the designs shown in Figure 27.1(b) and (c) would be considered equivalent.



(a) (b) (c) (d)

Figure 27.1 Necklaces with three black beads and three white beads.

In general, we say that two designs (arrangements of beads) A and B are *equivalent under a group* G of permutations of the arrangements if there is an element ϕ in G such that $\phi(A) = B$. That is, two designs are equivalent under G if they are in the same orbit of G. It follows, then, that the number of nonequivalent designs under G is simply the number of orbits of designs under G. (The set being permuted is the set of all possible designs or arrangements.)

Notice that the designs in Figure 27.1 divide into four orbits under the group of rotations but only three orbits under the group D_6, since the designs in Figure 27.1(b) and (c) form a single orbit under D_6. Thus, we could obtain all 20 tile designs from just four tiles, but we could obtain all 20 necklaces from just three of them.

Burnside's Theorem

Although the problems we have just posed are simple enough to solve by observation, more complicated ones require a more sophisticated approach. Such an approach was provided by Georg

Frobenius in 1887. Frobenius's theorem did not become widely known until it appeared in the classic book on group theory by William Burnside in 1911. By an accident of history, Frobenius's theorem has come to be known as Burnside's Theorem. Before stating this theorem, we recall some notation introduced in Chapter 7 and introduce new notation. If G is a group of permutations on a set S and $i \in S$, then $\text{stab}_G(i) = \{\phi \in G \mid \phi(i) = i\}$ and $\text{orb}_G(i) = \{\phi(i) \mid \phi \in G\}$. For any set X, we use $|X|$ to denote the number of elements in X.

Definitions Elements Fixed by ϕ

For any group G of permutations on a set S and any ϕ in G, we let $\text{fix}(\phi) = \{i \in S \mid \phi(i) = i\}$. This set is called the *elements fixed by ϕ* (or more simply, "fix of ϕ").

Theorem 27.1 Burnside's Theorem

If G is a finite group of permutations on a set S, then the number of orbits of elements of S under G is

$$\frac{1}{|G|}\sum_{\phi \in G} |\text{fix}(\phi)|.$$

PROOF Let n denote the number of pairs (ϕ, i), with $\phi \in G, i \in S$, and $\phi(i) = i$. We begin by counting these pairs in two ways. First, for each particular ϕ in G, the number of such pairs is exactly $|\text{fix}(\phi)|$. So,

$$n = \sum_{\phi \in G} |\text{fix}(\phi)|.$$

Second, for each particular i in S, observe that $|\text{stab}_G(i)|$ is exactly the number of pairs (ϕ, i) for which $\phi(i) = i$. So,

$$n = \sum_{i \in S} |\text{stab}_G(i)|.$$

It follows from Exercise 67 in Chapter 7 that if s and t are in the same orbit of G, then $\text{orb}_G(s) = \text{orb}_G(t)$, and thus by the Orbit-Stabilizer Theorem (Theorem 7.4) we have $|\text{stab}_G(s)| = |G|/|\text{orb}_G(s)| = |G|/|\text{orb}_G(t)| = |\text{stab}_G(t)$. So, if we choose $s \in S$ and sum over $\text{orb}_G(s)$, we have

Table 27.1

Element	Number of Designs Fixed by Element
Identity	20
Rotation of 60°	0
Rotation of 120°	2
Rotation of 180°	0
Rotation of 240°	2
Rotation of 300°	0

$$\sum_{t\in \mathrm{orb}_G(s)} |\mathrm{stab}_G(t)| = |\mathrm{orb}_G(S)||\mathrm{stab}_G(S)| = |G|.$$

Finally, by summing over all the elements of G, one orbit at a time, it follows from Equations (1), (2), and (3) that

$$\sum_{\phi\in G} |\mathrm{fix}(\phi)| = \sum_{i\in S} |\mathrm{stab}(i)| = |G| \cdot (\text{number of orbits})$$

and the result follows. ▮

Applications

To illustrate how to apply Burnside's Theorem, let us return to the ceramic tile and necklace problems. In the case of counting hexagonal tiles with three black vertices and three white vertices, the objects being permuted are the 20 possible designs, whereas the group of permutations is the group of six rotational symmetries of a hexagon. Obviously, the identity fixes all 20 designs. We see from Figure 27.1 that rotations of 60°, 180°, or 300° fix none of the 20 designs. Finally, Figure 27.2 shows fix(ϕ) for the rotations of 120° and 240°. These data are collected in Table 27.1.

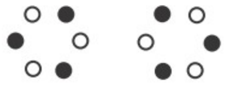


Figure 27.2 Tile designs fixed by 120° rotation and 240° rotation.

So, applying Burnside's Theorem, we obtain the number of orbits under the group of rotations as

$$\frac{1}{6}(20 + 0 + 2 + 0 + 2 + 0) = 4.$$

Now let's use Burnside's Theorem to count the number of necklace arrangements consisting of three black beads and three white beads. (For the purposes of analysis, we may arrange the beads in the shape of a regular hexagon.) For this problem, two arrangements are equivalent if they are in the same orbit under D_6. Figure 27.3 shows the arrangements fixed by a reflection across a diagonal. Table 27.2 summarizes the information needed to apply Burnside's Theorem.

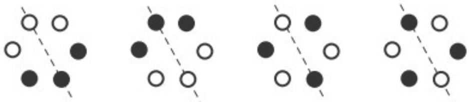

Figure 27.3 Bead arrangements fixed by the reflection across a diagonal.

Table 27.2

Type of Element	Number of Elements of This Type	Number of Arrangements Fixed by Type of Element
Identity	1	20
Rotation of order 2 (180°)	1	0
Rotation of order 3 (120° or 240°)	2	2
Rotation of order 6 (60° or 300°)	2	0
Reflection across diagonal	3	4
Reflection across side bisector	3	0

So, there are

$$\frac{1}{12}(1 \cdot 20 + 1 \cdot 0 + 2 \cdot 2 + 2 \cdot 0 + 3 \cdot 4 + 3 \cdot 0) = 3$$

nonequivalent ways to string three black beads and three white beads on a necklace.

Now that we have gotten our feet wet on a few easy problems, let's try a more difficult one. Suppose that we have the colors red (R), white (W), and blue (B) that can be used to color the edges of a regular tetrahedron (see Figure 5.1). First, observe that there are $3^6 = 729$ colorings without regard to equivalence. How shall we decide when two colorings of the tetrahedron are nonequivalent? Certainly, if we were to pick up a tetrahedron colored in a certain manner, rotate it, and put it back down, we would think of the tetrahedron as being positioned differently rather than as being colored differently (just as if we picked up a die labeled in the usual way and rolled it, we would not say that the die is now differently labeled). So, our permutation group for this problem is just the group of 12 rotations of the tetrahedron shown in Figure 5.1 and is isomorphic to A_4. (The group consists of the identity; eight elements of order 3, each of which fixes one vertex; and three elements of order 2, each of which fixes no vertex.) Every rotation permutes the 729 colorings, and to apply Burnside's Theorem we must determine the size of $\text{fix}(\phi)$ for each of the 12 rotations of the group.

Clearly, the identity fixes all 729 colorings. Next, consider the element (234) of order 3, shown in the bottom row, second from the left in Figure 5.1. Suppose that a specific coloring is fixed by this element (i.e., the tetrahedron appears to be colored the same before and after this rotation). Since (234) carries edge 12 to edge 13, edge 13 to edge 14, and edge 14 to edge 12, these three edges must agree in color (edge ij is the edge joining vertex i and vertex j). The same argument shows that the three edges 23, 34, and 42 also must agree in color. So, $|\text{fix}(234)| = 3^2$, since there are three choices for each of these two sets of three edges. The nine columns in Table 27.3 show the possible colorings of the two sets of three edges. The analogous analysis applies to the other seven elements of order 3.

Now consider the rotation (12)(34) of order 2. (See the second tetrahedron in the top row in Figure 5.1.) Since edges 12 and 34 are fixed, they may be colored in any way and will appear the same after the rotation (12)(34). This yields $3 \cdot 3$ choices for those two edges. Since edge 13 is carried to edge 24, these two edges must agree in color. Similarly, edges 23 and 14 must agree. So, we have three choices for the pair of edges 13 and 24 and three choices for the pair of edges 23 and 14. This means that we have

Table 27.3 Nine Colorings Fixed by (234).

Edge	Colorings								
12	R	R	R	W	W	W	B	B	B
13	R	R	R	W	W	W	B	B	B
14	R	R	R	W	W	W	B	B	B
23	R	W	B	W	R	B	B	R	W
34	R	W	B	W	R	B	B	R	W
24	R	W	B	W	R	B	B	R	W

3·3·3·3 ways to color the tetrahedron that will be equivalent under (12)(34). (Table 27.4 gives the complete list of 81 colorings.) So, $|\text{fix}((12)(34))| = 3^4$, and the other two elements of order 2 yield the same results.

Now that we have analyzed the three types of group elements, we can apply Burnside's Theorem. In particular, the number of distinct colorings of the edges of a tetrahedron with three colors is

$$\frac{1}{12}(1 \cdot 3^6 + 8 \cdot 3^2 + 3 \cdot 3^4) = 87.$$

Surely it would be a difficult task to solve this problem without Burnside's Theorem.

Just as surely, you are wondering who besides mathematicians are interested in counting problems such as the ones we have discussed. Well, chemists are. Indeed, one set of benzene derivatives can be viewed as six carbon atoms arranged in a hexagon with one of the three radicals NH_2, COOH, or OH attached at each carbon atom. See Figure 27.4 for one example.

So Burnside's Theorem enables a chemist to determine the number of benzene molecules (see Exercise 4). Another kind of molecule considered by chemists is visualized as a regular tetrahedron with a carbon atom at the center and any of the four radicals $HOCH_2$ (hydroxymethyl), C_2H_5 (ethyl), Cl (chlorine), or H (hydrogen) at the four vertices. Again, the number of such molecules can be easily counted using Burnside's Theorem.

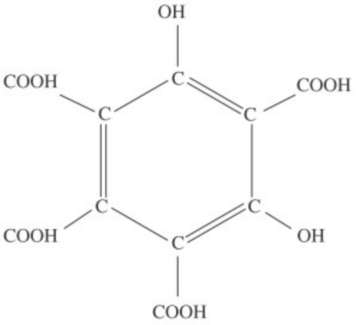

Figure 27.4 Benzene derivative.

Table 27.4 81 Colorings Fixed by (12)(34) (X and Y can be any of R, W, and B.)

Edge	Colorings								
12	X	X	X	X	X	X	X	X	X
34	Y	Y	Y	Y	Y	Y	Y	Y	Y
13	R	R	R	W	W	W	B	B	B
24	R	R	R	W	W	W	B	B	B
23	R	W	B	W	R	B	B	R	W
14	R	W	B	W	R	B	B	R	W

Group Action

Our informal approach to counting the number of objects that are considered nonequivalent can be made formal as follows. If G is a group and S is a set of objects, we say that G *acts on* S if there is a homomorphism γ from G to $\text{sym}(S)$, the group of all permutations on S. (The homomorphism is sometimes called the *group action*.) For convenience, we denote the image of g under γ as γ_g. Then two objects x and y in S are viewed as equivalent under the action of G if and only if $\gamma_g(x) = y$ for some g in G.

Notice that when γ is one-to-one, the elements of G may be regarded as permutations on S. On the other hand, when γ is not one-to-one, the elements of G may still be regarded as permutations on S, but there are distinct elements g and h in G such that γ_g and γ_h induce the same permutation on S [that is, $\gamma_g(x) = \gamma_h(x)$ for all x in S]. Thus, a group acting on a set is a natural generalization of the permutation group concept.

As an example of group action, let S be the two diagonals of a square and let G be D_4, the group of symmetries of the square. Then γ_{R_0}, $\gamma_{R_{180}}$, γ_D, $\gamma_{D'}$ are the identity; $\gamma_{R_{90}}$, $\gamma_{R_{270}}$, γ_H, γ_V interchange the two diagonals; and the mapping $g \to \gamma_g$ from D_4 to sym(S) is a group homomorphism. As a second example, note that $GL(n, F)$, the group of invertible $n \times n$ matrices with entries from a field F, acts on the set S of $n \times 1$ column vectors with entries from F by multiplying the vectors on the left by the matrices. In this case, the mapping $g \to \gamma_g$ from $GL(n, F)$ to sym(S) is a one-to-one homomorphism.

We have used group actions several times in this text without calling them that. The proof of Cayley's Theorem (Theorem 6.5) has a group G acting on the elements of G; the proofs of Sylow's Second Theorem and Third Theorem (Theorems 23.4 and 23.5) have a group acting on the set of conjugates of a Sylow p-subgroup; and the proof of the Generalized Cayley Theorem (Theorem 24.3) has G acting on the left cosets of a subgroup H.

Exercises

The greater the difficulty, the more glory in surmounting it.

Epicurus

1. Determine the number of ways in which the four corners of a square can be colored with two colors. (It is permissible to use a single color on all four corners.)

2. Determine the number of different necklaces that can be made using 13 white beads and 3 black beads.

3. Determine the number of ways in which the vertices of an equilateral triangle can be colored with five colors so that at least two colors are used.

4. A benzene molecule can be modeled as six carbon atoms arranged in a regular hexagon in a plane. At each carbon atom, one of three radicals NH_2, COOH, or OH can be attached. How many such compounds are possible? (Make no distinction between single and double bonds between the atoms.)

5. Suppose that in Exercise 4 we permit only NH_2 and COOH for the radicals. How many compounds are possible?

6. Determine the number of ways in which the faces of a regular dodecahedron (regular 12-sided solid) can be colored with three colors.

7. Determine the number of ways in which the edges of a square can be colored with six colors so that no color is used on more than one edge.

8. Determine the number of ways in which the edges of a square can be colored with six colors with no restriction placed on the number of times a color can be used.

9. Determine the number of different 11-bead necklaces that can be made using two colors.

10. Determine the number of ways in which the faces of a cube can be colored with three colors.

11. Suppose a cake is cut into six identical pieces. How many ways can we color the cake with n colors assuming that each piece receives one color?

12. How many ways can the five points of a five-pointed crown be painted if three colors of paint are available?

13. Let G be a finite group and let $\text{sym}(G)$ be the group of all permutations on G. For each g in G, let ϕ_g denote the element of $\text{sym}(G)$ defined by $\phi_g(x) = gxg^{-1}$ for all x in G. Show that G acts on itself under the action $g \to \phi_g$. Give an example in which the mapping $g \to \phi_g$ is not one-to-one.

14. Let G be a finite group, let H be a subgroup of G, and let S be the set of left cosets of H in G. For each g in G, let γ_g denote the element of $\text{sym}(S)$ defined by $\gamma_g(xH) = gxH$. Show that G acts on S under the action $g \to \gamma_g$.

15. For a fixed square, let L_1 be the perpendicular bisector of the top and bottom of the square and let L_2 be the perpendicular bisector of the left and right sides. Show that D_4 acts on $\{L_1, L_2\}$ and determine the kernel of the mapping $g \to \gamma_g$.

William Burnside

In one of the most abstract domains of thought, he [Burnside] has systematized and amplified its range so that, there, his work stands as a landmark in the widening expanse of knowledge. Whatever be the estimate of Burnside made by posterity, contemporaries salute him as a Master among the mathematicians of his own generation.

A. R. FORSYTH

By permission of the Master and Fellows of Pembroke College in the University of Oxford

WILLIAM BURNSIDE was born on July 2, 1852, in London. After graduating from Cambridge University in 1875, Burnside was appointed lecturer at Cambridge, where he stayed until 1885. He then accepted a position at the Royal Naval College at Greenwich and spent the rest of his career in that post.

Burnside wrote more than 150 research papers in many fields. He is best remembered, however, for his pioneering work in group theory and his classic book *Theory of Groups*, which first appeared in 1897. Because of Burnside's emphasis on the abstract approach, many consider him to be the first pure group theorist. One mark of greatness in a mathematician is the ability to pose important and challenging problems—problems that open up new areas of research for future generations. Here, Burnside excelled. It was he who first conjectured that a group G of odd order has a series of normal subgroups, $G = G_0 \geq G_1 \geq G_2 \geq \cdots \geq G_n = \{e\}$, such that G_i/G_{i+1} is Abelian. This extremely important conjecture was finally proved more than 50 years later by Feit and Thompson in a 255-page paper (see Chapter 24 for more on this). In 1994, Efim Zelmanov received the Fields Medal for his work on a variation of one of Burnside's conjectures.

Burnside was elected a Fellow of the Royal Society and awarded two Royal Medals. He served as president of the Council of the London Mathematical Society and received its De Morgan Medal. Burnside died on August 21, 1927.

1.1 Radiation in General

By definition, a radiation field must be able to carry energy to infinity. If the amplitude of the field is a distance r from the source in the direction (θ, ϕ) is $A(r, \theta, \phi)$, then the flux at r is $F(r, \theta, \phi) \propto A^2(r, \theta, \phi)$. If, for simplicity, we assume that the radiation is spherically symmetric, $A(r, \theta, \phi) = A(r)$, then the luminosity at a distance r must be $\mathcal{L}(r) = \text{Flux} \times \text{Area} \propto A^2(r) \times (4\pi r^2)$.

Projective Transformations

This chapter develops an alternative method of coordinatising a metric affine plane, by embedding it into a *projective* plane, and using the orthogonality relation to define a matrix-representable transformation on the line at infinity. The construction will be central to our subsequent treatment of metric affine spaces of higher dimension, and its description now requires us to review a substantial body of additional ideas.

3.1 Projective Planes

On a couple of occassions in the previous chapter we alluded to the idea of parallel lines meeting at a "point at infinity". This can be made precise in the following way. Let $\alpha = (\mathcal{P}, \mathcal{L}, \mathcal{I})$ be an affine plane. The relation $L \parallel M$ of parallelism is an equivalence relation on $\mathcal{L}$. $\mathcal{P}$ is enlarged by adding one new point for each parallelism class, and then the set of all these new points is declared to be a new line L_∞ "at infinity". A set-theoretically convenient way to carry this out is to *define* L_∞ to be the set of equivalence classes (parallelism classes) of $\mathcal{L}$ under the relation $\parallel$. The new incidence structure can then be specified to be

$$\pi(\alpha) = (\mathcal{P} \cup L_\infty, \mathcal{L} \cup \{L_\infty\}, \mathcal{I}'),$$

where $a\mathcal{I}'L$ iff either

(1) $a\mathcal{I}L$ in α; or

(2) $a \in L_\infty$, and either $L = L_\infty$, or else $L \in a$ (i.e. the α-line L belongs to the parallelism class a).

It is then straightforward to show that $\pi(\alpha)$ satisfies the following properties.

P1. *Any two distinct points lie on exactly one line.*

P2. *Any two distinct lines pass through exactly one point.*

P3. *There exists* a four-point, *i.e. a set of four distinct points, no three of which are collinear.*

Any incidence structure satisfying P1, P2, P3, is called a *projective plane*. We have just seen that an affine plane α can be embedded in a projective plane $\pi(\alpha)$ - the *completion* of α. Conversely, if $\pi = (\mathcal{P}, \mathcal{L}, \mathcal{I})$ is a projective plane, any line L in π may be selected to act as the "line at infinity", and be deleted to give the incidence structure

$$\alpha(\pi - L) = (\mathcal{P} - \{a : a\mathcal{I}L\}, \mathcal{L} - \{L\}, \mathcal{I}),$$

which proves to be an affine plane. There is a natural isomorphism between π and the completion of $\alpha(\pi - L)$, which identifies L with the line at infinity of this completion by identifying point a on L with the parallelism class of all lines in α that meet at a in π.

Axioms P1 and P2 indicate that points and lines have equal "status" in projective planes, and leads to the *principle of duality*, stating that from any theorem provable from P1 - P3 another such theorem results immediately by interchanging the roles of points and lines. For instance, the dual of P3 states that there exist four lines, no three of which are concurrent. As the reader may care to verify, this can be derived from P1 - P3. Thus if $\pi = (\mathcal{P}, \mathcal{L}, \mathcal{I})$ is a projective plane, so too is the *dual plane*

$$\pi^{\partial} = (\mathcal{L}, \mathcal{P}, \mathcal{I}^{-1}),$$

where "point" L is incident with "line" a in π^{∂} if, and only if, $a\mathcal{I}L$ in π.

A property will be satisfied by π^{∂} precisely when its dual is satisfied in π. Thus if a property holds in all projective planes, then in particular it holds in all duals π^{∂}, and so its dual property holds in all projective planes π.

Desarguesian Planes

A pair of triangles (non-collinear triples of points) a, b, c, and a', b', c' are *centrally perspective* from a point p if corresponding vertices are collinear with p, i.e. if the lines aa', bb', and cc' all pass through p (Figure 3.1).

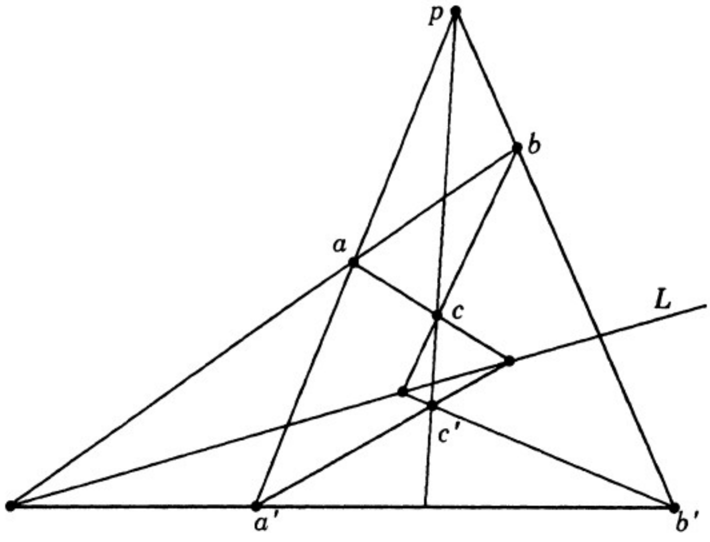

Figure 3.1

Dually, two triangles are *axially perspective* from a line L if corresponding sides are concurrent with L, i.e. if the points $ab \cap a'b'$, $ac \cap a'c'$, and $bc \cap b'c'$ all lie on L (strictly speaking, this dual statement should refer to *trilaterals* (non-concurrent triples of lines) associated with a, b, c and a', b', c'. Recall that the notation $L \cap M$ stands for the intersection point of lines L and M.)

A projective plane is *Desarguesian* if it has the

DESARGUES PROPERTY: *any two centrally perspective triangles are axially perspective.*

Notice that the dual of the Desargues property is its converse. In fact any Desarguesian plane satisfies this converse (cf. e.g. Garner [1981], p.73), so the principle of duality holds for the class of Desarguesian projective planes.

The Desarguesian property may be analysed more closely relative to a line L in a projective plane, as follows.

DESARGUES (L) PROPERTY: *if two triangles are centrally perspective from any point p not on L, and two pairs of corresponding sides meet on L, then the third pair of corresponding sides meet on L.*

LITTLE DESARGUES (L) PROPERTY: *if two triangles are centrally* *perspective from a point p on L, and two pairs of corresponding sides meet on L, then so does the third.*

The Desargues (L) property implies the Little Desargues (L) property (exercise: prove this by drawing a diagram, or see §5.2 of Stevenson [1972] for a more sophisticated proof involving transitivity of groups of collineations).

Recalling the Affine Desargues properties of §2.1 (Figures 2.4, 2.5), it is evident that an affine plane α is Desarguesian precisely when its projective completion $\pi(\alpha)$ has the Desarguesian (L_∞) property. Likewise, α has the Little Affine Desargues property precisely when $\pi(\alpha)$ has the Little Desargues (L_∞) property. Thus if π is any Desarguesian projective plane, and L is a line in π, the affine plane $\alpha(\pi - L)$ got by deleting L will be Desarguesian in the affine sense (since L may be regarded as the line at infinity in the completion of $\alpha(\pi - L)$).

Pappian Planes

PAPPUS (L, M, N) PROPERTY: *if a, b, c and a', b', c' are triples of collinear points on lines M and N, respectively, such that the points $ab' \cap a'b$ and $ac' \cap a'c$ lie on L, then $bc' \cap b'c$ lies on L as well* (Figure 3.2).

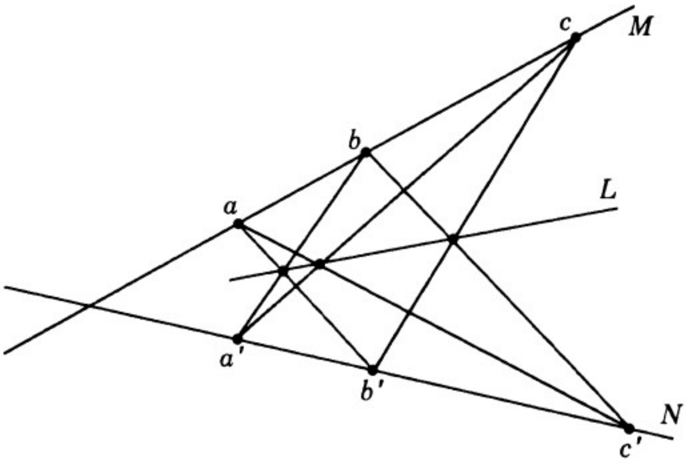

Figure 3.2

PAPPUS (L) PROPERTY: *the Pappus (L, M, N) property holds for all lines M and N distinct from L.*

A projective plane is *Pappian* if it has the Pappus (L) property for all lines L. Since the Pappus (L) property implies the Desargues (L) property (e.g. Stevenson [1972], §6.2), any Pappian projective plane is Desarguesian.

Recalling the Affine Pappus property of §2.1, we see that an affine plane α is Pappian precisely when its completion $\pi(\alpha)$ has the Pappus (L_∞) property. Thus if π is a Pappian projective plane, the planes of the form $\alpha(\pi - L)$ will all be Pappian affine planes.

Coordinates

Canonical examples of Pappian projective planes may be constructed out of the three-dimensional vector spaces F^3 over fields F. Let $\mathcal{P}$ be the set of all *lines* passing through the origin $\mathbf{o}$ in F^3, and $\mathcal{L}$ the set of *planes* of F^3 that pass through $\mathbf{o}$. If $p \in \mathcal{P}$ and $L \in \mathcal{L}$, define p to be *incident* with L if the line p lies in the plane L. This defines an incidence structure π_F which is readily seen to be a projective plane (any two lines (planes) through $\mathbf{o}$ are on a unique plane (line) through $\mathbf{o}$, etc.), and is moreover Pappian. Thus the bundle of affine lines and planes through the origin in F^3 becomes the collection of "points" and "lines" of π_F, which is known as the *projective plane over the point* $\mathbf{o}$, or the *plane at infinity* of F^3.

Now a line through the origin is a set of vectors of the form

$$p = \{\lambda b : \lambda \in F\},$$

where b is a particular (non-zero) direction vector for p. We may use b, or any of its scalar multiples λb as "coordinates" for the point p in π_F. Classically, particularly in relation to the real projective plane $\pi_{\mathbb{R}}$, it was customary to refer to points as being non-zero triples $b = (b_1, b_2, b_3)$ of "homogeneous" coordinates, and to regard any scalar multiple of b as determining the same point. Set-theoretically, we may consider the equivalence relation $\sim$ of *proportionality* on $F^3 - \{\mathbf{o}\}$, where

$$(x_1, x_2, x_3) \sim (y_1, y_2, y_3) \quad \text{iff} \quad \text{there exists } \lambda \in F \text{ with } x_i = \lambda \cdot y_i \text{ for } i = 1, 2, 3.$$

Observe that a *proportionality class*

$$[x_1, x_2, x_3] = \{(y_1, y_2, y_3) : (x_1, x_2, x_3) \sim (y_1, y_2, y_3)\}$$

(together with $\mathbf{o}$) is precisely a line through the origin in F^3. Thus we may take the points of π_F to be the set of such classes $[x_1, x_2, x_3]$.

A plane through the origin in F^3 is given by an equation

$$a_1 \cdot x_1 + a_2 \cdot x_2 + a_3 \cdot x_3 = 0, \tag{1}$$

with $a_1, a_2, a_3 \in F$ being not all zero. Replacing the coefficients of this equation by any proportional triple $(\lambda \cdot a_1, \lambda \cdot a_2, \lambda \cdot a_3)$ would give another equation for the same plane. Hence a line in π_F may be taken to be a proportionality class $< a_1, a_2, a_3 >$, with point $[x_1, x_2, x_3]$ being incident with point $< a_1, a_2, a_3 >$ precisely when equation (1) is satisfied. The use of the two different bracket notations $< \cdots >$ and $[\cdots]$ serves to distinguish points and lines in π_F. The fact that both are determined by non-zero triples of elements of F underscores the duality between points and lines in projective planes.

The association of the projective plane π_F with the three-dimensional geometry of F^3 provides a source of visual imagery that will guide much of what follows. For now it will be used to explain how π_F can be identified with (i.e. is isomorphic to) the projective completion $\pi(\alpha_F)$ of the affine field-plane α_F.

To begin with, α could be identified with a plane of F^3 that does not pass through the origin, say the horizontal plane $z = 1$. The correspondence $(x, y) \mapsto (x, y, 1)$ establishes this (Figure 3.3).

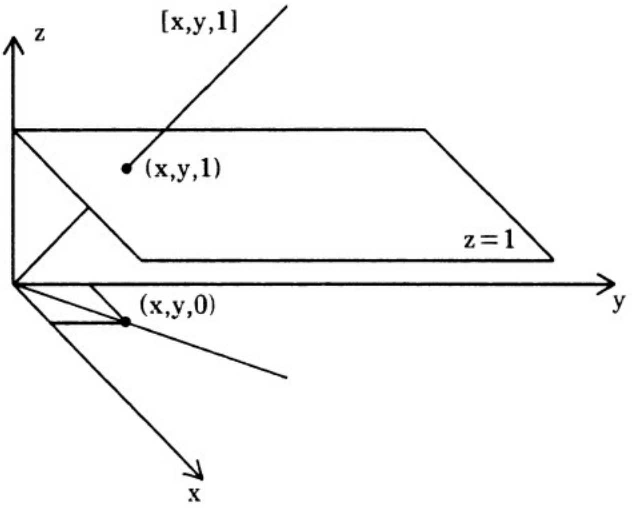

Figure 3.3

Alternatively, identify (x, y) with the projective point $[x, y, 1]$ in π_F (i.e. the line joining $(x, y, 1)$ to the origin). Thus the points of α_F

correspond to the lines through **o** that meet the plane $z = 1$, i.e. all lines through **o** except those, of the form $[x, y, 0]$, that lie in the x-y-plane. Any plane through **o** other than the x-y-plane will cut the plane $z = 1$ in a line, and so will correspond to a line in α_F. It then becomes clear that the x-y-plane itself corresponds to the line at infinity in the completion of α_F. For, given a line L through **o** in the x-y-plane, the bundle of all planes of F^3 containing L will cut $z = 1$ in a family of parallel lines. Moreover, any family of parallel lines in $z = 1$ arises from a line L of this type in the manner described, and the description establishes an exact correspondence between points of π_F of the form $[x, y, 0]$ and parallelism classes of lines in α_F, i.e. points at infinity in $\pi(\alpha_F)$.

This construction also provides a solution to the coordinatisation problem for any Pappian projective plane π. If L is a line in π, the structure $\alpha(\pi - L)$ is a Pappian affine plane, so is isomorphic to the plane α_F over some field F. Hence, as above, $\alpha(\pi - L)$ is isomorphic to the plane of all points $[x, y, z]$ with $z \neq 0$ in α_F. But then this isomorphism extends to one between π and π_F: each point p of L corresponds to a parallelism class of lines in $\alpha(\pi - L)$ (those lines having p as their point at infinity) and such a class of lines corresponds to a point of π_F of the form $[x, y, 0]$. In this way it is seen that any Pappian projective plane is isomorphic to a projective field-plane π_F. Furthermore, this *coordinatisation* can be set up in such a way that any prescribed line L becomes the line at infinity, i.e. the line $<0, 0, 1>$ of points of the form $[x, y, 0]$.

3.2 Projectivities and Involutions

If L is a line in a projective plane, the set $[L]$ of points on L is called a *range*, with *axis* L. If p is a point, the set $[p]$ of all lines passing through p is a *pencil*, with *centre* p.

If p is not on L, there is a natural bijection $f : [L] \to [p]$ obtained by joining each point of L to p, i.e. f maps point x on L to the unique line xp of the pencil $[p]$ that passes through x (Figure 3.4). f is called the *projection* of the range $[L]$ from p, and will be denoted $[L] \triangleright [p]$.

Dually there is the bijection $g : [p] \to [L]$ obtained by intersecting each line through p with L, i.e. $g(M) = M \cap L$ (Figure 3.5). g is the *section* of the pencil $[p]$ by L, and will be denoted $[p] \triangleleft [L]$. Clearly $[p] \triangleleft [L]$ is the inverse function to $[L] \triangleright [p]$.

A *projectivity* is a function obtained by composing a finite sequence of projections and sections. Such a sequence must consist *alternately* of projections and sections, since a projection can only

2. Glue the sides of the polygons according to the permutation α in such a way that the orientation of the sides glued together is always opposite; this condition guarantees that the resulting surface will be oriented, see Fig. 1.19.

3. At each vertex, the darts will be automatically glued in a cyclic order according to the permutation $\sigma = \varphi^{-1}\alpha^{-1}$.

It remains to verify that in the topological space thus obtained, a neighborhood of every point is homeomorphic to an open disk in $\mathbb{R}^2$. For points inside the polygons it is true because they are parts of the plane. For points on edges it is true because we glue together exactly two polygons. Finally, for vertices it is true exactly because of the cyclic order on the "angles" of the polygons. See Fig. 1.19.

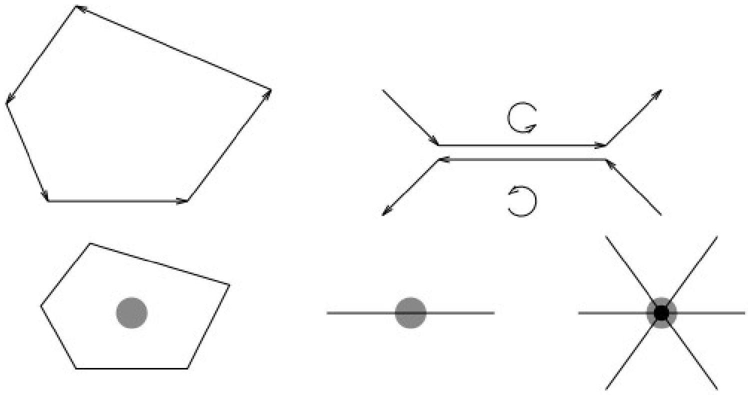

Fig. 1.19. Various stages of gluing a surface out of polygons

Remark 1.3.21. Let us return once more to the example shown in Fig. 1.11. There is no problem in labelling the darts. The permutation α is determined by the graph structure. We may even introduce σ: the cyclic order of the darts at each vertex is determined by the fact that the graph is drawn on an oriented surface. (In fact, in this example there is only one vertex of degree greater than 2, where such an order is significant.) Then why have we said that this figure does not represent a map? What exactly does not work here?

The answer is as follows. Having found α and σ, compute φ. You will get a face of degree 1 inside the loop, and an "outer face" of degree 5. Now apply the procedure of Construction 1.3.20. What you will find is not the torus but the sphere. If we insist on considering this figure as a map, we must consider it as a *plane* map. It is drawn on the sphere, and the handle of the torus stole in illegally.

Construction 1.3.22 (From a covering to a map). Let us give one more construction, which is probably even more efficient than the previous one.

%9 ' ' it ;;;

According to Proposition 1.2.15, for any constellation there exists a ramified covering of the sphere determined by this constellation. Take the constellation $[\sigma, \alpha, \varphi]$, and let $y_1, y_2, y_3 \in S^2$ be the corresponding ramification points on the sphere. Then the map in question is obtained as the preimage of the following "degenerate map" on S^2, shown in Fig. 1.20: it does not have even a single edge but only a half-edge, or a dart, represented by a segment connecting y_1 to y_2.

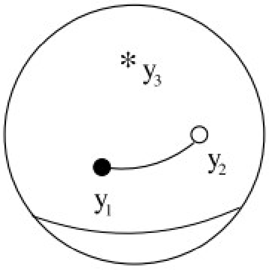

Fig. 1.20. A half-edge drawn on S^2; its preimage under the ramified covering corresponding to a constellation $[\sigma, \alpha, \varphi]$ is the map corresponding to the same constellation.

The preimages of y_2 are often called the *midpoints* of the edges, and the preimages of y_3 are often called the *centers* of the faces.

All the above considerations lead us to the following definition:

Definition 1.3.23 (Combinatorial map). A *combinatorial map* is a 3-constellation $[\sigma, \alpha, \varphi]$ in which α is an involution without fixed points. Two combinatorial maps are *isomorphic* if the corresponding constellations are isomorphic.

Remark 1.3.24. Many authors give an equivalent definition, in which they consider only the pair $[\sigma, \alpha]$ instead of the triple $[\sigma, \alpha, \varphi]$, because φ is determined by σ and α.

The correspondence between topological maps and combinatorial maps is one to many, because each topological map may be labelled in many different ways. But if two topological maps are isomorphic, then the corresponding combinatorial maps are also isomorphic.

A dictionary may easily be established between the two notions. For the vertices it looks like this:

a vertex of a map	a cycle of σ
vertex degree	length of the cycle
number of vertices	number of cycles in σ

and the same for the edges and α and for the faces and φ. On a more profound level, the following definition may be given:

Definition 1.3.25 (Automorphism group). The automorphism group of a map M, denoted by $\mathrm{Aut}(M)$, is the centralizer of its cartographic group G in S_n, that is, the set of the permutations which commute with all the elements of G:

$$\mathrm{Aut}(M) = \{h \mid h^{-1}gh = g \quad \forall g \in G\}.$$

Of course, in order to verify that a permutation h belongs to this set, it is sufficient to verify that h commutes with σ and α.

Remark 1.3.26. Here the reader should make a pause and meditate a little upon the difference between the notions of isomorphism and that of automorphism. The permutation model possesses many advantages, but there is also a disadvantage with which we will often struggle in the future. Namely, it is the possibility to label the same topological object in too many ways (in the "generic" case, in $n!$ ways), and thus obtain yet more and more new triples $[\sigma, \alpha, \varphi]$. All of them are isomorphic. (In the future we will try to reduce the number of labellings by imposing various restrictions on them.) But for the notion of automorphism the corresponding difficulty does not exist. In the above definition, the triple $[\sigma, \alpha, \varphi]$ is chosen arbitrarily at first, but is fixed afterwards; therefore, a permutation commuting with it is a "true" automorphism whose existence is not due to a relabelling. For the overwhelming majority of maps the automorphism group is trivial: $\mathrm{Aut}(M) = \{\mathrm{id}\}$.

Exercise 1.3.27. Verify on examples that if a map is mirror symmetric, then the permutation expressing this mirror symmetry is not an automorphism.

Remark 1.3.28. There exists one more subtle point hidden in Definition 1.3.25. In general, the centralizer is an object associated not to a group but to a pair consisting of a group and of its subgroup (it is the centralizer of the subgroup inside a given group). A cartographic group is a permutation group, and as such is embedded into S_n. But the same "abstract" group may act on different number n of points, and thus be embedded into different S_n. For example, the group A_5 acting on 5 points has trivial centralizer, while "the same" group A_5 acting on 60 points has as a centralizer a group isomorphic to A_5 (it is the automorphism group of the icosahedron). In this latter case both groups A_5 are embedded into S_{60}, but they are embedded differently. Geometrically this becomes clear if we note that the automorphism group respects the incidence of darts to vertices, edges and faces, while the cartographic group does not respect these relations. See also the discussion in Sec. 1.7.3.

Recalling the notation $c(g)$ for the number of cycles of a permutation g (see Notation 1.1.9) we may rewrite the Euler formula:

$$\chi(M) = c(\sigma) - c(\alpha) + c(\varphi) = 2 - 2g. \tag{1.3}$$

' '

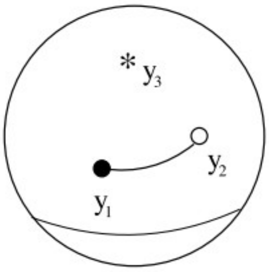

Fig. 1.20. A half-edge drawn on S^2; its preimage under the ramified covering corresponding to a constellation $[\sigma, \alpha, \varphi]$ is the map corresponding to the same constellation.

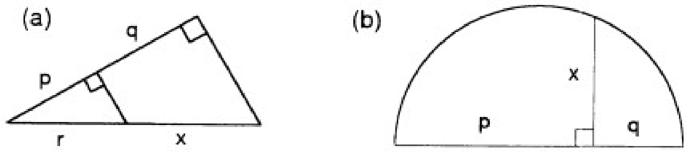

FIGURE 1.7.

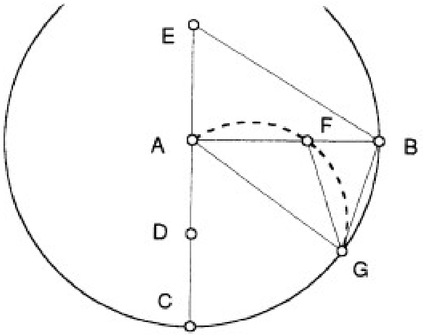

FIGURE 1.8.

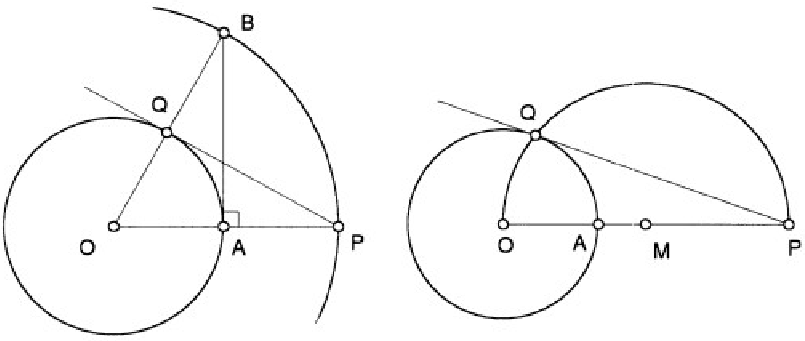

FIGURE 1.6.

Euclid III.37. If Q,R,S are points on a circle, point P is outside the circle, secant $\overleftrightarrow{RS}$ passes through P, and $(PR)(PS) = PQ^2$, then $\overleftrightarrow{PQ}$ is a tangent to the circle.

We turn to the constructions from Book IV of the *Elements* after mentioning only the following two easy constructions from later Books. Figure 1.7a illustrates VI.12. Here, we have $p/q = r/x$ and so $x = rq/p$. Hence, by taking p or q to be 1, we see that VI.12 essentially gives us the product of given lengths r and q as well as the quotient of given lengths r and p. Figure 1.7b illustrates VI.13, which echoes II.14. Here, we have $p/x = x/q$ and so $x = \sqrt{pq}$. Hence, we see that VI.13 gives us $\sqrt{pq}$, the geometric mean of given lengths p and q.

Euclid VI.12. Construct a fourth proportional to three given segments. (Given segments of lengths p,q,r, then construct a segment of length x such that $p/q = r/x$.)

Euclid VI.13. Construct a mean proportional to two given segments. (Given segments of lengths p and q, then construct a segment of length x such that $p/x = x/q$.)

We are going to jump over the first nine constructions from Book IV. Read the statement below of IV.10 and try to think why you might want to solve this problem.

Euclid IV.10. Construct an isosceles triangle having base angles that are double the third angle.

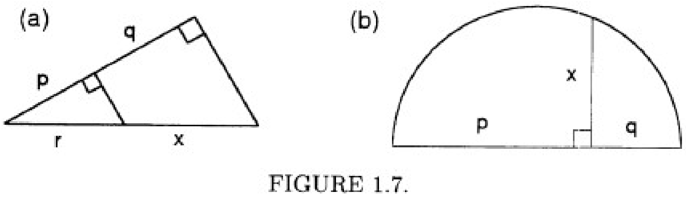

FIGURE 1.7.

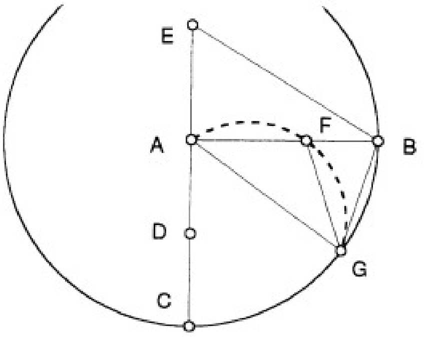

FIGURE 1.8.

Construction for IV.10. Given A_B, let the perpendicular to $\overline{AB}$ at A intersect A_B at C. Let D be the midpoint of $\overline{AC}$. Let D_B intersect $\overrightarrow{CA}$ at E, and let A_E intersect $\overline{AB}$ at F. Let B_{AF} intersect A_B at G. Then $m\angle BAG = 36$, and $m\angle ABG = m\angle AGB = 2\,m\angle BAG = 72$.

Proof. By Euclid II.11, point F is constructed on $\overline{AB}$ such that $(AB)(BF) = AF^2 = BG^2$. See Figure 1.8. Point G is constructed such that $BG = AF$. Since $BG^2 = (BF)(BA)$, then $\overleftrightarrow{BG}$ is tangent to the circumcircle of $\triangle AFG$. (Here is where we use III.37, which is given above.) Hence, $\angle BAG \cong \angle FGB$. Then, by the Exterior Angle Theorem applied to $\triangle GAF$, we have $m\angle BFG = m\angle BAG + m\angle FGA$. So $\angle BFG \cong \angle BGA$. Since $\triangle ABG$ is isosceles, then $\angle FBG \cong \angle BGA$. Hence, $\triangle GBF$ is isosceles and $GF = BG = AF$. So, $\angle FGA \cong \angle FAG$. Then $m\angle BGA = 2m\angle BAG$. Therefore, $m\angle BAG = 36$, as desired. ∎

We now know how to construct a regular decagon, since we can construct an angle of 36°. In Figure 1.8, we can march along the circumference of A_B marking off vertices of distance BG each from another. Taking alternate vertices of the regular decagon, we have the vertices of a regular pentagon. This would be a great construction for a regular pentagon if there were not an even better one that we have already done without realizing it. We will show that $\overline{BE}$ in Figure 1.8 is congruent to a side of a regular pentagon inscribed in A_B. Because $BG = AF = AE$, we already know $\overline{AE}$ is congruent to a side of a regular decagon inscribed in A_B.

Definition. Let s_n denote the length of a side of a regular n-gon inscribed in a circle having unit radius.

Consider a regular n-gon inscribed in a circle with radius 1. With the perpendicular drawn from the center to one side, it follows from elementary trigonometry that $\sin(360/2n)^\circ = (s_n/2)/1$. Hence, $s_n = 2\sin(180/n)^\circ$. We have already determined that $s_{10} = AE/AB = (-1+\sqrt{5}\,)/2$ in Figure 1.8. Since $s_{10} = 2\sin 18^\circ = 2\cos 72^\circ$, then $\cos 72^\circ = s_{10}/2 = (-1+\sqrt{5}\,)/4$. By the half-angle formula $\sin(x/2) = \sqrt{(1-\cos x)/2}$ from trigonometry, we

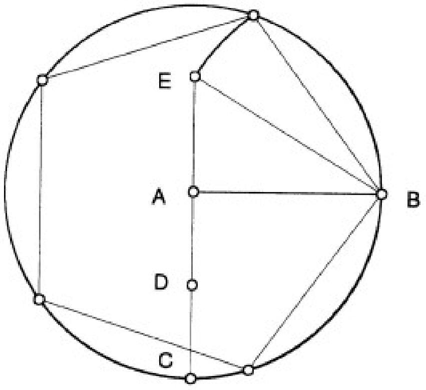

FIGURE 1.9.

have $\sin 36° = \sqrt{(1 - \cos 72°)/2}$. Therefore,

$$s_5 = 2 \sin 36° = 2\sqrt{(1 - \cos 72°)/2} = \sqrt{(5 - \sqrt{5}\,)/2}.$$

We put this together with some results that are easier to get:

Theorem. In general, $s_n = 2 \sin(180/n)°$. In particular,

$$s_3 = \sqrt{3}, \quad s_4 = \sqrt{2}, \quad s_5 = \sqrt{\frac{5 - \sqrt{5}}{2}}, \quad s_6 = 1, \quad s_{10} = \frac{-1 + \sqrt{5}}{2}.$$

You may be less than excited about finding s_5. However, the remarkable thing about our calculation of s_5 is that it is now just a trivial calculation in arithmetic to prove the following theorem of Euclid.

Euclid XIII.10.

$$s_5^2 = s_6^2 + s_{10}^2.$$

In Figure 1.8, we have $s_6 = AB/AB$, $s_{10} = AE/AB$, and $\triangle ABE$ is a right triangle. Hence, from XIII.10 and the Pythagorean Theorem, we see that $s_5 = BE/AB$ in the figure. The points F and G are used for the proof of the construction for IV.10 but are not needed for the construction of $\overline{BE}$. Therefore, as a consequence of XIII.10, we have the promised shorter construction that leads to a regular pentagon. This is stated below. See Figure 1.9, where we have $BE/AB = s_5$ and $AE/AB = s_{10}$. That is, $\overline{BE}$ is congruent to a side of a regular pentagon inscribed in A_B, and $\overline{AE}$ is congruent to a side of a regular decagon inscribed in A_B.

Construction for a regular pentagon and a regular decagon (Euclid). Let the perpendicular to $\overline{AB}$ at A intersect A_B at C. Let D be the midpoint of $\overline{AC}$. Let D_B intersect $\overrightarrow{CA}$ at E. Then $\overline{BE}$ is congruent to a side of a regular pentagon inscribed in A_B, and $\overline{AE}$ is congruent to a side of a regular decagon inscribed in A_B .

A pentadecagon is a 15-gon. We offer the following construction for a regular triangle (an equilateral triangle) inscribed in a given circle O_P. Check it out.

O_P, P_O	A_B, O_P	$\triangle ABC$
A, B	B, C	

Since we can construct an equilateral triangle and a regular pentagon with ruler and compass, it follows that we can construct angles of 60° and 36°. The existence of a ruler and compass construction for a regular pentadecagon now follows from a simple theorem of arithmetic: $360/15 = 24 = 60 - 36$.

Euclid IV.16. In a given circle, inscribe a regular pentadecagon.

If a regular n-gon can be constructed with a ruler and a compass, then a regular $2n$-gon can be constructed with a ruler and a compass. We can now construct all the regular polygons that the ancient Greeks could construct with a ruler and a compass:

The regular n-gons constructible with a ruler and a compass in antiquity. Values for n:

$$\begin{array}{l} 3, 6, 12, 24, 48, 96, \dots, \\ 4, 8, 16, 32, 64, 128, \dots, \\ 5, 10, 20, 40, 80, 160, \dots, \\ 15, 30, 60, 120, 240, 480, \dots . \end{array}$$

This is where things stood until March 29, 1796, when at age eighteen Carl Friedrich Gauss (1777–1855) created a ruler and compass construction for a regular 17-gon. Gauss's birthday was April 30 and so he was nineteen when he announced the result on the first day of June. This construction of the regular heptadecagon by the greatest mathematician since Newton (1642–1727) was published in 1801. Which regular n-gons are constructible with a ruler and a compass will be explained in the next chapter.

Herbert W. Richmond of King's College, Cambridge, gave an efficient ruler and compass construction for a regular heptadecagon in 1893 and again with more detail in 1909. We give, without proof, Richmond's construction for a regular 17-gon that is inscribed in a circle and has vertices V, V_1, V_2, V_3, … , V_{16}. It is sufficient to find adjacent vertices V_3 and V_4 in order to determine a side of the inscribed heptadecagon. See Figure 1.10.

Construction for a regular heptadecagon (H. W. Richmond). Let O_V be a unit circle with diameter $\overline{VA}$. Let $\angle BOV$ be right with $BO =$

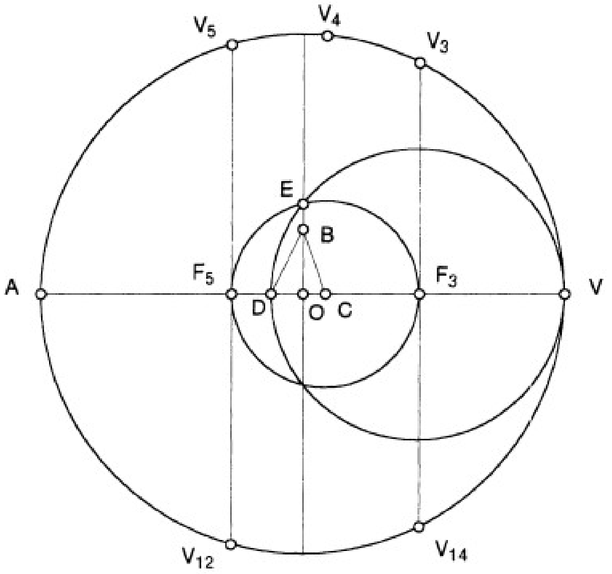

FIGURE 1.10.

$OV/4$. Let C be on $\overline{OV}$ with $m\angle OBC = (m\angle OBV)/4$. Let D be on $\overline{OA}$ with $m\angle CBD = 45$. Let the circle with diameter $\overline{DV}$ intersect $\overrightarrow{OB}$ at E. Let C_E intersect $\overrightarrow{CV}$ at F_3 and intersect $\overrightarrow{CA}$ at F_5. Let the perpendiculars to $\overleftrightarrow{VA}$ at F_3 and F_5 intersect a semicircle on $\overline{VA}$ at V_3 and V_5. Let V_4 be the intersection of O_V and the perpendicular bisector of the segment with endpoints V_3 and V_5. Then $V_3V_4 = s_{17}$.

You should do both of the following exercises now. If you can resist, do not read Exercise 1.5 until you have completed Exercise 1.4.

Exercise 1.4. Read over Richmond's construction for a regular heptadecagon until you feel familiar with it. With ruler, compass, and watch at hand, give yourself a large circle that takes up one full page. Note the time. Carry out the Richmond construction with the ruler and compass to the point of determining the seventeen vertices. Note the time when you are finished and calculate the time it took you to execute the construction. Do the construction only once, even if it "doesn't work."

Exercise 1.5. With ruler, compass, and watch at hand, give yourself a large circle that takes up one full page. Note the time. By trial and error, determine to a reasonable degree of accuracy the vertices of a regular heptadecagon inscribed in your circle. Note the time it takes to get your seventeen points. If you have not already done so, do Exercise 1.4; compare your two times and your two figures. What conclusions can you draw from these two exercises?

The rule of the game of geometric constructions that limits the tools to the ruler and the compass is called the "Platonic restriction" and predates Euclid. Although we cannot be sure what prompted Plato, this limitation does provide an elegant game. The ruler and compass constructions are constructions by means of the most basic geometric elements—the lines and the circles. However, the ruler and compass are not the only possible construction tools. We shall look at several possibilities in this book.

The one nonplatonic tool that we consider now is the *tomahawk*. The inventor of this charming construction tool is unknown. Descriptions appeared thirty years before the publication of the extensive study by Pierre-Joseph Glotin, a retired French naval officer and member of the Légion d'Honneuer from Bordeaux. Glotin's 1863 paper begins: A very ingenious pratical solution to the problem of trisecting angles employs the use of the well-known instrument named *trisector*. Glotin's ("depuis longtemps connu") trisector, which could not have been too well known, was reported in detail to the larger mathematical community in 1877 by Henri Brocard. Pierre Glotin's trisector is our tomahawk.

The essential skeleton of the tomahawk (or shoemaker's knife) is shown in Figure 1.11a, where $AB = BC = CD$, the semicircle has diameter $\overline{BD}$, and $\overrightarrow{BE} \perp \overline{BA}$. A decorative, fleshed-out version is shown in Figure 1.11b, where the use of the tomahawk is also illustrated. The tomahawk's special function is to trisect angles. The tomahawk is inserted in a given angle $\angle UVW$ so that V lies on $\overrightarrow{BE}$, point A lies on one side of the angle, and the semicircle is tangent to the other side of the angle. Now, you are to convince yourself that $\overrightarrow{VB}$ and $\overrightarrow{VC}$ do trisect the given angle.

Attaching to a tomahawk the proper rigid T, hinged at the point of the tomahawk, as indicated in Figure 1.11c, we produce an angle quinquesector that is actually a quinsector. (To quinquesect a given angle is to construct an angle having measure one-fifth the measure of the given angle; to quinsect a given angle is to divide the angle into five congruent parts. "Quinquesector" seems to have a more interesting ring to it than "quinsector" and the frequently used word "quintisector.") Attaching more T's, we would produce a construction tool that divides an angle into any odd number of congruent parts, as Glotin pointed out in 1863. An alternative method for doing this is to use several congruent tomahawks at once. For example, by attaching two congruent tomahawks together (such that at its point A one pivots about the point C of the other) as in Figure 1.11d, we can achieve the quinsection of a given angle.

Until recently, all geometers would know many of Euclid's propositions by number. Although this is no longer the case, we shall assume hereafter that the statement of each of Euclid I.2, Euclid I.3, and Euclid I.31 is known by number and we shall refer to them in this way. Euclid I.2 is important to us because the problem requires showing a modern compass and a euclidean compass are equivalent. Note that we have shown above only that they are equivalent in the presence of a ruler. We will want to find out whether the

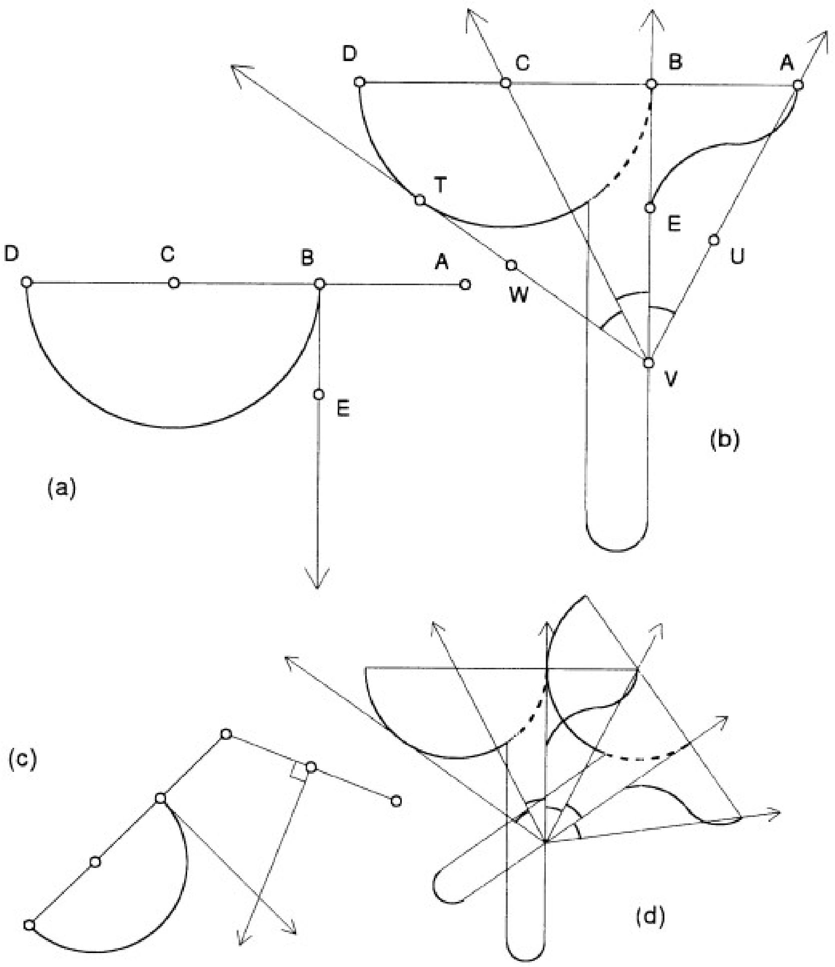

FIGURE 1.11.

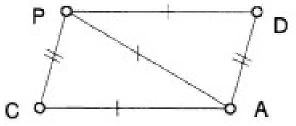
ruler is necessary for this equivalence. As previously mentioned, Euclid I.3 describes what a dividers does. Later, we shall investigate what we can do with a ruler and a dividers, without a compass. Finally, Euclid I.31 is intrinsically important simply because of the importance of parallels in euclidean geometry. This proposition will turn up repeatedly and we shall want to refer to some of the particular solutions to this problem. The following catalog of constructions is by no means exhaustive. SAS, SSS, and SAA denote the familiar congruence theorems for triangles. You will be able to deduce what we are calling the Side-splitting Theorem from the fourth construction. We are constructing the line through P that is parallel to $\overleftrightarrow{AB}$, where P is off $\overleftrightarrow{AB}$.

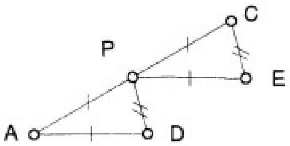
(1) Using alternate interior angles (Euclid):

$A_P, \overleftrightarrow{AB}$	P_A, A_{PC}	$\overleftrightarrow{PD}$
C	D $\overline{DC}$ intersects $\overleftrightarrow{AP}$	



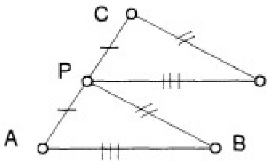
(2) Using corresponding angles:

$P_A, \overleftrightarrow{AP}$	$A_P, \overleftrightarrow{AB}$	P_C, C_{PD}	$\overleftrightarrow{PE}$
A, C	D	E $\overline{DE}$ doesn't intersect $\overleftrightarrow{AP}$	



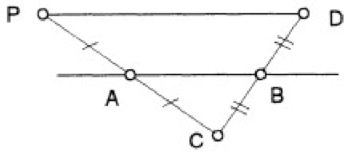
(3) Using corresponding angles and SSS:

$P_A, \overleftrightarrow{AP}$	C_{PB}, P_{AB}	$\overleftrightarrow{PD}$
A, C	D $\overline{BD}$ doesn't intersect $\overleftrightarrow{AP}$	



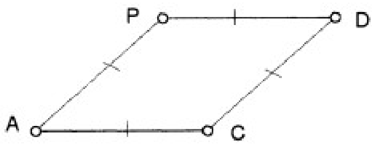
(4) Using the Side-splitting Theorem:

$A_P, \overleftrightarrow{AP}$	$B_C, \overleftrightarrow{BC}$	$\overleftrightarrow{PD}$
P, C	C, D	



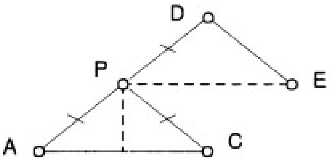
(5) Using a rhombus:

$A_P, \overleftrightarrow{AB}$	C_A, P_A	$\overleftrightarrow{PD}$
C	A, D	



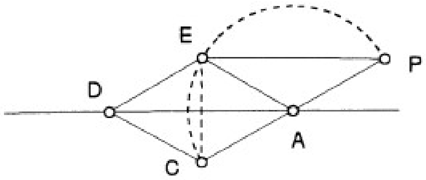
(6) $\perp$ to $\perp$, using angle bisectors of a linear pair of angles are $\perp$; take $PA \geq PB$ (so that $C \neq A$ below):

$P_A, \overleftrightarrow{AB}$	$P_A, \overleftrightarrow{AP}$	C_P, D_P	$\overleftrightarrow{PE}$
A, C	A, D	P, E	



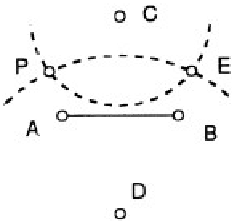
(7) $\perp$ to $\perp$, using Theorem of Thales; take $PA \geq PB$:

$A_P, \overleftrightarrow{AP}$	$C_A, \overleftrightarrow{AB}$	D_C, A_C	$\overleftrightarrow{PE}$
P, C	A, D	C, E	



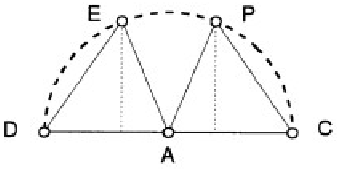
(8) Using $\perp$ to $\perp$ again; take $\perp$ bisector of $\overline{AB}$ off P:

A_B, B_A	C_P, D_P	$\overleftrightarrow{PE}$
C, D	P, E	



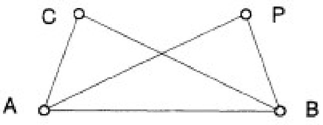
(9) Equidistant curve; take $PA \geq PB$:

$A_P, \overleftrightarrow{AB}$	A_P, D_{CP}	$\overleftrightarrow{PE}$
C, D	E $\overline{PE}$ doesn't intersect $\overleftrightarrow{AB}$	



(10) Short but requires having $\perp$ bisector of $\overline{AB}$ off P:

A_{BP}, B_{AP}	$\overleftrightarrow{PC}$
C $\overline{PC}$ doesn't intersect $\overleftrightarrow{AB}$	



(11) Quick and dirty:

P_{AB}, B_{AP}	$\overleftrightarrow{PC}$
C $\overline{AC}$ intersects $\overleftrightarrow{BP}$	

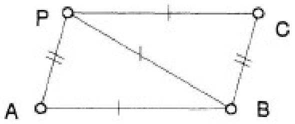


FIGURE 1.12.

One of the amazing successes of secondary education is the respect that is learned for mathematics. It is not unusual for a student who has done Exercises 1.4 and 1.5 to compare a pathetic curve that doesn't even form a polygon but was drawn with a ruler and compass to an apparently perfect regular 17-gon that was drawn by trial and error and then to conclude that the ruler and compass construction is "the better 17-gon because it is—or could be—more accurate," in spite of the presence of the obvious contradictory evidence. On the other hand, this faith does have its foundation. The pathetic curve does represent an interesting theorem, while the handsome polygon is just that, a drawing and nothing more. If we want a drawing of a regular 17-gon, we do not go to Richmond's construction for directions. Exaggeration often helps to see things more clearly. Would we seriously consider following the very lengthy directions, which do exist(!), for a ruler and compass construction of a regular 257-gon? We know beforehand that our result would most likely be way off. Our experience has taught us that the accuracy of even a very simple construction drawing is a function of how recently we sharpened our pencil. The point of all this is that we are interested in the mathematical theory suggested by the tools. If not, then we should do something else instead of studying geometric constructions. Geometric constructions is an interesting mental game. Our imperfect construction drawings can only suggest our perfect construction theorems.

$$\vec{l} = \vec{r} \times \vec{p}.$$

Here, $\vec{r}$ is the vector that points from the center of the circle to the particle, and $\vec{p}$ is the momentum of the particle. All three vectors are shown in Figure 7.1. It is easy to see that although $\vec{r}$ and $\vec{p}$ change directions along the circle, this is not the case for $\vec{l}$. In fact, according to classical physics, $\vec{l}$ is a constant of motion, which means that $\vec{l}$ can only be changed under the influence of external forces. Other, perhaps better known, constants of motion are energy and momentum. The fact that $\vec{l}$ is a constant of motion also explains why you can ride a bicycle and that, in principle, this becomes easier the faster you drive.

7 Rotations

7.1 Angular momentum and moment of inertia

Before discussing the quantum theoretical treatment of rotations, we will briefly describe two fundamental concepts of physics. They should actually be well known(!), but it may be useful to repeat their definitions here.

The first quantity is that of the angular momentum. We first consider a particle moving on a circular path; see Figure 7.1. The angular momentum $\vec{l}$ is a vector that is defined as

$$\vec{l} = \vec{r} \times \vec{p}. \tag{7.1}$$

Here, $\vec{r}$ is the vector that points from the center of the circle to the particle, and $\vec{p}$ is the momentum of the particle. All three vectors are shown in Figure 7.1. It is easy to see that although $\vec{r}$ and $\vec{p}$ change directions along the circle, this is not the case for $\vec{l}$. In fact, according to classical physics, $\vec{l}$ is a constant of motion, which means that $\vec{l}$ can only be changed under the influence of external forces. Other, perhaps better known, constants of motion are energy and momentum. The fact that $\vec{l}$ is a constant of motion also explains why you can ride a bicycle and that, in principle, this becomes easier the faster you drive.

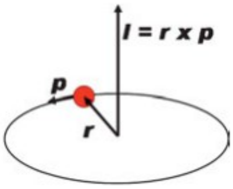

Figure 7.1: The angular momentum of a particle moving on a circular path.

Some movements are more complex and cannot be described by a simple circular path. Figure 7.2 shows an example of such a movement. Each small animal undergoes a superposition of two circular movements: on the one hand, the whole system with all the animals rotates around a common axis, and on the other hand, each cup with one animal rotates around its axis. Also, for this composite motion, there is an angular momentum vector, namely the sum of the vectors of the individual motions.

This is shown in Figure 7.3 for an example. Here, the three angular momentum vectors for three circular motions, which are not even in the same plane, are vectorially added together to form a total angular momentum vector.

There is a simple reason why we are interested in angular momenta. Electrons or atomic nuclei, which make any closed, more or less circular movements, ultimately form nothing but small circuits. Such can be influenced by magnetic fields, which is

https://doi.org/10.1515/9783110742206-007

Figure 7.2: A more complex movement composed of several circular movements.

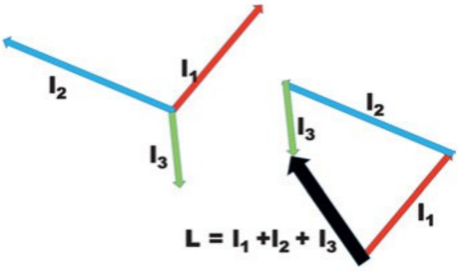

Figure 7.3: The total angular momentum, $\vec{L}$, for a motion composed of three separate rotations with angular momenta $\vec{l}_1$, $\vec{l}_2$, and $\vec{l}_3$, respectively.

what is exploited in magnetic resonance spectroscopy (NMR, ESR, EPR, for example). Because, as always, the energy is quantized (i. e., can only assume certain values), a small circuit in a magnetic field can only have a finite number of energies, whose energy differences then can be measured by means of spectroscopy. These energy levels depend not only on the applied magnetic field but also on a property of the circuits—their angular momenta. We will discuss this relationship in more detail in Section 7.5.

The second quantity that we will briefly reintroduce is the moment of inertia. Again we consider the system of Figure 7.1. The particle, with mass m, rotates about an axis (containing the angular momentum vector) at a distance r to this. The moment of inertia around this axis is defined as

$$I = mr^2. \tag{7.2}$$

If we have several particles that can have different masses and distances to the axis, the total moment of inertia is given by

$$I = \sum_i m_i r_i^2. \tag{7.3}$$

Here, m_i is the mass of the ith particle and r_i its distance to the axis. We emphasize that the moment of inertia makes sense only if you define the associated axis.

Equation (7.3) can be generalized so that also larger bodies can be treated. We let $\rho(\vec{s})$ be the density of the body at the point $\vec{s}$ and then have in general the analogy to above,

$$I = \int \rho(\vec{s}) r^2(\vec{s})\, d\vec{s}. \tag{7.4}$$

$r(\vec{s})$ is the distance from the point $\vec{s}$ to the axis.

7.2 2D rotor

Before we present the correct quantum mechanical treatment of the two-dimensional rotor, we discuss a simplified treatment based mainly on classical arguments.

We consider a system as in Figure 7.1, a particle moving at a constant angular velocity on a circular path. Our arguments, however, are not limited to this example, but the result will be generally valid if we consider a body with a given moment of inertia rotating about an axis with constant angular velocity. But let us start with the system of Figure 7.1.

The total energy of the particle is equal to the kinetic energy because we assume that no forces are acting on the system. So

$$E = E_{\text{kin}} = \frac{p^2}{2m}. \tag{7.5}$$

At the same time, the magnitude of the angular momentum equals

$$l = pr. \tag{7.6}$$

We have set the mass and momentum of the particle equal to m and p, respectively, while r is the radius of the circular orbit.

By combining equations (7.5) and (7.6), we get

$$E = \frac{l^2}{2mr^2} = \frac{l^2}{2I}. \tag{7.7}$$

Here is

$$I = mr^2 \tag{7.8}$$

the moment of inertia of the system.

At this point, we introduce the de Broglie relation, which provides a link between the wave and particle nature of quantum mechanical objects,

$$p = \frac{h}{\lambda}. \tag{7.9}$$

λ is the wavelength of the system if the system is considered as a quantum mechanical wave. This wave is accordingly located on the circular path. Requiring that the wave does not annihilate itself (in other words, requiring that there is a constructive interference), a whole number of waves must fit on the circular path. Accordingly, the length of this path, $2\pi r$, must be equal to an integral multiple of λ,

$$2\pi r = n\lambda, \tag{7.10}$$

with $n = 1, 2, 3, \ldots$.

From equations (7.6), (7.9), and (7.10), we obtain then

$$l = pr = \frac{hr}{\lambda} = \frac{hr}{2\pi r/n} = n \cdot \frac{h}{2\pi} = n \cdot \hbar, \tag{7.11}$$

and according to equation (7.7) the energy becomes then

$$E = \frac{\hbar^2}{2I} n^2. \tag{7.12}$$

This means that both the energy and the magnitude of the angular momentum are quantized.

We will now show that this result is also obtained by a “correct” quantum theoretical treatment. For this, we assume that the particle is moving in the (x, y) plane and that it moves around the origin of the coordinate system. The two-dimensional Schrödinger equation then becomes

$$-\frac{\hbar^2}{2m}\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}\right)\psi = E \cdot \psi. \tag{7.13}$$

Actually, we only have one motional degree of freedom because

$$x^2 + y^2 = r^2 \tag{7.14}$$

is constant. Therefore, equation (7.14) is less useful. Instead, we introduce polar coordinates in two dimensions,

$$\begin{aligned} x &= r \cdot \cos\phi \\ y &= r \cdot \sin\phi. \end{aligned} \tag{7.15}$$

If the above expressions are used in equation (7.14), we need expressions like

$$\frac{\partial}{\partial x} = \frac{\partial}{\partial r} \cdot \frac{\partial r}{\partial x} + \frac{\partial}{\partial \phi} \cdot \frac{\partial \phi}{\partial x} \tag{7.16}$$

and

$$\frac{\partial^2}{\partial x^2} = \frac{\partial^2}{\partial r^2} \cdot \left(\frac{\partial r}{\partial x}\right)^2 + \frac{\partial}{\partial r} \cdot \frac{\partial^2 r}{\partial x^2} + \frac{\partial^2}{\partial \phi^2} \cdot \left(\frac{\partial \phi}{\partial x}\right)^2 + \frac{\partial}{\partial \phi} \cdot \frac{\partial^2 \phi}{\partial x^2} \tag{7.17}$$

and the similar expressions for the derivatives with respect to y. If you do not make mistakes (or you just look up in a mathematical collection of formulas where you can easily find those formulas), you get

$$\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}=\frac{\partial^2}{\partial r^2}+\frac{1}{r}\frac{\partial}{\partial r}+\frac{1}{r^2}\frac{\partial^2}{\partial \phi^2}. \tag{7.18}$$

In our case, the whole becomes particularly simple: because r is constant, all differentiations with respect to r can be ignored (r can not be varied), so that the Schrödinger equation (7.13) can be written as

$$-\frac{\hbar^2}{2m}\frac{1}{r^2}\frac{\partial^2}{\partial \phi^2}\psi(\phi)=E\psi(\phi) \tag{7.19}$$

Here, we have also taken advantage of the fact that the wave function depends only on the angle ϕ.

Equation (7.19) can be rewritten as

$$-\frac{\hbar^2}{2I}\frac{\partial^2}{\partial \phi^2}\psi(\phi)=E\psi(\phi). \tag{7.20}$$

This equation has the solutions

$$\psi(\phi)=A\cdot e^{im_l\phi} \tag{7.21}$$

with A equal to a constant and

$$m_l=\pm\sqrt{\frac{2IE}{\hbar^2}}. \tag{7.22}$$

We must have (see Figure 7.4) that

$$\psi(\phi+2\pi)=\psi(\phi), \tag{7.23}$$

(this is called cyclic boundary conditions), from which we get that m_l must be integral. Then equation (7.23) becomes

$$E=\frac{\hbar^2 m_l^2}{2I},\quad m_l=0,\pm1,\pm2,\dots, \tag{7.24}$$

i. e., just as in equation (7.12).

The angular momentum vector in this case lies along the z axis, so that its x and y components vanish, and the length of the angular momentum vector becomes equal to the absolute value of its z component. The quantum mechanical operator of its z component is

$$\hat{l}_z=\hat{x}\cdot\hat{p}_y-\hat{y}\cdot\hat{p}_x=\frac{\hbar}{i}\left(x\frac{\partial}{\partial y}-y\frac{\partial}{\partial x}\right)=\frac{\hbar}{i}\frac{\partial}{\partial \phi} \tag{7.25}$$

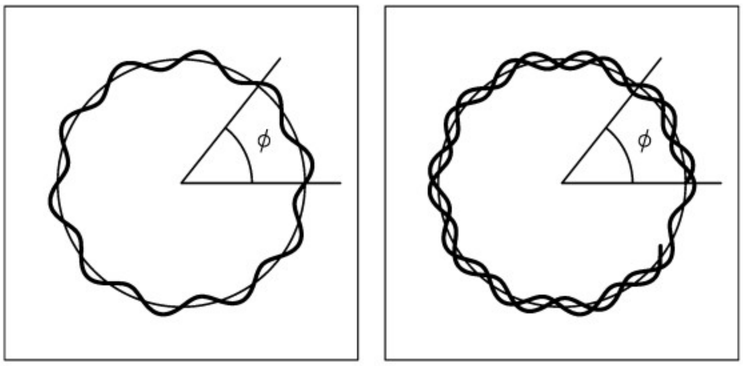

Figure 7.4: The cyclic boundary conditions for the two-dimensional rotor. The picture shows the imaginary part of $e^{im\phi}$, i. e. $\sin(im\phi)$, for (left) m integral and (right) m nonintegral. The thicker curve shows the function value relative to 0 (shown as the thinner curve) as a function of the angle ϕ. It can be seen how only in the left panel the function is mapped onto itself, when ϕ is increased by 2π.

by expressing it in terms of polar coordinates. For the functions of equation (7.21), we obtain immediately,

$$\hat{l}_z\psi(\phi) = \frac{\hbar}{i}\frac{\partial}{\partial\phi}(A \cdot e^{im_l\phi}) = \hbar m_l A \cdot e^{im_l\phi} = \hbar m_l \psi(\phi), \tag{7.26}$$

i. e., the wave function is also an eigenfunction to $\hat{l}_z$ with the eigenvalue $m_l\hbar$.

Finally, we determine the normalization constant A of the wave function. Because the wave function is to be normalized over its entire domain (i. e., ϕ from 0 to 2π), we have

$$\int_0^{2\pi} |\psi(\phi)|^2 \, d\phi = |A|^2 \cdot 2\pi \equiv 1, \tag{7.27}$$

where we choose

$$A = \frac{1}{\sqrt{2\pi}}. \tag{7.28}$$

In Figure 7.5, the real and imaginary parts of the wave functions are shown for some of the smallest, nonnegative values of m_l. This figure also shows the angular momentum vectors.

7.3 3D rotor

For the two-dimensional rotor, we considered a particle that could move in a two-dimensional plane, with the restriction that the distance to a certain point, which

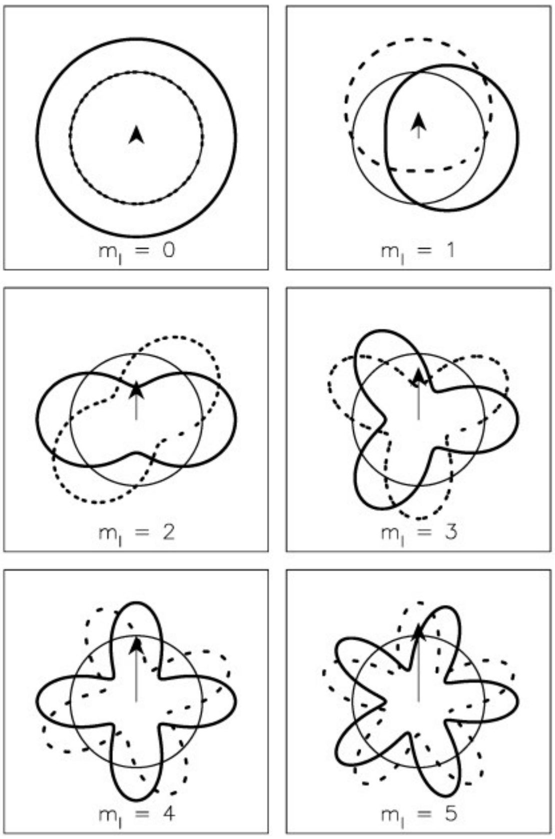

Figure 7.5: The six energetic lowest states for the two-dimensional rotor. The thick solid curves represent the real parts of the wave functions, and the thick, dashed curves represent the imaginary parts. The thin curves represent 0, and the arrows in the center show the angular momentum vectors, which are supposed to be perpendicular to the plane of the images.

we later chose as the origin of the coordinate system, is constant. For the three-dimensional rotor, we proceed in a similar way. This time, the particle can move in a three-dimensional space with the restriction that the distance to a certain point, which in turn we will choose as the origin of the coordinate system, must be constant. In this case, we will present only the quantum theoretical treatment.

As with the two-dimensional rotor, it is again convenient to use a suitable coordinate system. This time, we will use the polar coordinates in three dimensions, also called spherical coordinates. Their definition is shown in Figure 7.6.

We have

$$\begin{aligned} x &= r\sin\theta\cos\phi \\ y &= r\sin\theta\sin\phi \\ z &= r\cos\theta. \end{aligned} \tag{7.29}$$

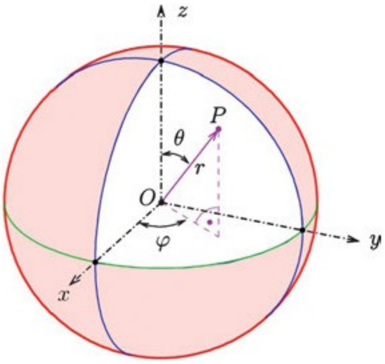

Figure 7.6: The definition of polar coordinates in three dimensions, also called spherical coordinates.

Also, for these coordinates, we need the expression of the Laplace operator [see equation (2.4)]

$$\begin{aligned}\nabla^2 &= \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \\ &= \frac{\partial^2}{\partial r^2} + \frac{2}{r}\frac{\partial}{\partial r} + \frac{1}{r^2 \sin^2\theta}\frac{\partial^2}{\partial \phi^2} + \frac{1}{r^2 \sin\theta}\frac{\partial}{\partial \theta}\sin\theta\frac{\partial}{\partial \theta} \\ &\equiv \frac{\partial^2}{\partial r^2} + \frac{2}{r}\frac{\partial}{\partial r} + \frac{1}{r^2}\hat{\Lambda}^2. \end{aligned} \tag{7.30}$$

We have here introduced the operator

$$\hat{\Lambda}^2 = \frac{1}{\sin^2\theta}\frac{\partial^2}{\partial \phi^2} + \frac{1}{\sin\theta}\frac{\partial}{\partial \theta}\sin\theta\frac{\partial}{\partial \theta} \tag{7.31}$$

that contains all differentiations with respect to the two angles ϕ and θ.

For the three-dimensional rotor, r is constant, so that in the Schrödinger equation all terms with derivatives with respect to r can be ignored. Then the Schrödinger equation becomes

$$-\frac{\hbar^2}{2mr^2}\hat{\Lambda}^2\psi(\theta,\phi) = E\psi(\theta,\phi), \tag{7.32}$$

where we have explicitly stated that the wave function ψ depends on the two angles θ and ϕ, but not on r. Equation (7.32) can also be written as

$$\hat{\Lambda}^2\psi(\theta,\phi) = -\frac{2IE}{\hbar^2}\psi(\theta,\phi), \tag{7.33}$$

where I is the moment of inertia about the origin of the coordinate system (in contrast to the previous section, not about an axis but about a point, because the particle is moving about a single point).

In Sections 2.2 and 4.11, we have seen that it can be helpful to use a product Ansatz in solving differential equations that depend on multiple variables. Thus, we set

$$\psi(\theta,\phi) = \Theta(\theta)\cdot\Phi(\phi). \tag{7.34}$$

By inserting this into equation (7.33), we get

$$\hat{\Lambda}^2\psi = \frac{1}{\sin^2\theta}\Theta\Phi'' + \Phi\frac{1}{\sin\theta}\frac{\partial}{\partial\theta}[\sin\theta\Theta'] = -\frac{2IE}{\hbar^2}\Theta\Phi. \tag{7.35}$$

By dividing by the product $\Theta\Phi$, it follows

$$\frac{\Phi''}{\Phi} + \frac{1}{\Theta}\sin\theta\frac{\partial}{\partial\theta}[\sin\theta\Theta'] = -\frac{2IE}{\hbar^2}\sin^2\theta \tag{7.36}$$

or

$$\frac{\Phi''}{\Phi} = -\frac{1}{\Theta}\sin\theta\frac{\partial}{\partial\theta}[\sin\theta\Theta'] - \frac{2IE}{\hbar^2}\sin^2\theta = -m_l^2. \tag{7.37}$$

In the last identity, we have exploited that the left-hand side depends only on ϕ, while the expression in the middle depends only on θ. This means that they can only be identical if they are a constant. We call this constant $-m_l^2$, for reasons that will become clear soon.

From equation (7.37), we obtain two equations: one for Θ and one for Φ. The latter is

$$\frac{\Phi''}{\Phi} = -m_l^2. \tag{7.38}$$

This has the solution

$$\Phi(\phi) = Ae^{im_l\phi}, \tag{7.39}$$

whereby m_l can be positive, zero, or negative.

As for the two-dimensional rotor, cyclic boundary conditions also apply here:

$$\Phi(\phi + 2\pi) = \Phi(\phi) \tag{7.40}$$

where

$$\Phi(\phi) = \frac{1}{\sqrt{2\pi}}e^{im_l\phi}. \tag{7.41}$$

m_l is accordingly equal to an integer. Furthermore, we have chosen A in equation (7.39) such that $\Phi(\phi)$ is normalized,

$$\int_0^{2\pi} |\Phi(\phi)|^2\, d\phi = |A|^2\cdot 2\pi \equiv 1. \tag{7.42}$$

The other equation, which is given in equation (7.37), is the equation for $\Theta(\theta)$. This equation is

$$\sin\theta\frac{\partial}{\partial\theta}[\sin\theta\Theta'] + \left[\frac{2IE}{\hbar^2}\sin^2\theta - m_l^2\right]\Theta = 0. \tag{7.43}$$

This equation is not easy to solve. It is called Legendre's equation, and fortunately, the solutions to the equation are known. The solutions can be expressed using the so-called Legendre polynomials (after Adrien-Marie Legendre). These are given by

$$P_l(z) = \frac{1}{2^l l!}\frac{d^l}{dz^l}(z^2 - 1)^l. \tag{7.44}$$

We see that here we have introduced a second number l (besides m_l). l can take the values $0, 1, 2, \ldots$. Using the Legendre polynomials, the (normalized) solutions to equation (7.43) are then expressed as

$$\Theta(\theta) = S_{lm_l}(\theta) = (-1)^{m_l}\sqrt{\frac{2l+1}{2}}\sqrt{\frac{(l-m_l)!}{(l+m_l)!}}\sin^{m_l}(\theta)\frac{d^{m_l}P_l(\cos(\theta))}{(d\cos(\theta))^{m_l}}. \tag{7.45}$$

One often introduces the so-called associated Legendre functions

$$P_l^{m_l}(z) = (1 - z^2)^{m_l/2}\frac{d^{m_l}}{dz^{m_l}}P_l(z). \tag{7.46}$$

Then the wave functions ψ in equation (7.47) become

$$\begin{aligned}\psi(\theta,\phi) &= \Theta(\theta)\cdot\Phi(\phi) \equiv Y_{lm_l}(\theta,\phi)\\ &= \begin{cases}(-1)^{m_l}\sqrt{\frac{2l+1}{2}}\sqrt{\frac{(l-m_l)!}{(l+m_l)!}}P_l^{m_l}(\cos\theta)\frac{e^{im_l\phi}}{\sqrt{2\pi}} & m_l \geq 0\\ (-1)^{m_l}Y^*_{l,-m_l}(\theta,\phi) & m_l < 0.\end{cases}\end{aligned} \tag{7.47}$$

It turns out that there are solutions for only certain values of (l, m_l):

$$\begin{aligned}l &= 0, 1, 2, \ldots\\ m_l &= -l, -l+1, -l+2, \ldots, l-2, l-1, l.\end{aligned} \tag{7.48}$$

Moreover, the Y functions are called **spherical harmonic functions** or just **spherical harmonics**.

The mathematical expressions of the spherical harmonics for $l = 0$, 1, 2, and 3 are shown in Table 7.1.

The solutions to the Schrödinger equation, equation (7.32), can therefore be expressed in terms of the spherical harmonics. This equation is a two-dimensional differential equation (we have two coordinates: θ and ϕ), and so their solution leads to the introduction of two quantum numbers, which we have labeled l and m_l, and which

Table 7.1: The spherical harmonic functions for $l = 0, 1, 2$, and 3.

l	m_l	$Y_{lm_l}(\theta, \phi)$
0	0	$\sqrt{\frac{1}{4\pi}}$
1	1	$-\sqrt{\frac{3}{8\pi}} \sin\theta e^{i\phi}$
	0	$\sqrt{\frac{3}{4\pi}} \cos\theta$
	−1	$\sqrt{\frac{3}{8\pi}} \sin\theta e^{-i\phi}$
2	2	$\sqrt{\frac{15}{32\pi}} \sin^2\theta e^{2i\phi}$
	1	$-\sqrt{\frac{15}{8\pi}} \sin\theta \cos\theta e^{i\phi}$
	0	$\sqrt{\frac{5}{16\pi}} (3\cos^2\theta - 1)$
	−1	$\sqrt{\frac{15}{8\pi}} \sin\theta \cos\theta e^{-i\phi}$
	−2	$\sqrt{\frac{15}{32\pi}} \sin^2\theta e^{-2i\phi}$
3	3	$-\frac{1}{8}\sqrt{\frac{35}{\pi}} \sin^3\theta e^{3i\phi}$
	2	$\frac{1}{4}\sqrt{\frac{105}{2\pi}} \cos\theta \sin^2\theta e^{2i\phi}$
	1	$-\frac{1}{8}\sqrt{\frac{21}{\pi}} (5\cos^2\theta - 1) \sin\theta e^{i\phi}$
	0	$\frac{1}{4}\sqrt{\frac{7}{\pi}} (5\cos^2\theta - 3) \cos\theta$
	−1	$\frac{1}{8}\sqrt{\frac{21}{\pi}} (5\cos^2\theta - 1) \sin\theta e^{-i\phi}$
	−2	$\frac{1}{4}\sqrt{\frac{105}{2\pi}} \cos\theta \sin^2\theta e^{-2i\phi}$
	−3	$\frac{1}{8}\sqrt{\frac{35}{\pi}} \sin^3\theta e^{-3i\phi}$

can only assume certain values. This applies in general: a Schrödinger equation in P dimensions leads to P quantum numbers that can only assume certain values.

The energy we obtain is

$$E = \frac{l(l+1)\hbar^2}{2I}. \tag{7.49}$$

We see that E depends only on l but not on m_l. This means that all $2l + 1$ wave functions Y_{lm_l} with the same l but the different m_l values lead to the same energy: they are energetically degenerate.

At the end of this chapter, we discuss the angular momentum. In Section 7.1, we saw that the angular momentum can be written as

$$\vec{l} = (l_x, l_y, l_z) = \vec{r} \times \vec{p} = (yp_z - zp_y, zp_x - xp_z, xp_y - yp_x). \tag{7.50}$$

In Section 7.2, we also introduced the quantum mechanical operator for l_z,

$$\hat{l}_z = \frac{\hbar}{i}\frac{\partial}{\partial\phi} \tag{7.51}$$

It can also be shown that the operator for the square of the length of the angular momentum vector becomes

$$\hat{l}^2 = \hat{l}_x\hat{l}_x + \hat{l}_y\hat{l}_y + \hat{l}_z\hat{l}_z = -\hbar^2\hat{\Lambda}^2. \tag{7.52}$$

Except for a factor $2I$, $\hat{l}^2$ is therefore identical to the Hamilton operator so that

$$\hat{l}^2 Y_{lm_l} = l(l+1)\hbar^2 Y_{lm_l}. \tag{7.53}$$

Simultaneously, it is easily shown by inserting that

$$\hat{l}_z Y_{lm_l} = m_l\hbar Y_{lm_l}. \tag{7.54}$$

The spherical harmonics are thus eigenfunctions both for the operator for the square of the length of the angular momentum vector and for the operator for its z component. At the same time, the second identify in equation (7.48) must be satisfied, which we write as

$$|m_l\hbar| \leq l\hbar \leq \sqrt{l(l+1)}\hbar \tag{7.55}$$

(and the "=" in the second identity applies only to $l = m_l = 0$). This means that the z component of the angular momentum vector is smaller than the length of the angular momentum vector, i. e., the vector cannot lie along the z axis. This result for the angular momentum can be interpreted as shown in Figure 7.7.

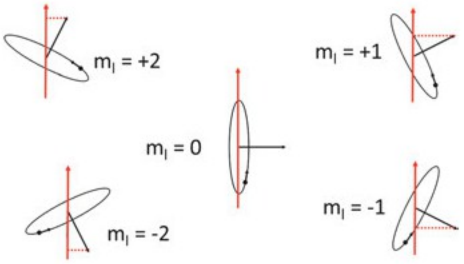

Figure 7.7: The five allowed orientations of the angular momentum vector for $l = 2$. The normal (which is parallel to the angular momentum vector) of the circular orbit of the rotating particle makes a fixed angle to the z axis (shown in red).

Thus, our results give that both the length of the angular momentum and its z component are quantized. But we know nothing about the x and y components, which in principle can take any values. For given l and m_l, the angular momentum vector can therefore lie at any point on one of the circles shown in the right part of Figure 7.8. The vector can even follow a path on this circle. One speaks then of precession.

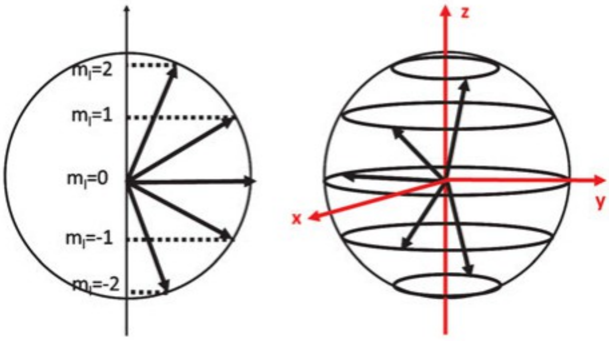

Figure 7.8: The allowed orientations of the angular momentum vector for $l = 2$. As in Figure 7.7, the normal (which is parallel to the angular momentum vector) of the circular orbit of the rotating particle makes a fixed angle to the z axis (shown in red). But because the angles to the other two directions are not fixed, all points on the circles in the right part of the figure are allowed directions of the angular momentum vector.

Precisely because of this precession, the x and y components of the angular momentum vector have no unique values. Would you try, e. g., to measure the x component after determining the z component, the precession will rotate and then take place around the x axis. This means that now, although the x component of the angular momentum vector is known, you lose any information about the z component. Ultimately, this is a consequence of the fact that the three components of the angular momentum vector do not commute,

$$\begin{aligned}[\hat{l}_x, \hat{l}_y] &= i\hbar\hat{l}_z \\ [\hat{l}_y, \hat{l}_z] &= i\hbar\hat{l}_x \\ [\hat{l}_z, \hat{l}_x] &= i\hbar\hat{l}_y, \end{aligned} \tag{7.56}$$

so that the exact determination of more components of the angular momentum vector is not possible [cf. equation (3.71)].

From equation (7.47), it is easy to see that $|Y_{lm_l}(\theta,\phi)|^2$ is independent of ϕ, and that

$$|Y_{lm_l}(\theta,\phi)|^2 = |Y_{l,-m_l}(\theta,\phi)|^2. \tag{7.57}$$

In order to depict the spherical harmonics $|Y_{lm_l}(\theta,\phi)|^2$, one can proceed as follows. Y_{lm_l} is a function of the two angles θ and ϕ, which describe a direction in the three-dimensional coordinate system. Therefore, one chooses a direction (i. e., values for θ and ϕ), computes $|Y_{lm_l}(\theta,\phi)|^2$, and marks a point with this value along the direction (θ,ϕ). Having done this for all values of θ and ϕ, one has generated a surface in three-dimensional space that can be depicted, as done in Figure 7.9.

The spherical harmonics we have introduced are generally complex, meaning that they take complex (rather than purely real) values. From these spherical harmonics,

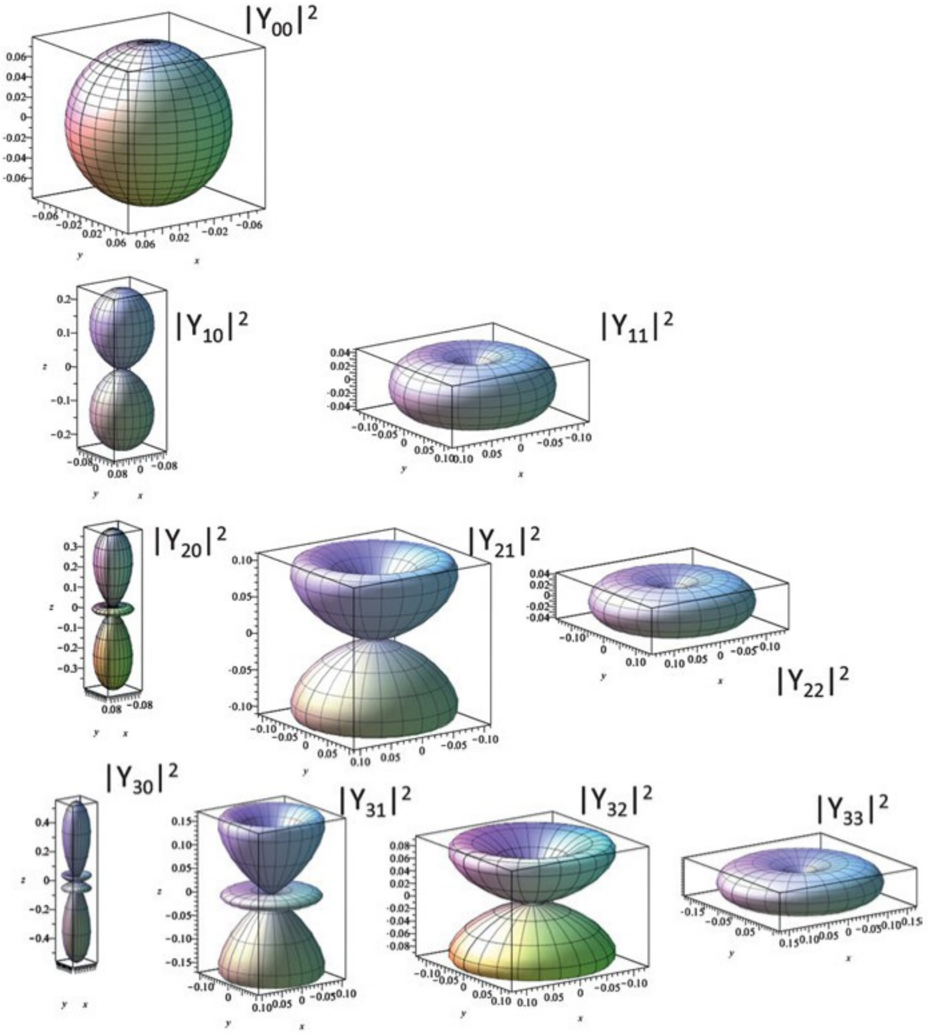

Figure 7.9: Representation of the squared absolute values of some of the complex spherical harmonics.

however, the more well-known s, p_x, … functions can be constructed that take only real values. In general, one creates two new functions from Y_{l,m_l} and $Y_{l,-m_l}$ for $m_l \neq 0$,

$$Y_{l,m_l,\pm} = \frac{c_{l,m_l,\pm}}{\sqrt{2}}(Y_{l,m_l} \pm Y_{l,-m_l}), \tag{7.58}$$

while the functions $Y_{l,0}$ remain unchanged. By judicious choice of the constants $c_{l,m_l,\pm}$ (e. g., $c_{l,m_l,\pm} = \pm 1$ or $\pm i$), it can be achieved that the functions $Y_{l,m_l,\pm}$ are real (rather than complex). For example, p_x and p_y are formed from $Y_{1,1}$ and $Y_{1,-1}$, while $d_{x^2-y^2}$ and d_{xy} are formed from $Y_{2,2}$ and $Y_{2,-2}$. These functions are shown in Figure 7.10. Also, these

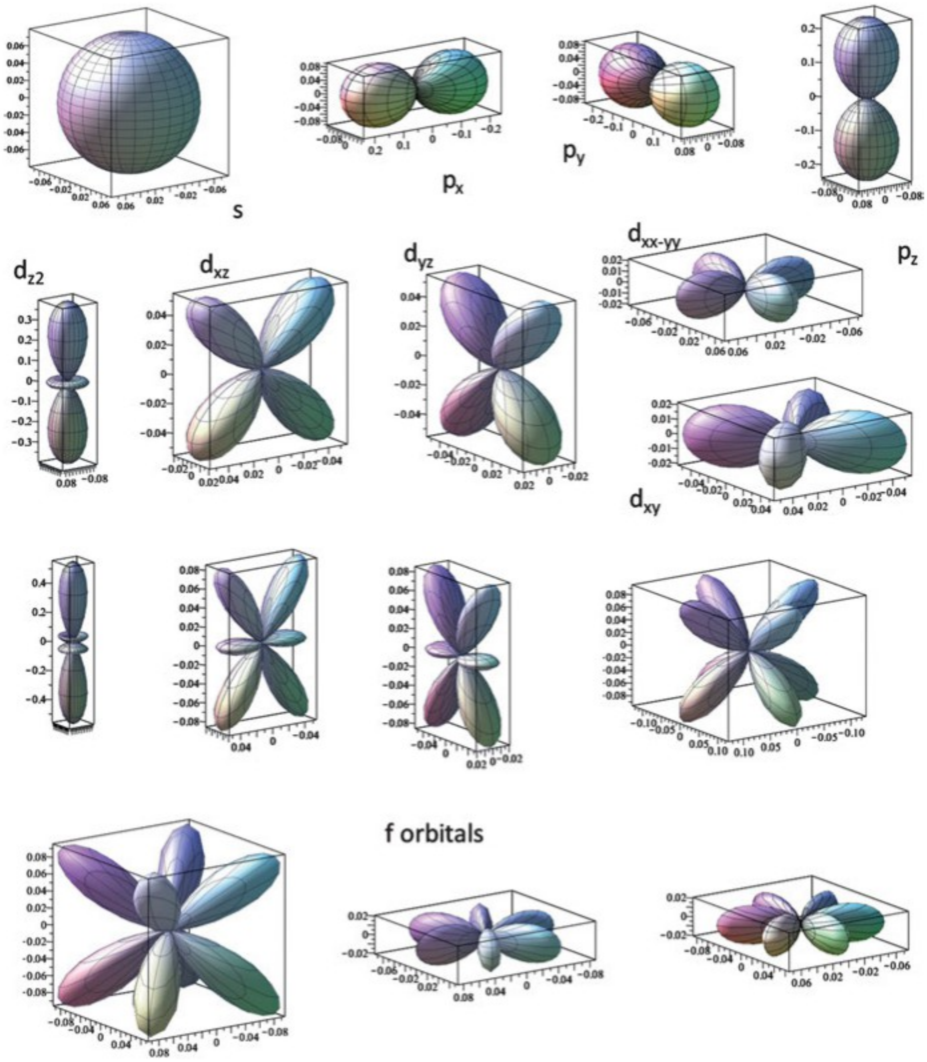

Figure 7.10: Representation of the real spherical harmonics.

functions are eigenfunctions for the Hamilton operator as well as for $\hat{l}^2$ but only for $m_l = 0$ also for $\hat{l}_z$.

That also the real spherical harmonics are eigenfunctions to $\hat{H}$ can be seen as follows. We consider two functions, ψ_1 and ψ_2, that both are eigenfunctions to some (linear) Hamilton operator $\hat{H}$ with the same eigenvalue,

$$\begin{aligned}\hat{H}\psi_1 &= E\psi_1\\ \hat{H}\psi_2 &= E\psi_2.\end{aligned} \tag{7.59}$$

Then, for any linear combination of ψ_1 and ψ_2 we find

$$\hat{H}(c_1\psi_1 + c_2\psi_2) = c_1\hat{H}\psi_1 + c_2\psi_2 = c_1E\psi_1 + c_2E\psi_2 = E(c_1\psi_1 + c_2\psi_2), \tag{7.60}$$

i. e., this is also an eigenfunction to $\hat{H}$. In the present case where we combine Y_{l,m_l} and $Y_{l,-m_l}$ for $m_l \neq 0$, similar arguments can be used to show that the resulting linear combination is also an eigenfunction to $\hat{l}^2$.

7.4 Addition of angular momenta

For systems with several angular momenta, they are added vectorially both in the classical case and in the quantum mechanical case (see Figure 7.3). Then, in the quantum mechanical case, too, the length of the total angular momentum and its z component are quantized. In the general case, however, this does not apply to the individual angular momentum vectors, but only to their sum, if the individual motions influence each other. For example, electrons of an atom are charged and repel each other, so that the motion of each electron depends on those of the others.

For us, it is often the case that the angular momentum will be caused by electrons moving in some orbits. The motion of a single electron generates an angular momentum vector, and from the individual ones a total angular momentum vector is then formed. Then it may happen that the sum disappears.

In the general case, we have that if

$$\vec{L} = \vec{l}_1 + \vec{l}_2 + \cdots + \vec{l}_n \tag{7.61}$$

we have for the corresponding quantum mechanical operator [where $\Psi(\vec{x}_1, \vec{x}_2, \ldots, \vec{x}_n)$ is the wave function of the total system of the n particles]

$$\hat{L}^2\Psi(\vec{x}_1, \vec{x}_2, \ldots, \vec{x}_n) = L(L+1)\hbar^2\Psi(\vec{x}_1, \vec{x}_2, \ldots, \vec{x}_n) \tag{7.62}$$

with L equal to an integer. $L = 0$ is then possible. Furthermore,

$$\hat{L}_z\Psi(\vec{x}_1, \vec{x}_2, \ldots, \vec{x}_n) = M_L\hbar\Psi(\vec{x}_1, \vec{x}_2, \ldots, \vec{x}_n). \tag{7.63}$$

The integer M_L satisfies

$$-L \leq M_L \leq L. \tag{7.64}$$

Similar formulas do not apply for the operators of the individual angular momenta, $\vec{l}_1$, $\vec{l}_2, \ldots, \vec{l}_n$.

As an example, we consider two electrons in one atom. If we first assume that their motions are independent of each other, we can calculate the total angular momentum in equation (7.61) obtained by adding the angular momenta of the individual electrons,

$$\vec{L} = \vec{l}_1 + \vec{l}_2, \tag{7.65}$$

whereby we initially assume that the individual angular momentum vectors are quantized,

$$\begin{aligned}|\vec{l}_1|^2 &= l_1(l_1+1)\hbar^2\\ |\vec{l}_2|^2 &= l_2(l_2+1)\hbar^2.\end{aligned} \tag{7.66}$$

If subsequently the motions of the individual electrons are allowed to influence each other, only the sum will be quantized,

$$|\vec{L}|^2 = L(L+1)\hbar^2, \tag{7.67}$$

and it turns out that the possible values of L are

$$L = |l_1 - l_2|, |l_1 - l_2| + 1, \dots, l_1 + l_2 - 1, l_1 + l_2. \tag{7.68}$$

Specifically, we first have assumed that the two electrons are in the two (different) orbitals ψ_1 and ψ_2, for which

$$\begin{aligned}\hat{l}_1^2\psi_1 &= l_1(l_1+1)\hbar^2\psi_1\\ \hat{l}_2^2\psi_2 &= l_2(l_2+1)\hbar^2\psi_2.\end{aligned} \tag{7.69}$$

Subsequently, the total wave function of the two electrons Ψ is not an eigenfunction to the operators $\hat{l}_1^2$ and $\hat{l}_2^2$, but only to $\hat{L}^2$.

Finally, we mention that we have repeatedly discussed the z component of the angular momentum vector that is quantized while the x and y components are not. It is said that the z direction is the quantization direction. But there is no coordinate system in normal everyday life, and then the choice of the z direction is actually arbitrary. However, there may be experimental conditions that define a “special” or “preferred” direction. This is the case, e. g., when the system is in a magnetic field (a case we will discuss in the next section). Then the direction of the magnetic field is “special” or “preferred” and it is then often convenient to choose this as the z direction.

7.5 Spin of the electron

In 1922, the physicists Otto Stern and Walther Gerlach carried out an experiment in Frankfurt am Main, the results of which led to the discovery of the electron’s spin. However, the exact existence of the spin was not suggested before 1925 and then by Samuel Abraham Goudsmit and George Eugene Uhlenbeck.

So far, we have considered small bodies that can move in more or less circular orbits. When these bodies carry a charge, this results in a small circuit. Such a circuit corresponds to a magnetic moment, $\vec{\mu}$, which is proportional to the angular momentum of the body,

$$\vec{\mu} \propto \vec{l}. \tag{7.70}$$

In a magnetic field with field vector $\vec{B}$, the energy of the magnetic moment equals

$$E_{\text{magn}} = \vec{\mu} \cdot \vec{B}. \tag{7.71}$$

We now place such small circuits in an inhomogeneous magnetic field as in Figure 7.11. Those for which $\vec{\mu}$ is parallel to $\vec{B}$ can reduce their energy by moving in the direction in which $\vec{B}$ becomes smaller. The reverse applies to those for which $\vec{\mu}$ is antiparallel to $\vec{B}$. Overall, the force acting on a circuit depends on the angle between $\vec{\mu}$ and $\vec{B}$, assuming that $|\vec{\mu}|$ is constant.

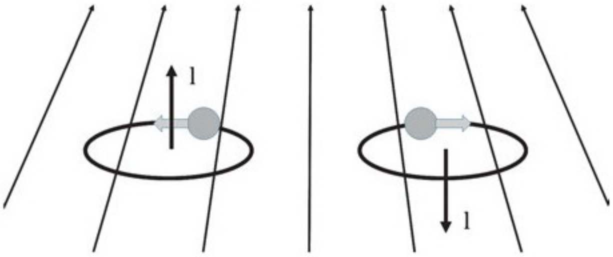

Figure 7.11: Small circuits that are in an inhomogeneous magnetic field. The figure shows two such circuits whose angular momenta point in opposite directions. The thinner lines represent the magnetic field lines. The smaller distances between the field lines in the upper part of the figure compared with the lower part illustrates the inhomogeneity of the field.

Exactly the latter, according to the discussion in this chapter, is the case because $\vec{l}$ is quantized. Furthermore, of convenience, we have introduced a quantization direction through the magnetic field, which in turn means that $\vec{\mu} \cdot \vec{B}$ can only assume discrete values.

Stern and Gerlach used Ag atoms in their experiment. For these, we have to consider the total angular momentum, but it turns out that for Ag atoms in their ground state $\vec{L} = \vec{0}$. This would mean that for all small circuits (= atoms) $\vec{\mu} \cdot \vec{B} = 0$, and that no forces act on the circuits / atoms. But the experiment revealed something else; see Figure 7.12. The Ag atoms were collected on a glass plate, so that one could see exactly where the atoms arrived after passing through the magnetic field. And it was found that there were two groups of atoms. This was explained by the fact that $\vec{\mu} \cdot \vec{B}$ can assume two different values, i. e., that the z component of the angular momentum can take two values.

This result is not easy to explain. We have seen that actually $\vec{L} = \vec{0}$, which means that M_L can only be equal to 0, so that $\vec{B} \cdot \vec{\mu} \propto BM_L$ (if making the convenient choice of placing the z axis along the magnetic field) can only assume one value, 0. It could be suggested that the outermost valence electron of the Ag atom is not in the $5s$ but in the $5p$ orbital, but this would give $L = 1$, so that M_L could assume three different values. The experimental finding that there are only two values for the magnetic moment of

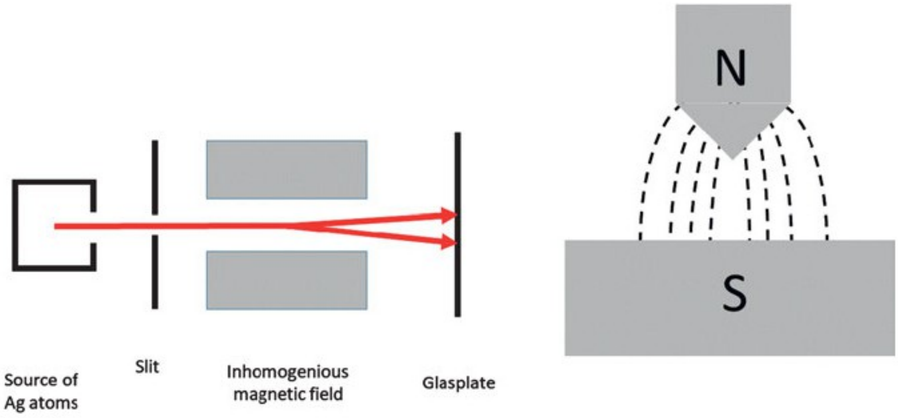

Figure 7.12: Schematic representation of the Stern-Gerlach experiment. Ag atoms enter an inhomogeneous magnetic field and are deflected in two directions and collected on a glass plate. On the right is a cross-section of the magnetic field outlined.

the individual Ag atoms cannot be explained by our previous results that L always has to be an integer, implying that $2L + 1$ is odd and can never be equal to 2.

Nevertheless, one makes the following interpretation: The splitting comes from an additional rotation, which we have not considered so far. The electron cannot only revolve around the nucleus, but also around its own axis (just as the earth revolves around the sun as well as around its own axis). This second rotation is also quantized, and for whatever reason, this motion can be described by means of an angular momentum vector whose length is always equal to $\sqrt{\frac{1}{2}(\frac{1}{2}+1)}\hbar$. This rotational motion is called spin, and its angular momentum is denoted by $\vec{s}$. So this quantum number is always for an electron

$$s = \frac{1}{2} \tag{7.72}$$

so that

$$m_s = -\frac{1}{2}, \frac{1}{2}. \tag{7.73}$$

This interpretation is not perfect. We have found that every rotational motion is quantized and that the allowed quantum numbers can only be integers. In fact, the existence of a spin can only be explained by the combination of quantum theory and the theory of relativity, as Paul Andre Maurice Dirac showed. This combination yields a different equation than the Schrödinger equation (the so-called Dirac equation). It is easy to see that the Schrödinger equation can not be reconciled so easily with the relativity theory. The time-dependent Schrödinger equation (see Section 2.1) includes a second-order differentiation with respect to the position coordinates but only a first-order differentiation with respect to time. The theory of relativity, however, deals with time and position coordinates equivalently. To remedy this contradiction, Dirac introduced a new equation, the Dirac equation, which becomes equivalent to the Schrödinger equation in the limiting case that the speed of light approaches infinity. But as a result of the Dirac equation, one obtains that particles also have a spin which is an integral multiple of a half. As we have seen, it equals a half for electrons.

The Dirac equation will hardly play a role in this course, except for the introduction of the so-called spin-orbit coupling which will be discussed later in Section 11.4.

7.6 Relevance for experiment

By measuring the rotational energy levels of a molecule, information about the moments of inertia of the molecule is obtained. This is part of rotational spectroscopy. This information can be helpful in characterizing the molecule. If the theory in this chapter is used directly to interpret the results, it is assumed that the molecule is rigid. Then one would obtain spectra as shown in Figure 7.13. As this figure suggests, there are so-called selection rules that state that only transitions between neighboring energy levels are possible. This issue shall not be discussed further here. Since the number of degenerate states (i. e., states with the same l but different m_l) increases with l, the heights of the peaks increase initially with l, i. e., with energy. On the other hand, due to the Boltzmann distribution (for the reader who is less familiar with this, see Section 16.4), the number of molecules with a higher energy decreases and, in total, we obtain a curve like that shown in the lower part of Figure 7.13.

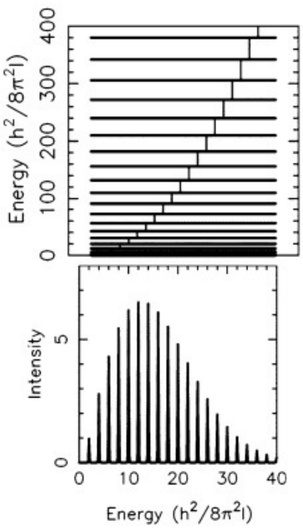

Figure 7.13: Schematic representation of the energy levels of a rigid rotor (upper part) and the accompanying absorption spectrum (lower part). The small, vertical lines in the upper panel show the allowed transitions.

The assumption that the molecule is rigid may be too simple. For example, one can imagine that the molecule expands when it rotates fast (because of the centrifugal force). Then the theory has to be modified accordingly.

Furthermore, one will often simultaneously excite both vibrational and rotational levels. This produces rotational-vibrational spectra, as shown in Figure 7.14. Figure 7.15 shows that the spectrum of the HCl molecule has a fine structure that is even finer than what is caused by the rotation. These are produced by isotope effects: if one isotope is replaced by another, the mass of the corresponding atom changes, and thus also the moment of inertia, and so does the energy level splitting. The analysis of such spectra gives further information on the structure of the molecule.

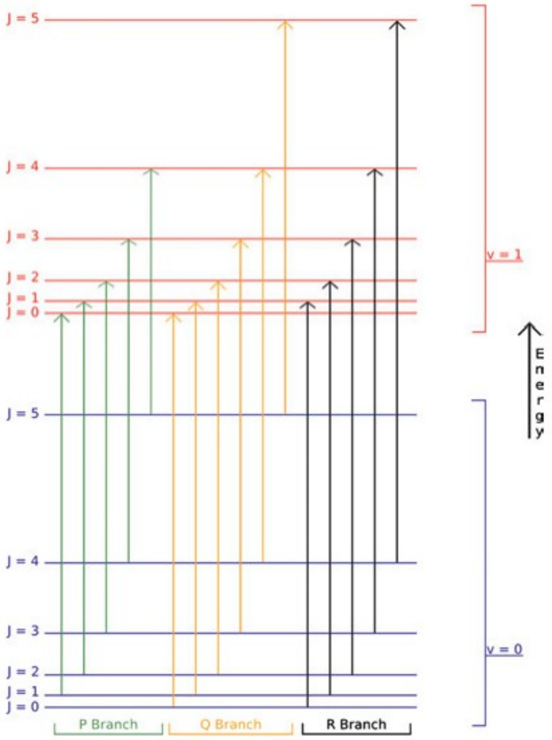

Figure 7.14: The schematic representation of the rotational-vibrational levels of a rotor. $v = 0$ and $v = 1$ represent two levels of vibration, while J represents the different levels of rotation. The vertical arrows show the possible excitations.

But one of the experimentally most important results of this chapter is the existence of spin. The spin also corresponds to an angular momentum vector and therefore couples with the other angular momentum vectors. This, as we shall see later, is important for spin-orbit coupling. Furthermore, the mere existence of a spin is important every-

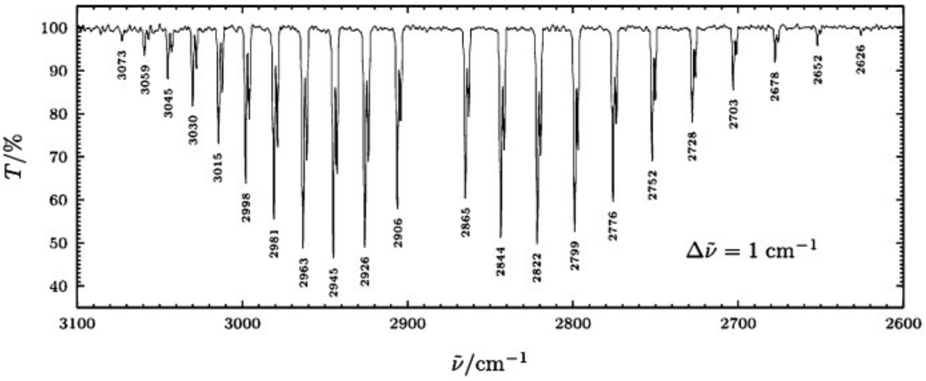

Figure 7.15: The rotation-vibration absorption spectrum of a HCl molecule. Copied on 03.02.17 from https://commons.wikimedia.org/wiki/File:Ir_hcl_rot-vib_mrtz.svg. From mrtzmrtz [CC BY-SA 2.5 (http://creativecommons.org/licenses/by-sa/2.5)], via Wikimedia Commons.

where. Thus, spin-resonance experiments are used to characterize molecules (e. g., NMR, ESR, EPR spectroscopy). The existence of magnetism can to a large part be attributed to the existence of a spin.

In such spin-resonance experiments, it is exploited that those particles that have an angular momentum vector often are charged so that their rotational motion is ultimately equivalent to a small circuit. One can influence this in an external magnetic field. In describing the resulting effect, it is convenient to choose a coordinate system so that the z axis is parallel to the magnetic field. Because the coupling between magnetic field and angular momentum is quantified by the scalar product between magnetic field vector and angular momentum vector, the fact that the z component of the angular momentum vector is quantized means that the size of the coupling can only take finite, discrete values. If one finally measures these couplings, one obtains information about the magnetic field at the place where the particle is located. This magnetic field is not only the externally applied magnetic field, but also has a component, which is due to the fact that all other particles (especially electrons) of the system respond to the externally applied magnetic field and shield it partly. Thus, the information about the magnetic field at the place where the particle is located describes the distribution of the other particles. This provides important chemical information.

Here, we have based the discussion on that the z axis lies along the externally applied magnetic field and the z axis is defined as the quantization direction. This is not necessary: in the end, you would get the same results regardless of how you choose the coordinate system. But this choice is very useful, because it makes all considerations and calculations easier.

7.7 Problems with answers

1. **Problem:** Consider the operators: $\hat{l}_x = \hat{y}\hat{p}_z - \hat{z}\hat{p}_y$, $\hat{l}_y = \hat{z}\hat{p}_x - \hat{x}\hat{p}_z$, $\hat{l}_z = \hat{x}\hat{p}_y - \hat{y}\hat{p}_x$, and $\hat{l}^2 = \hat{l}_x\hat{l}_x + \hat{l}_y\hat{l}_y + \hat{l}_z\hat{l}_z$. Determine the operators $[\hat{l}_x, \hat{l}_y]$, $[\hat{l}_y, \hat{l}_z]$, $[\hat{l}_z, \hat{l}_x]$, and $[\hat{l}_z, \hat{l}^2]$.
Answer: We use

$$\begin{aligned} [\hat{q}_k, \hat{q}_l] &= 0 \\ [\hat{p}_k, \hat{p}_l] &= 0 \\ [\hat{q}_k, \hat{p}_l] &= i\hbar\delta_{k,l}. \end{aligned} \tag{7.74}$$

Then

$$\begin{aligned} [\hat{l}_x, \hat{l}_y] = \hat{l}_x\hat{l}_y - \hat{l}_y\hat{l}_x &= (\hat{y}\hat{p}_z - \hat{z}\hat{p}_y)(\hat{z}\hat{p}_x - \hat{x}\hat{p}_z) - (\hat{z}\hat{p}_x - \hat{x}\hat{p}_z)(\hat{y}\hat{p}_z - \hat{z}\hat{p}_y) \\ &= \hat{y}\hat{p}_z\hat{z}\hat{p}_x - \hat{z}\hat{p}_y\hat{z}\hat{p}_x - \hat{y}\hat{p}_z\hat{x}\hat{p}_z + \hat{z}\hat{p}_y\hat{x}\hat{p}_z \\ &\quad - \hat{z}\hat{p}_x\hat{y}\hat{p}_z + \hat{z}\hat{p}_x\hat{z}\hat{p}_y + \hat{x}\hat{p}_z\hat{y}\hat{p}_z - \hat{x}\hat{p}_z\hat{z}\hat{p}_y \\ &= \hat{y}\hat{p}_z\hat{z}\hat{p}_x + \hat{z}\hat{p}_y\hat{x}\hat{p}_z - \hat{z}\hat{p}_x\hat{y}\hat{p}_z - \hat{x}\hat{p}_z\hat{z}\hat{p}_y = -\hat{y}\hat{p}_x[\hat{z}, \hat{p}_z] + \hat{x}\hat{p}_y[\hat{z}, \hat{p}_z] \\ &= \hat{l}_z[\hat{z}, \hat{p}_z] = i\hbar\hat{l}_z. \end{aligned} \tag{7.75}$$

Subsequently, we use the cyclic permutation

$$\begin{aligned} \hat{l}_x &\to \hat{l}_y \\ \hat{l}_y &\to \hat{l}_z \\ \hat{l}_z &\to \hat{l}_x \end{aligned} \tag{7.76}$$

which changes equation (7.75) into

$$[\hat{l}_y, \hat{l}_z] = i\hbar\hat{l}_x \tag{7.77}$$

and subsequently

$$[\hat{l}_z, \hat{l}_x] = i\hbar\hat{l}_y. \tag{7.78}$$

From these commutator relations, we get

$$\begin{aligned} \hat{l}_z\hat{l}_x &= \hat{l}_x\hat{l}_z + i\hbar\hat{l}_y \\ \hat{l}_x\hat{l}_z &= \hat{l}_z\hat{l}_x - i\hbar\hat{l}_y \\ \hat{l}_z\hat{l}_y &= \hat{l}_y\hat{l}_z - i\hbar\hat{l}_x \\ \hat{l}_y\hat{l}_z &= \hat{l}_z\hat{l}_y + i\hbar\hat{l}_x. \end{aligned} \tag{7.79}$$

Then

$$\begin{aligned} [\hat{l}_z, \hat{l}^2] &= \hat{l}_z(\hat{l}_x\hat{l}_x + \hat{l}_y\hat{l}_y + \hat{l}_z\hat{l}_z) - (\hat{l}_x\hat{l}_x + \hat{l}_y\hat{l}_y + \hat{l}_z\hat{l}_z)\hat{l}_z \\ &= \hat{l}_z\hat{l}_x\hat{l}_x - \hat{l}_x\hat{l}_x\hat{l}_z + \hat{l}_z\hat{l}_y\hat{l}_y - \hat{l}_y\hat{l}_y\hat{l}_z \end{aligned}$$

$$\begin{aligned} &= (\hat{l}_z\hat{l}_x)\hat{l}_x - \hat{l}_x(\hat{l}_x\hat{l}_z) + (\hat{l}_z\hat{l}_y)\hat{l}_y - \hat{l}_y(\hat{l}_y\hat{l}_z) \\ &= (\hat{l}_x\hat{l}_z + i\hbar\hat{l}_y)\hat{l}_x - \hat{l}_x(\hat{l}_z\hat{l}_x - i\hbar\hat{l}_y) + (\hat{l}_y\hat{l}_z - i\hbar\hat{l}_x)\hat{l}_y - \hat{l}_y(\hat{l}_z\hat{l}_y + i\hbar\hat{l}_x) \\ &= 0. \end{aligned} \tag{7.80}$$

Since the commutator vanishes, it is possible to identify states that are eigenfunctions to both operators simultaneously.

2. **Problem:** Consider a system with two *p* electrons. What values can the total spin quantum number *S* and the total angular momentum quantum number *L* assume? Justify the answer.
Answer: It is always true that for a sum like

$$\vec{L} = \vec{l}_1 + \vec{l}_2, \tag{7.81}$$

for which the individual angular momentum vectors

$$\begin{aligned} |\vec{l}_1|^2 &= l_1(l_1+1)\hbar^2 \\ |\vec{l}_2|^2 &= l_2(l_2+1)\hbar^2, \end{aligned} \tag{7.82}$$

are quantized, the sum will also be quantized,

$$|\vec{L}|^2 = L(L+1)\hbar^2. \tag{7.83}$$

The possible values of *L* are then given by

$$L = |l_1 - l_2|, |l_1 - l_2| + 1, \dots, l_1 + l_2 - 1, l_1 + l_2. \tag{7.84}$$

For the *p* electrons $l_1 = l_2 = 1$, so that the values

$$L = 0, 1, 2 \tag{7.85}$$

are possible.
The same applies to the spin, where $s_1 = s_2 = \frac{1}{2}$, so that the values

$$S = 0, 1 \tag{7.86}$$

are possible.

7.8 Problems

1. Explain the Stern–Gerlach experiment.
2. Describe how the energies of the 2-dimensional rotor depend on the quantum number.
3. Sketch the five energetically lowest wave functions of the 2-dimensional rotor.

4. How do the energies of the 2-dimensional rotor change when (a) the mass is doubled or (b) the length of the rotor is doubled?
5. Compare the spherical harmonics Y_{lm_l}, $l = 1$, with the p_x, p_y, and p_z functions. Sketch the functions in (x, y), (x, z), and (y, z) planes.
6. Compare the spherical functions Y_{lm_l}, $l = 2$, with the d_{xz}, d_{yz}, d_{xy}, d_{z^2}, and $d_{x^2-y^2}$ functions. Sketch the functions in (x, y), (x, z), and (y, z) planes.
7. Why is it difficult to explain the spin as a rotation of an electron about its own axis when using the Schrödinger equation?
8. Explain the vector model of the angular momenta.
9. Explain the term "product Ansatz."
10. Consider a system with two d electrons. What values can the total spin quantum number S and the total angular momentum quantum number L assume? Justify the answer.
11. Consider a system with one p electron and one d electron. What values can the total spin quantum number S and the total angular momentum quantum number L assume? Justify the answer.
12. Show that the Y_{lm_l} functions are eigenfunctions to the operator $\hat{l}^2 + \hat{l}_z^2$. Which maximum value or minimum value can the eigenvalue have for a given l?

2.6 *Triangulations: Reconstructing Lengths from Length Cross-Ratios*

To deal with Riemann surfaces that are given in terms of Schottky data (Sect. 8.2) we will need to reconstruct a function $\ell : E_\Sigma \to \mathbb{R}_{>0}$ satisfying (9) from given length cross-ratios. (It is not required that the function ℓ satisfies the triangle inequalities.) To this end, we define auxiliary quantities c^i_{jk} attached to the angles of the triangulation. The value at vertex i of the triangle $ijk \in F$ is defined as

$$c^i_{jk} = \frac{\ell_{jk}}{\ell_{ij}\ell_{ki}}. \tag{11}$$

Then (9) is equivalent to

$$\mathrm{lcr}_{ij} = \frac{c^i_{jk}}{c^i_{lj}}. \tag{12}$$

Now, given a function $\mathrm{lcr} : E^{int} \to \mathbb{R}_{>0}$ defined on the set of interior edges E^{int} and satisfying the product condition (10) around interior vertices, one can find parameters c^i_{jk} satisfying (11) by choosing one value at each vertex and then successively multiplying length cross-ratios. The corresponding function ℓ is then determined by

$$\ell_{ij} = \frac{1}{\sqrt{c^i_{jk}c^j_{ki}}} = \frac{1}{\sqrt{c^i_{lj}c^j_{il}}}. \tag{13}$$

complex numbers. Throughout this chapter, "calculation" is used when exact results are obtained, whereas "computation" is used for numerical results.

Apart from the restriction to an exact representation, all of the algorithms discussed in detail in this chapter are general in the sense that they apply to all compact connected Riemann surfaces. An appendix is presented discussing the use of a few algorithms that apply to a restricted class of algebraic curves and Riemann surfaces, such as elliptic and hyperelliptic surfaces. This appendix contains many examples, but no detailed explanation of the specifics of the algorithms.

All of the descriptions of the algorithms of the main body of this chapter are preceded by the next section which outlines the connection between plane algebraic curves and Riemann surfaces with a level of detail appropriate for what follows. The work reviewed here may be found in [DvH01, DP07a, Pat07, vH95, vH94]. The examples of the implementations use commands available in Maple 11 (Released Spring 2007). A few commands are used that are not available in Maple 11 yet. They are identified as such in the text.

2.2 Relationship Between Plane Algebraic Curves and Riemann Surfaces

In this section, some required background from the theory of Riemann surfaces is introduced. More details can be found in such standard references as [FK92, Spr57]. Excellent places to read up on Riemann surfaces and how they relate to plane algebraic curves that do not require an extensive background are the monographs by Brieskorn and Knörrer [BK86] and Griffiths [Gri89].

Consider a plane algebraic curve, defined over the complex numbers $\mathbb{C}$, i.e., consider the subset of $\mathbb{C}^2$ consisting of all points (x, y) satisfying a polynomial relation in two variables x and y with complex coefficients:

$$f(x,y) = a_n(x)y^n + a_{n-1}(x)y^{n-1} + \ldots + a_1(x)y + a_0(x) = 0 \,. \tag{2.1}$$

Here $a_j(x)$, $j = 0, \ldots, n$ are polynomials in x. Write $a_j(x) = \sum_i a_{ij}x^i$, where the coefficients a_{ij} are complex numbers. Assuming $a_n(x)$ does not vanish identically, n is the degree of $f(x, y)$ considered as a polynomial in y. We only consider irreducible algebraic curves, so $f(x, y)$ cannot be written as the product of two non-constant polynomials with complex coefficients.

Let d denote the degree of $f(x, y)$ as a polynomial in x and y, i.e., d is the largest $i + j$ for which the coefficient a_{ij} of $x^i y^j$ in $f(x, y)$ is non-zero. The behavior at infinity for both x and y is examined by homogenizing $f(x, y) = 0$ by letting

$$x = X/Z \,, \quad y = Y/Z \,, \tag{2.2}$$

and investigating

$$F(X,Y,Z) = Z^d f(X/Z, Y/Z) = 0 \,. \tag{2.3}$$

Here $F(X, Y, Z)$ is a homogeneous polynomial equation of degree d. Finite points $(x, y) \in \mathbb{C}^2$ on the algebraic curve correspond to triples $(X : Y : Z)$ with $Z \neq 0$. Since for these points $(X : Y : Z) = (X/Z : Y/Z : 1)$, we may equate $Z = 1$, so finite points can be denoted unambiguously by (x, y) instead of $(X/Z, Y/Z)$. Points at infinity correspond to triples $(X : Y : Z)$, with $Z = 0$. Hence, at a point at infinity, at least one of the two coordinate functions x or y is infinite. Because $F(X, Y, 0)$ is a homogeneous polynomial of degree d, there are at most d points at infinity.

The algebraic curve can have singular points. An algorithm to efficiently calculate the singular points of an algebraic curve is discussed in Sect. 2.5. Here we briefly discuss singularities as they need to be dealt with in order to construct the Riemann surface from an algebraic curve. Finite singular points on the algebraic curve specified by $f(x, y) = 0$ satisfy $f(x, y) = 0 = \partial_x f(x, y) = \partial_y f(x, y)$. Points at infinity can also be singular. Singular points at infinity satisfy $\partial_X F(X, Y, Z) = \partial_Y F(X, Y, Z) = \partial_Z F(X, Y, Z) = 0$ (then also $F(X, Y, Z) = 0$, by Euler's theorem for homogeneous functions). Desingularizing the algebraic curve results in a Riemann surface, i.e., a one-dimensional complex-analytic manifold (so it is two-dimensional over the real numbers; it is a surface). There are various ways of desingularizing algebraic curves. Our methods use Puiseux series, as detailed in Sect. 2.3. Each nonsingular point on the algebraic curve corresponds to one place[1] on the Riemann surface, whereas a singular point on the algebraic curve can correspond to multiple places on the Riemann surface.

In what follows, Γ is used to denote the Riemann surface obtained by desingularizing and compactifying (by adding the places at infinity) the algebraic curve represented by $f(x, y) = 0$. All Riemann surfaces obtained this way are connected (because $f(x, y)$ is irreducible) and compact (because the points at infinity are included). Conversely, as stated in Chap. 1 it is known that every compact connected Riemann surface can be obtained as described above [BBE$^+$94, Spr57]. From here on out, all Riemann surfaces considered are understood to be connected and compact. We use $\hat{\Gamma}$ to denote the compactified, not desingularized algebraic curve.

2.3 Puiseux Series

Many of the algorithms presented in the next sections make use of local coordinates on an algebraic curve. For our algorithms, this local behavior is understood using Puiseux expansions. These expansions allow us to distinguish between regular points, branch points and singular points. Further, in addition to determine the nature of singular points, Puiseux expansions characterize

---

[1] We use the term "point" to denote a value in the complex x-plane. On the other hand, "place" is used to denote a location on the Riemann surface Γ, or, unambiguously, a location on the desingularized plane algebraic curve.

7.3.1 Exceptional configurations

From now on we will study birational maps between algebraic surfaces. We know (see [311], Chapter V, §5) that any birational morphism $\pi : Y \to X$ of nonsingular projective surfaces can be factored into a composition of blow-ups with centers at closed points. Let

$$\pi : Y = Y_N \xrightarrow{\pi_N} Y_{N-1} \xrightarrow{\pi_{N-1}} \dots \xrightarrow{\pi_2} Y_1 \xrightarrow{\pi_1} Y_0 = X \tag{7.28}$$

be such a factorization. Here $\pi_i : Y_i \to Y_{i-1}$ is the blow-up of a point $x_i \in Y_{i-1}$. Set

$$\pi_{ki} := \pi_{i+1} \circ \dots \circ \pi_k : Y_k \to Y_i, \quad k > i.$$

Let

$$E_i = \pi_i^{-1}(x_i), \quad \mathcal{E}_i = \pi_{Ni}^*(E_i). \tag{7.29}$$

$$\rho_{\text{Critical}} = \left(\frac{d_{\text{f}} + d_{\text{s}}}{2\varepsilon_{\text{Critical}}}\right)\left\{\frac{1 + 2\eta + \chi\eta^2}{(1 + \eta)(1 + \chi\eta)}\right\}$$

Accordingly, the strain at the top surface of the film–substrate structure is expressed in the form

$$\varepsilon_{\text{Top}} \text{ for compliant substrate} = \varepsilon_{\text{Top}} \text{ for non-compliant substrate} \times \left(\frac{y'}{y}\right) = \left(\frac{d_{\text{f}} + d_{\text{s}}}{2\rho}\right)\left\{\frac{1 + 2\eta + \chi\eta^2}{(1 + \eta)(1 + \chi\eta)}\right\} \tag{2.48}$$

2.5 Critical strain and critical radius of curvature

The functionality of a flexible electronics component is impaired, i.e. disturbed to an unacceptable degree as compared to its normal operation, when the component is exposed to a certain level of strain referred to as the critical strain ε_{C}. This critical strain is produced when the external bending forces acting on the component can cause mechanical damage resulting in electrical or optical failure (for an optoelectronic component). Hence, critical strain is associated with a critical radius of curvature ρ_{C}, which is defined as the value of radius of curvature at which the component fails mechanically or in its electrical/optical functions. Since maximum strains take place on surfaces, and the common flexible electronic devices are made from different films, metallic, semiconducting or insulating, formed over substrates, the strain at the topmost surface of the device becomes crucial. Within the realms of elasticity and ignoring dissipative processes, e.g. yielding of the substrate, equation (2.48) is re-arranged and expressed in the form

$$\rho_{\text{Critical}} = \left(\frac{d_{\text{f}} + d_{\text{s}}}{2\varepsilon_{\text{Critical}}}\right)\left\{\frac{1 + 2\eta + \chi\eta^2}{(1 + \eta)(1 + \chi\eta)}\right\} \tag{2.49}$$

An inverse proportionality relationship holds between ρ_{Critical} and $\varepsilon_{\text{Critical}}$, i.e.

$$\rho_{\text{Critical}} \propto 1/\varepsilon_{\text{Critical}} \tag{2.50}$$

This relationship depends on the geometry of the multilayer structure as well as its mechanical properties.

For the special case,

$$\frac{Y_{\text{f}}}{Y_{\text{s}}} = \chi \leqslant 10, \quad \frac{d_{\text{f}}}{d_{\text{s}}} = \eta \ll 1 \tag{2.51}$$

Equation (2.49) is simplified to

$$\rho_{\text{Critical}} = \frac{d_{\text{f}} + d_{\text{s}}}{2\varepsilon_{\text{Critical}}} \approx \frac{d_{\text{s}}}{2\varepsilon_{\text{Critical}}} \tag{2.52}$$

or,

$$\varepsilon_{\text{Critical}} = \frac{d_{\text{s}}}{2\rho_{\text{Critical}}} \tag{2.53}$$

Table 2.1. Distinguishing flexible electronics from compliant and stretchable electronics.

Sl. no.	Property	Flexible electronics	Compliant electronics	Stretchable electronics
1.	Critical strain $\varepsilon_{\text{Critical}}$	<2%	$2\% < \varepsilon_{\text{Critical}} < 10\%$	$\varepsilon_{\text{Critical}} > 10\%$
2.	Critical radius of curvature ρ_{Critical}	ρ_{Critical} up to 10 mm	$\rho_{\text{Critical}} \sim$ a few mm	$\rho_{\text{Critical}} <$ a few mm

For a given ρ_{Critical}, the $\varepsilon_{\text{Critical}}$ is low for a thin substrate (small d_s) so that a thin substrate experiences lower peak strain and components mounted on such a substrate can withstand smaller ρ_{Critical} values.

2.6 $\varepsilon_{\text{Critical}}$ and ρ_{Critical} as characteristic parameters defining flexible, compliant and stretchable electronics

Defining the ρ_{Critical} and $\varepsilon_{\text{Critical}}$ terms enables us to differentiate between the three intermingling branches (Leterrier 2015):

(i) Flexible electronics: Here the components can sustain critical strain $\varepsilon_{\text{Critical}} < 2\%$ and can withstand bending up to the radius of curvature $\rho_{\text{Critical}} = 10$ mm. Flexible electronics components are fabricated on thin substrates with thicknesses in the range of 100 μm.

(ii) Compliant electronics: Critical strain sustaining capability is between 2%–10%, i.e. $2\% < \varepsilon_{\text{Critical}} < 10\%$. Critical radius of curvature ρ_{Critical} level is ~ a few mm. Some degree of in-plane loading is permissible. Thicker substrates can be used.

(iii) Stretchable electronics: The components and circuits can endure $\varepsilon_{\text{Critical}} > 10\%$. Critical radius of curvature can be < a few mm. Conformability is possible to a wide variety of two-dimensional surfaces. The aforementioned features are summarized in table 2.1.

2.7 Discussion and conclusions

The key terminology and formulae of mechanical bending form the foundations for visualizing the meaning of flexibility in the context of electronics.

Review exercises

2.1 Do curvature and radius of curvature have the same meaning?
2.2 What is the radius of curvature of a straight flat surface?
2.3 ‘A unit vector is dimensionless.’ Right or wrong?
2.4 Derive the popular equation for radius of curvature of a beam

$$\rho = \frac{(1 + y'^2)^{3/2}}{y''}, \tag{2.54}$$

where $y' = dy/dx$ and $y'' = d^2y/dx^2$.

Preface vii

1. Manifolds 1
   - 1.1 Preliminaries . . . 1
     - 1.1.1 Space and Coordinatization . . . 1
     - 1.1.2 The implicit function theorem . . . 3
   - 1.2 Smooth manifolds . . . 6
     - 1.2.1 Basic definitions . . . 6
     - 1.2.2 Partitions of unity . . . 9
     - 1.2.3 Examples . . . 10
     - 1.2.4 How many manifolds are there? . . . 20

2. Natural Constructions on Manifolds 23
   - 2.1 The tangent bundle . . . 23
     - 2.1.1 Tangent spaces . . . 23
     - 2.1.2 The tangent bundle . . . 27
     - 2.1.3 Transversality . . . 29
     - 2.1.4 Vector bundles . . . 33
     - 2.1.5 Some examples of vector bundles . . . 37
   - 2.2 A linear algebra interlude . . . 41
     - 2.2.1 Tensor products . . . 41
     - 2.2.2 Symmetric and skew-symmetric tensors . . . 46
     - 2.2.3 The “super” slang . . . 53
     - 2.2.4 Duality . . . 56
     - 2.2.5 Some complex linear algebra . . . 64
   - 2.3 Tensor fields . . . 67
     - 2.3.1 Operations with vector bundles . . . 67
     - 2.3.2 Tensor fields . . . 69
     - 2.3.3 Fiber bundles . . . 73

3. Calculus on Manifolds 79

- 3.1 The Lie derivative . . . 79
  - 3.1.1 Flows on manifolds . . . 79
  - 3.1.2 The Lie derivative . . . 81
  - 3.1.3 Examples . . . 86
- 3.2 Derivations of $\Omega^\bullet(M)$ . . . 88
  - 3.2.1 The exterior derivative . . . 88
  - 3.2.2 Examples . . . 93
- 3.3 Connections on vector bundles . . . 94
  - 3.3.1 Covariant derivatives . . . 94
  - 3.3.2 Parallel transport . . . 100
  - 3.3.3 The curvature of a connection . . . 101
  - 3.3.4 Holonomy . . . 105
  - 3.3.5 The Bianchi identities . . . 108
  - 3.3.6 Connections on tangent bundles . . . 109
- 3.4 Integration on manifolds . . . 111
  - 3.4.1 Integration of 1-densities . . . 111
  - 3.4.2 Orientability and integration of differential forms . . . 115
  - 3.4.3 Stokes' formula . . . 123
  - 3.4.4 Representations and characters of compact Lie groups . . . 127

Chapter 3

Properties of meteoroids from forward scatter radio observations

Hervé Lamy

3.1 Radio meteor theory

When a meteoroid enters the Earth's atmosphere with velocities in excess of $\sim$10 km s^{-1}, it impacts the atoms and molecules of the upper atmosphere with a kinetic energy large enough to ionize them. It also heats up to high temperatures and starts to ablate. As a result, a trail of ions and electrons forms along the trajectory path behind the meteoroid.

If a radio wave of a given frequency is sent towards space from a ground-based transmitter, it can be temporarily reflected by the meteor trail towards the ground. The incident radio wave is scattered only by electrons as ions are too heavy. Under some geometrical conditions (see below), it can be recorded by a receiver tuned to the same frequency. The signal recorded at the receiving station is called a meteor trail echo. Its duration is directly related to the lifetime of the meteor trail as the electrons tend to quickly scatter into the neutral ambient atmosphere. A meteor radar corresponds to the case where the transmitter and the receiver are located at the same place. When the transmitter and receiver(s) are not on the same site, we talk about forward scatter observations (see figure 3.1) which is the topic of this chapter.

Meteor echoes are usually classified into two categories called underdense and overdense, according to the value of the line electron density α (expressed in number of electrons per meter). This is based on McKinley's [1] classical radio meteor theory, where it is first assumed that the trail is a stationary straight line of electrons, a hypothesis made because the longitudinal extent of the trail (typically a few kilometers to a few tens of kilometers) is much larger than its radial extent (from a few tens of centimeters to a few meters). Additional factors are then included, such as the initial radius effect, to take into account the finite radial extent of the trail (assumed to be cylindrical), and the ambipolar diffusion to model the scattering of trail electrons into the ambient neutral atmosphere. The typical duration of

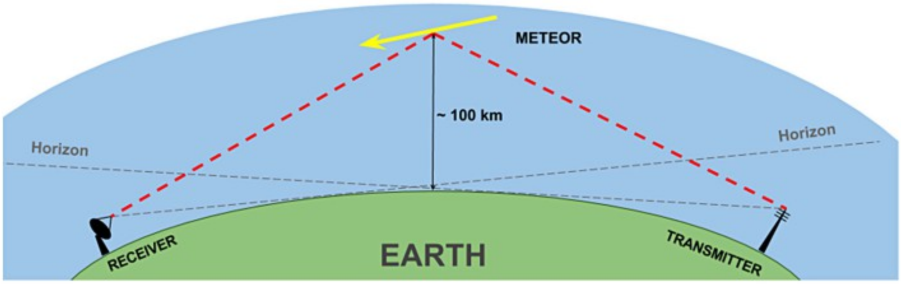

Figure 3.1. Sketch of the general principle of radio forward scatter observations.

underdense meteor echoes is a fraction of a second while overdense meteor echoes can typically last from ∼one second to a few tens of seconds.

Underdense meteor echoes have typical line electron densities $\alpha < 10^{13}\,\mathrm{e-m^{-1}}$ while overdense meteor echoes have $\alpha > 10^{15}\,\mathrm{e-m^{-1}}$. There are of course a lot of meteor echoes with intermediate electron line densities for which the physics is more complex. Some recent developments (e.g. [2]) are trying to model these meteor echoes, but this is beyond the goal of this chapter. From a physics point of view, the radio wave can penetrate underdense meteor trails and is scattered by individual electrons while for overdense meteor trails, the electron density is large enough that the dielectric constant of the medium becomes negative and the trail behaves as a plasma. The classical theory of McKinley [1] models the overdense meteor echoes as if the radio wave was reflected on the surface of an expanding metallic cylinder. As we will see below, this theory for overdense meteor echoes has limited applications as it is too simplistic and does not include additional phenomena.

One fundamental property of underdense meteor echoes is that the reflection of the radio wave is specular, which means that the majority of the received power reflected off the trail occurs when the so-called specular reflection point is created on the meteoroid path. The position of this reflection point is easy to determine as it is the point along the meteoroid path that is tangential to an ellipsoid whose foci are the transmitter and the receiver (see figure 3.2).

This property simply results from adding elemental small contributions from each electron individually along the path. The vast majority of the power actually comes from a small region centered on the specular reflection point and called the first Fresnel zone, whose size depends mostly on the meteor speed and on the wavelength of the radio wave. Contributions from other parts of the meteor trail can add constructively or destructively to this main signal, leading to so-called Fresnel oscillations in the signal.

An important consequence of the specular reflection is that a given system made of a transmitter and one receiver cannot detect all meteors. This is illustrated in figure 3.3. If the reflection point is located too high in the atmosphere (bottom case), the atmosphere is too thin at these altitudes such that the created ionization is not large enough to reflect a detectable amount of power. On the other hand, if the reflection point is located too low in the atmosphere (top case), the meteoroid might be completely ablated before this point is created and therefore no signal at all will be detected at the receiver. In figure 3.3, what is called the ‘meteor zone’ refers to a

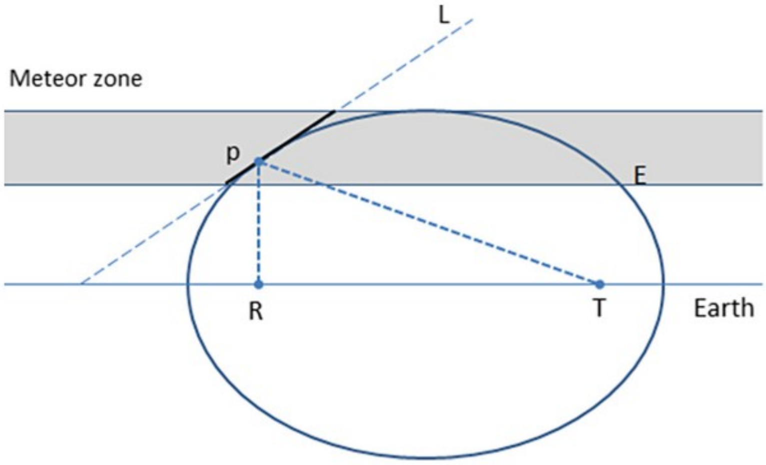

Figure 3.2. Illustration of the specularity condition. The specular reflection point *p* is the point along the meteoroid path *L* that is tangential to the ellipsoid *E* whose foci are the transmitter *T* and receiver *R*.

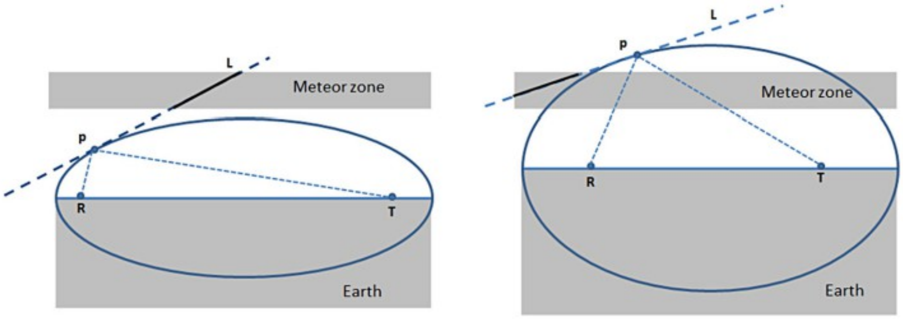

Figure 3.3. Consequences of the specularity condition. For given *L*, *T* and *R*, if the specular point *p* is too low (left) or too high (right), no signal will be recorded at *T*.

region in altitude where most meteor echoes should occur and can roughly be considered as 85–110 km.

The theory of forward scatter of radio waves has been developed by McKinley [1] as an extension of the classical theory for back scatter/radar systems. It provides formulas for the power profile, namely the amount of power in the meteor echo as a function of time.

For underdense meteor echoes, the power at the receiver is given by

$$P_R = \frac{P_T G_T G_R \lambda^3 r_e^2 \alpha^2 \sin^2(\gamma)}{16\pi^2 R_T R_R (R_T + R_R)(1 - \sin^2(\phi)\cos^2(\beta))} \exp\left[-\frac{8\pi^2 r_0^2}{\lambda^2 \sec\phi}\right] \exp\left[-\frac{32\pi^2 D_a t}{\lambda^2 \sec\phi}\right] \{C^2 + S^2\}, \tag{3.1}$$

where P_T is the power sent by the transmitter, G_T and G_R are the antenna gains for the transmitter and receiver in the directions to the reflection point, λ is the wavelength, r_e is the classical radius of the electron, α is the electron line density, γ is the polarization of the radio wave, R_T and R_R are the distances between, respectively, the transmitter/receiver and the specular reflection point, ϕ is half of the scattering angle of the radio wave and β is the inclination of the meteor trail with respect to the propagation plane of the radio wave. The geometrical parameters are illustrated in figure 3.4.

The first term in equation (3.1) is the peak value obtained when the specular reflection point is created and assuming all electrons lie on a straight line. The actual peak value is corrected by the initial radius r_0 that takes into account that trail electrons are not located on a single line but inside a cylinder, which reduces the strength of the signal and leads to the first exponential in equation (3.1). The second exponential depends on time t and is due to the diffusion of trail electrons in the neutral atmosphere. D_a is the ambipolar diffusion coefficient. The final terms in equation (3.1), C and S, are Fresnel integrals:

$$C = \int \cos \frac{\pi x^2}{2} dx \quad S = \sin \frac{\pi x^2}{2} dx, \tag{3.2}$$

where $x = 2s/\sqrt{R_F \lambda}$ is the Fresnel length, s is the distance along the trail measured from the specular reflection point, counted positively in the direction where the meteoroid is moving, and R_F is the size of the first Fresnel zone. This term is at the origin of the Fresnel oscillations which superimposes on the main signal. Indeed, every time a new Fresnel zone is created along the meteoroid path, it creates signals

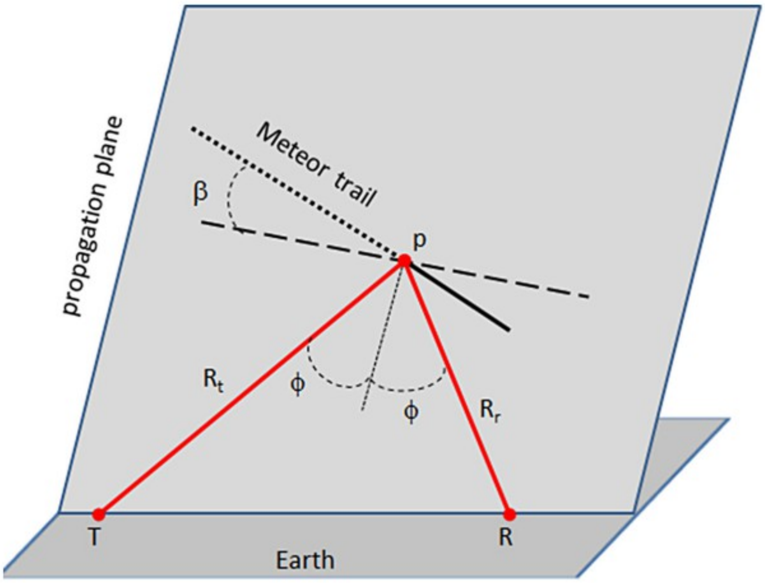

Figure 3.4. Geometrical parameters for forward scattering of radio waves.

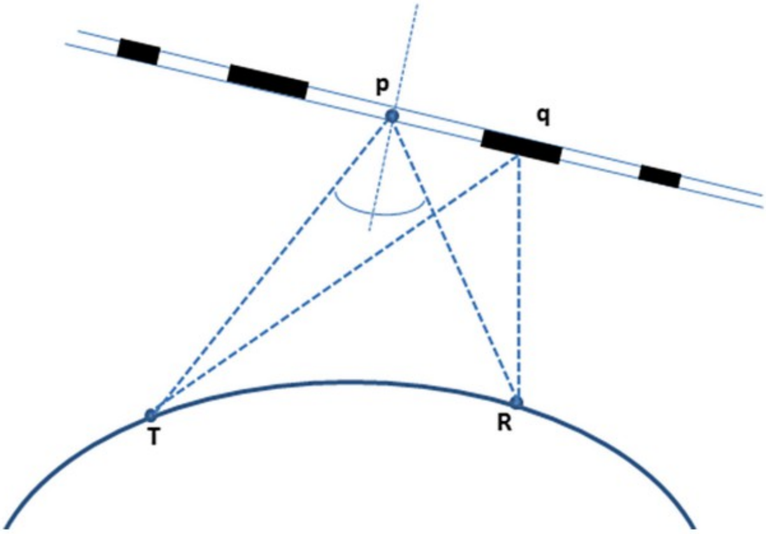

Figure 3.5. Illustration of Fresnel zones. The main Fresnel zone is centered on the specular reflection point *p*. Fresnel zones with constructive interference with the main signal are in white while those leading to destructive interference are in black.

which are alternatively in phase and out of phase with the main signal and leads to an increase/decrease of the total power. An example is given in figure 3.5 where the contribution from point q adds up to the main signal coming from point p in a destructive way, leading to a slight decrease of the power. Along a given meteoroid path and knowing the speed of the object, the positions of the Fresnel zones can be determined. In figure 3.5, the Fresnel zones leading to constructive interference with the main signal are depicted in white and those leading to destructive interference in black.

An example of an underdense meteor echo is shown in figure 3.6.

For overdense meteor echoes, the power at the receiver is given by

$$P_R = \frac{P_T G_T G_R \lambda^2 \cos\phi \sin^2\gamma}{32\pi^2 R_T R_R (R_T + R_R)(1 - \sin^2\phi \cos^2\beta)} r_c, \tag{3.3}$$

where r_c is the critical radius of the 'metallic' cylinder where the dielectric constant becomes negative,

$$r_c = \sqrt{r^2 \ln \frac{\alpha r_e \lambda^2 \sec^2\phi}{\pi^2 r^2}}, \tag{3.4}$$

where r is the radial distance perpendicular to the path. This model is rather poor as it neglects a number of phenomena, e.g. it does not take into account the effect of external parts of the cylinder which become increasingly underdense with time. More important, it neglects the influence of high-altitude mesospheric/thermospheric shear winds which can reach speeds from tens to a few hundreds of meters

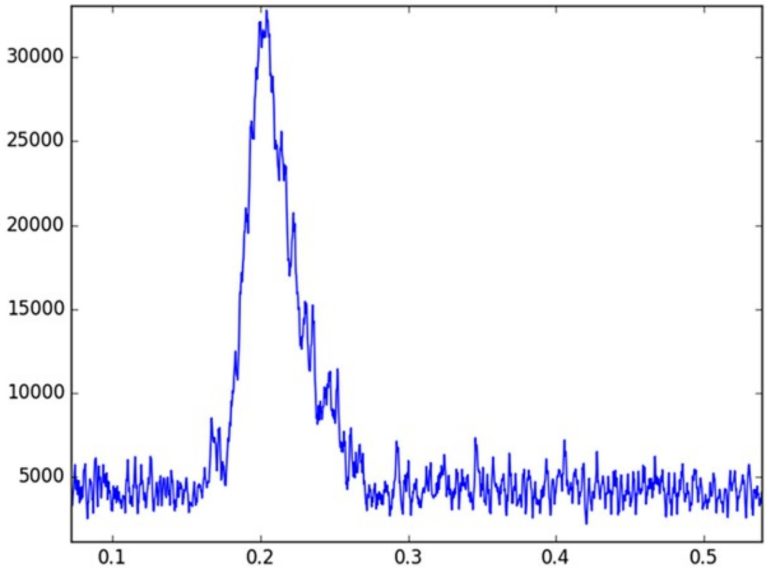

Figure 3.6. Typical underdense meteor echo. The vertical axis is power in arbitrary units while the horizontal axis is time in seconds.

per second. They can break the cylindrical trail into multiple parts and hence create multiple specular reflection points. The multiple reflections can then interfere constructively or destructively and lead to a much more complex power profile than the one modeled by equations (3.3) and (3.4).

An example of an overdense meteor echo is shown in figure 3.7.

Meteor trail echoes form the vast majority of meteor echoes detected by meteor radars such as, e.g., the Canadian Meteor Orbit Radar (CMOR, e.g. [3]) or by the Belgian Radio Meteor Stations (BRAMS) network that will be described in detail in the next section. Another type of meteor echo, mostly observed with larger objects, is the head echo which occurs when the incoming radio wave is reflected upon the ionized region forming in front of the meteoroid. This region moves at the same high speed ($>\sim 10\ \mathrm{km\ s^{-1}}$) as the meteoroid itself while the speed of the meteor trail depends mostly on the speed of high-altitude mesospheric/thermospheric winds. Consequently, the Doppler effects associated with these two types of meteor echoes are very different and allow one to easily discriminate them. Head echoes will not be discussed in detail in this chapter. Only a few examples of observations will be given in the section about optical versus radio observations of meteors.

3.2 The BRAMS project

3.2.1 The BRAMS network

BRAMS is a Belgian radio network using forward scatter techniques to detect and study meteoroids. It uses a dedicated transmitter located at the Geophysical Center in Dourbes in the south of Belgium and 26 identical receiving stations spread all over

(c) Show that if for every t there is some r such that the r-th derivative of β is non-zero, the conclusion still holds, except that the lift may not be immersed.

(d) What can you say in general?

Proposition 3.7.5 (tangent circle bundle has contact structure). *The tangent circle bundle of a smooth surface has a canonical contact structure, which is preserved by the derivative of any diffeomorphism.*

Proof of 3.7.5. We first look at $\mathbf{R}^2 \times S^1$, the tangent circle bundle of $\mathbf{R}^2$. This space is a double cover of the contact manifold $\mathbf{R}^2 \times \mathbf{RP}^1$ that we defined after Example 3.7.3—the fiber of the tangent circle bundle is a circle of unit tangent vectors, rather than a circle of directions. We give $\mathbf{R}^2 \times S^1$ the induced contact structure. Diffeomorphisms of $\mathbf{R}^2$ lift to contact automorphisms of $\mathbf{R}^2 \times S^1$, just as they lift to automorphisms of $\mathbf{R}^2 \times \mathbf{RP}^1$ in Example 3.7.3. Therefore, given an atlas for a surface, the contact structures on the tangent circle bundles of the chart domains patch together to give a contact structure on the tangent circle bundle of the surface. $\boxed{3.7.5}$

Example 3.7.6. As a corollary, T^3, $\mathbf{RP}^3$ and S^3 have contact structures. T^3 is diffeomorphic to the tangent circle bundle of the two-torus. $\mathbf{RP}^3$ is diffeomorphic to SO(3) (Exercise 2.7.7), which in turn can be identified with the tangent circle bundle of S^2 (why?). Therefore $\mathbf{RP}^3$ has a contact structure. Since S^3 is the double cover of SO(3), it also has a contact structure.

In fact, Martinet [Mar71] proved that every orientable compact three-manifold has a contact structure.

You can get a good physical sense for the contact structure on the tangent circle bundle of a surface by thinking about ice skating, or bicycling. A skate that is not scraping sideways describes a Legendrian curve in the tangent circle bundle to the ice. It can turn arbitrarily, but any change of position is in the direction it points. Likewise, as you cycle along, the direction of the bicycle defines a ray tangent to the earth at the point of contact of the rear wheel. Assuming you are not skidding, the rear wheel moves in the direction of this ray, and its motion describes a Legendrian curve in the tangent circle bundle of the earth.

Young children are sometimes given bicycles with training wheels, some distance off to the side of the rear wheel. The training wheel also traces out a Legendrian curve—in fact, for any real number t, the diffeomorphism ϕ_t of $\mathbf{R}^2 \times S^1$ that takes a tangent ray a signed distance t to the left of itself is a contact automorphism. The training wheel path is the image of the rear wheel path under such a transformation. Note that this transformation applied to curves in the plane often creates or removes cusps (Figure 3.25). The same thing happens when you mow a lawn, if you start by making a big circuit around the edge of the lawn and move inward.

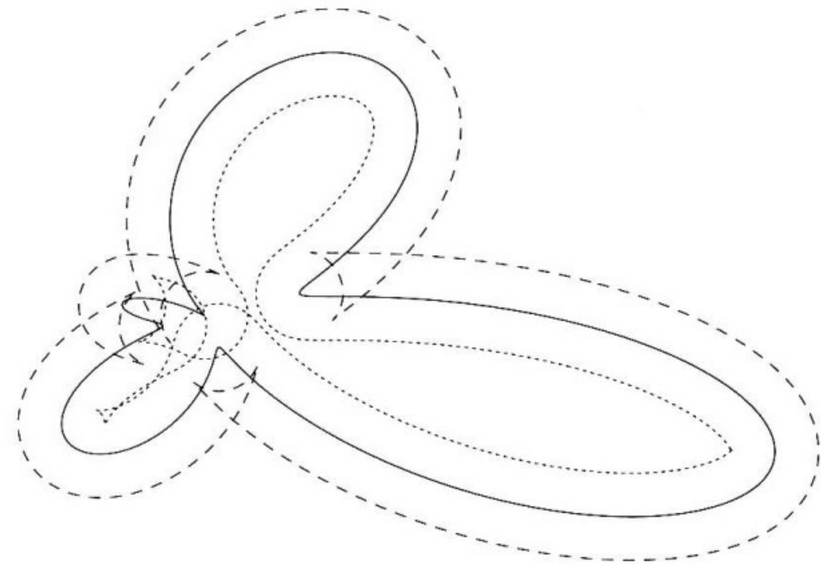

Figure 3.25. A family of parallel curves. The transformation ϕ_t of the tangent circle bundle of the plane which translates a ray a distance t to its left is a contact automorphism. The figure shows the projections to the plane of the images of a single curve, for various values of t. Notice how cusps develop.

The rear wheels of an automobile also follow Legendrian curves, related by a transformation ϕ_t. (The two wheels turn at slightly different speeds, thanks to the differential gear; otherwise one or both would skid whenever the car went around a curve.) Parallel parking implements the fact that any two points are connected by a Legendrian path. The front wheels are more complicated, since the line joining them is not perpendicular to their path unless the car is moving straight. The relation between the front and back wheels of a bicycle or a car is also complicated: the rear wheels depend not just on the current position and direction of the front wheels, but on their history.

The contact automorphism ϕ_t can be defined not only for $\mathbf{R}^2$, but for any oriented surface with a Riemannian metric. It sends each tangent ray to a tangent ray at a point obtained by translating it along the perpendicular geodesic, toward the left. (The surface needs to be oriented so we can decide consistently which way is left.) As t varies, the automorphisms ϕ_t form a flow ϕ. This is closely related to the surface's *geodesic flow*. The geodesic flow of a Riemannian manifold is the flow ψ that moves each unit tangent vector along its geodesic at unit speed. Really ϕ and ψ are the same flow in slightly different guises, identified by the map that rotates each unit tangent vector counterclockwise by 90°.

Exercise 3.7.7. (a) Proposition 3.7.5 gives one canonical plane field for the tangent circle bundle of a smooth surface. If the surface has a Riemannian metric, there is another: the Levi-Civita connection, restricted from the tangent bundle to the tangent sphere bundle. Compare the two, and explain the relation between the Levi-Civita connection and the geodesic flow (or the training-wheel flow) on the surface. See also Corollary 3.7.16.

(b) Describe the contact structures of Example 3.7.6 geometrically.

(c) What is the relationship among the contact structure on S^3, the Hopf flow, and Levi-Civita connection on S^2?

Problem 3.7.8 (Legendrian foliations). In a contact three-manifold, it is easy to construct, at least locally, a one-dimensional Legendrian foliation, that is, a foliation by Legendrian curves: in a small neighborhood, any nonzero section of τ is a vector field whose flow lines give such a foliation.

(a) Show that every Legendrian foliation is locally equivalent to the foliation by lines parallel to the x-axis in our model contact structure in $\mathbf{R}^3$.

(b) Work out an interpretation of contact three-manifolds with Legendrian foliations as three-manifolds locally modeled on the tangent circle bundle of $\mathbf{R}^2$, up to derivatives of diffeomorphisms.

(c) Find and analyze some interesting examples.

Let's return to our model plane field τ in $\mathbf{R}^3$. Let X be any smooth vector field tangent to τ. We claim that unless X is identically zero, the flow it generates cannot consist of contact automorphisms. For consider a short Legendrian arc α transversal to X at a point p. Under the flow, α sweeps out a quadrilateral, three sides of which

I& < 8 E

Show that in a contact three-manifold, most foliations transverse to the contact plane field are *not* locally equivalent to this foliation. (Compare Example 3.7.2 and Problem 3.7.8.)

3.8. The Eight Model Geometries

What is a geometry? Up till now, we have discussed three kinds of three-dimensional geometry: hyperbolic, Euclidean and spherical. They have in common the property of being as uniform as possible: their isometries can move any point to any other (homogeneity), and can take any orthonormal frame in the tangent space at a point to any other orthonormal frame at that point (isotropy). There are more possibilities if we remove the isotropy condition, allowing the space to have a grain, so to speak, so that certain directions are geometrically distinguished from others.

An enumeration of additional three-dimensional geometries depends on what spaces we wish to consider and what structures we use to define and to distinguish the spaces. For instance, do we think of a geometry as a space equipped with such notions as lines and planes, or as a space equipped with a notion of congruence, or as a space equipped with either a metric or a Riemannian metric? There are deficiencies in all of these approaches.

The problem with using lines and planes is that they aren't general enough. The five new geometries described in this section don't have any good notion of a plane—there are no totally geodesic surfaces passing through certain tangent planes. Besides, even in Euclidean geometry, information about geometric shapes is not determined by incidence properties of lines and planes.

Using congruence as the essence of the definition leads to an excessive proliferation of geometries. For instance, we would get different geometries by considering Euclidean space with the group of congruences consisting of translations, or the one consisting of horizontal translations together with vertical screw motions (where the amount of rotation is proportional to the vertical motion), and so on. Sometimes it is interesting to distinguish these different structures, but for the broad picture these variations should all be considered under the category of Euclidean geometry.

Using distance to determine the geometry is likewise unsatisfactory. First, by simply rescaling something like $\mathbf{H}^3$ or S^3, we get different metric spaces. Even if we consider as equivalent all metric spaces that are isometric up to a constant scaling factor, many of the spaces have a whole family of homogeneous metrics (sometimes with varying degrees of homogeneity) which are not equivalent up to scaling. The three-sphere, for instance, has an interesting family of homogeneous metrics obtained from the usual metric by picking a Hopf fibration and contracting or expanding the lengths of the circles, while keeping the metric constant in the orthogonal directions.

The best way to think of a geometry, really, is to keep in mind these different points of view all at the same time. If we regard changes of the group of congruences that do not change the metric and changes of the metric that do not change the group of congruences as inessential changes in the geometry, and if we also consider two geometries the same when the sets of compact manifolds modeled on them are identical, we end up with a reasonable enumeration of geometries.

For logical purposes, we must pick only one definition. We choose to represent a geometry as a space equipped with a group of congruences, that is, a (G, X)-space.

Definition 3.8.1 (model geometry). A *model geometry* (G, X) is a manifold X together with a Lie group G of diffeomorphisms of X, such that:

(a) X is connected and simply connected;
(b) G acts transitively on X, with compact point stabilizers;
(c) G is not contained in any larger group of diffeomorphisms of X with compact stabilizers of points; and
(d) there exists at least one compact manifold modeled on (G, X).

Condition (a) selects one representative from each class of locally equivalent geometries having different fundamental groups, since locally equivalent geometries are models for identical classes of manifolds (Exercise 3.3.1). Condition (b) means that the space possesses a homogeneous Riemannian metric invariant by G (Lemma 3.4.11), and that it is complete (see Proposition 3.4.15 and the paragraph following its proof). Condition (c) says that no Riemannian metric invariant by G is also invariant by any larger group. In particular, it selects at most one geometry for each isometry class of metric spaces. Another reason for condition (c) is that by enlarging the structure group G, we do not decrease the set of manifolds with that structure. Condition (d) is not phrased in an intrinsic way, but it is useful because it eliminates a whole continuous family of three-dimensional geometries that do not serve as models for any compact manifolds.

Theorem 3.8.2 (two-dimensional model geometries). *There are precisely three two-dimensional model geometries: spherical, Euclidean and hyperbolic.*

Proof of 3.8.2. Since G acts transitively on X, it follows that any G-invariant Riemannian metric on X has constant Gaussian curvature. When a metric is multiplied by a constant k, the Gaussian curvature is multiplied by k^2, so we can find a metric whose curvature is either 0, 1 or -1. It is a standard fact from Riemannian geometry that the only simply connected complete Riemannian n-manifolds with constant sectional curvature 0, 1 and -1 are $\mathbf{E}^n$, S^n and $\mathbf{H}^n$ (see [dC92, p. 163] or [GHL90, p. 135], for example). $\boxed{3.8.2}$

For an alternate proof, see Exercise 3.8.11.

Exercise 3.8.3. The similarities of $\mathbf{R}$ form a two-dimensional group $\mathrm{Sim}(1)$, which acts on itself by left multiplication. Why isn't $(\mathrm{Sim}(1), \mathrm{Sim}(1))$ a two-dimensional model geometry? (Hint: see Exercise 2.2.10.)

In enumerating three-dimensional model geometries (G, X), we will first look at the connected component of the identity of G—call it G'. The action of G' is still transitive, and the stabilizers G'_x of points $x \in X$ are connected. This is because the quotients $G'_x/(G'_x)_0$, where $(G'_x)_0$ is the component of the identity of G'_x, form a covering space of X. Since X is simply connected, the covering is trivial.

Therefore G'_x is a connected closed subgroup of $\mathrm{SO}(3)$. Using the fact that a closed subgroup of a Lie group is also a Lie group, and therefore a manifold, it is easy to see that there are only three possibilities: $\mathrm{SO}(3)$, $\mathrm{SO}(2)$ and the trivial group. The stabilizer G_x is a Lie group of the same dimension.

Theorem 3.8.4 (three-dimensional model geometries). *There are eight three-dimensional model geometries (G, X), as follows:*

(a) *If the point stabilizers are three-dimensional, X is S^3, $\mathbf{E}^3$ or $\mathbf{H}^3$.*

(b) *If the point stabilizers are one-dimensional, X fibers over one of the two-dimensional model geometries, in a way that is invariant under G. There is a G-invariant Riemannian metric on X such that the connection orthogonal to the fibers has curvature 0 or 1.*

  (b_1) *If the curvature is zero, X is $S^2 \times \mathbf{E}^1$ or $\mathbf{H}^2 \times \mathbf{E}^1$.*

  (b_2) *If the curvature is 1, we have nilgeometry (which fibers over $\mathbf{E}^2$) or the geometry of $\widetilde{\mathrm{SL}}(2, \mathbf{R})$ (which fibers over $\mathbf{H}^2$).*

(c) *The only geometry with zero-dimensional stabilizers is solvegeometry, which fibers over the line.*

The geometries in (a) we have already discussed extensively, and those in (b_1) are self-explanatory. The remaining ones will be described in more detail in the course of the proof. We start by giving X a G-invariant Riemannian metric (see the discussion after Definition 3.8.1).

Proof of 3.8.4(a). If G' acts with stabilizer SO(3), any tangent two-plane at any point can be taken by G to any tangent two-plane at any other point, so the metric has constant sectional curvature. As in the two-dimensional case, it follows that the geometry is spherical, Euclidean, or hyperbolic.

The full group of isometries G contains G' with index 2, and can be obtained by adding any orientation-reversing isometry. $\boxed{\text{3.8.4(a)}}$

Proof of 3.8.4(b). If G' acts with stabilizer SO(2), there is a nonzero, G'-invariant vector field V on X whose direction at each point gives the axis of rotation of the elements of G' that fix that point. The trajectories of V form a G'-invariant one-dimensional foliation $\mathcal{F}$. Also, the flow of V—call it ϕ_t at time t—commutes with the action of G', so if an element of G' fixes some point on a leaf F of $\mathcal{F}$, it fixes any other point on F: all points on the same leaf have the same stabilizer. This also implies that if an element of G' takes a point $x \in F$ to another point $y \in F$, it commutes with any element of the stabilizer $G'_x = G'_y$.

Now fix a leaf F and a point $x \in F$, and let g_t be an element of g taking $\phi_t(x)$ back to x. Then $g_t \circ \phi_t$ fixes x, and its derivative at x is a linear automorphism of T_xM. The derivative is the identity along the axis of the action of G'_x. It commutes with rotations around this axis, that is, with elements of G'_x. Then it must be itself a rotation around this axis, possibly composed with an expansion or contraction. But an expansion or contraction is ruled out, because the assumption that there is a compact manifold modeled on (G, X) implies that V must preserve volume:

Exercise 3.8.5 (divergence). The *divergence* of a vector field V on a manifold X with a volume form ω is a measure of how much V expands or contracts volume. More precisely, $\operatorname{div} V$ is the Lie derivative $L_V\omega$ (Problem 3.1.16), expressed in units of ω.

Now suppose that X is a manifold on which a Lie group G acts transitively, and that V and ω are a vector field and a volume form on X, both invariant under G. Show that $\operatorname{div} V$ is constant over X.

In the situation of the proof, if there is a compact manifold modeled on (G, X), this manifold inherits the vector field and the volume form from X. The vector field must preserve the total volume, and so must preserves volume at every point. Therefore V has divergence zero. Show that this implies that $g_t \circ \phi_t$ acts as a rotation on T_xM.

We conclude that the derivative of ϕ_t maps T_xM to $T_{\phi_t(x)}M$ isometrically. Since x was arbitrary, the flow of the vector field V is by isometries.

By considering a neighborhood of a point on a leaf and the fact that the leaf is invariant under a subgroup G'_x isomorphic to SO(2), we conclude that the leaf does not accumulate on itself, but is an embedded image of either S^1 or $\mathbf{R}$. In fact, it is easy to see that distinct leaves have disjoint neighborhoods. Therefore the quotient space $X/\mathcal{F}$ is a two-dimensional manifold Y. Since V acts by isometries, Y inherits a Riemannian metric from X (just ignore the component of the metric of X in the direction of the leaves), and a transitive action of G' by isometries. Also, Y is connected and simply connected because X is. By the proof of Theorem 3.8.2, Y must be one of the two-dimensional model geometries: $\mathbf{E}^2$, S^2 or $\mathbf{H}^2$. In addition, X is a principal fiber bundle over Y, with fiber and structure group equal to S^1 or $\mathbf{R}$.

The plane field τ orthogonal to $\mathcal{F}$ is a connection for this bundle. Since the group of isometries of X acts transitively, τ has constant curvature.

(b$_1$) If the curvature is zero, τ defines a foliation. Since Y is simply connected, the bundle is trivial by Proposition 3.6.15. There are three possibilities, depending on Y (an open circle indicates that no new geometry arises from this possibility):

- • If $Y = S^2$, we obtain the model geometry $S^2 \times \mathbf{E}^1$. As a compact manifold modeled on this geometry, we can take $S^2 \times S^1$ (see also Exercise 4.7.1).
- ○ If $Y = \mathbf{E}^2$, then $X = \mathbf{E}^2 \times \mathbf{E}^1 = \mathbf{E}^3$. Thus G' (and hence G) is contained in a bigger group of isometries, and we don't get a new model geometry.
- • If $Y = \mathbf{H}^2$, we obtain the model geometry $\mathbf{H}^2 \times \mathbf{E}^1$. Any compact hyperbolic surface cross a circle is an example.

In each of these two new geometries, the full group of isometries G contains G' with index 4, since we can reverse the orientation of either factor independently.

(b_2) If the curvature of τ is non-zero, τ defines a contact structure. After rescaling our metric in the direction of the fibers and choosing appropriate orientations for the base and the fiber, we can assume that the curvature is 1, expressed in terms of the standard bases for $\bigwedge^2 TY$ and TF. This, together with the condition that X is simply connected, essentially determines the geometry. If Y has non-zero curvature, X can be taken as the tangent circle bundle of Y (or rather, its universal cover) with the Levi-Civita connection (Corollary 3.7.16). The group is made of derivatives of isometries of Y, together with rotations of unit tangent vectors keeping the base point fixed.

- ○ If $Y = S^2$, the tangent circle bundle is SO(3), whose universal cover is S^3 (see Example 3.7.6). For G, we get the group of isometries of S^3 that preserve the Hopf fibration (Exercise 3.7.7(c)). This is not a maximal group acting with compact stabilizers, so it is not a model geometry.
- If $Y = \mathbf{E}^2$, we obtain *nilgeometry*. This can be defined in terms of our model contact structure τ of Section 3.7 (page 168) as the group of contact automorphisms that are lifts of isometries of the xy-plane (see Example 3.7.2). Exercise 3.8.6(e) shows that there exist compact manifolds modeled on this geometry.
- If $Y = \mathbf{H}^2$, the unit tangent bundle is $\mathrm{PSL}(2, \mathbf{R})$, the group of orientation-preserving isometries of $\mathbf{H}^2$ (see Exercise 2.6.6). Passing to the universal cover, we get $X = \widetilde{\mathrm{SL}}(2, \mathbf{R})$. The unit tangent bundle of a compact hyperbolic surface is an example of a three-manifold with this geometry.

For $\widetilde{\mathrm{SL}}(2, \mathbf{R})$ and nilgeometry, the contact structure determines an orientation of the geometry which cannot be reversed. However, the orientation of the base two-dimensional geometry can be reversed simultaneously with the orientation of the fiber, so the index of G' in G is 2. $\boxed{\text{3.8.4(b)}}$

Exercise 3.8.6 (isometries of nilgeometry). Let G be the group of isometries of nilgeometry.

(a) Compute the difference in elevation between the endpoints of a Legendrian curve for τ whose projection to the xy-plane $\mathbf{E}^2$ is a line segment with endpoints (x_0, y_0) and (x_1, y_1). (Answer: $\frac{1}{2}(x_1 + x_0)(y_1 - y_0)$.)

(b) Using this and the construction in Example 3.7.2, write down the formula for the elements of G that project to a given isometry of $\mathbf{E}^2$. (Remember that all such isometries differ by a vertical translation.)

(c) As a special case, an isometry that projects to a translation of $\mathbf{E}^2$ is of the form

$$(x, y, z) \mapsto (x + x_0, y + y_0, z + x_0 y + z_0),$$

where x_0, y_0, z_0 can be arbitrary real numbers. Show that the group H of such isometries is isomorphic to the *Heisenberg group* of real upper triangular 3×3 matrices with ones on the diagonal. (Hint: the action of H on $\mathbf{R}^3$ is free and transitive, so it makes $\mathbf{R}^3$ into a group isomorphic to H, with multiplication

$$(x_0, y_0, z_0)(x, y, z) \mapsto (x + x_0, y + y_0, z + x_0 y + z_0).$$

Now compare with the multiplication of two Heisenberg matrices.)

(d) If $h_a, h_b \in H$ project to translations by vectors a and b, the commutator $[h_a, h_b]$ is a vertical translation by a distance equal to the signed area of the parallelogram with sides a and b. Conclude that vertical translations form the center of H, of the identity component $G' \subset G$, and of G.

(e) Let h_a and h_b be as above, an assume that the translations a and b are linearly independent. Show that h_a and h_b generate a discrete cocompact subgroup. In particular, if a and b are the unit coordinate vectors, we get the group of upper triangular 3×3 matrices with integer coefficients, also called the *integer Heisenberg group* (Figure 3.26).

The Heisenberg group is †nilpotent—in fact, it is the only three-dimensional nilpotent but non-abelian connected and simply connected Lie group. This explains the term "nilgeometry" (see also Theorem 4.7.12).

Exercise 3.8.7 (geodesics in nilgeometry). Show that the Legendrian curves in Exercise 3.8.6(a) are geodesics of nilgeometry. Apart from these curves and vertical lines, what other geodesics are there?

It is easier to work with the radially symmetric model based on the contact structure σ.

Proof of 3.8.4(c). If G' acts with trivial stabilizers, it can be identified with its single orbit $X = G'/G'_x$, so X is itself a Lie group. Our task, then, is to investigate connected and simply connected three-dimensional Lie groups, asking which ones admit a discrete cocompact subgroup and are not subsumed by one of the preceding seven geometries.

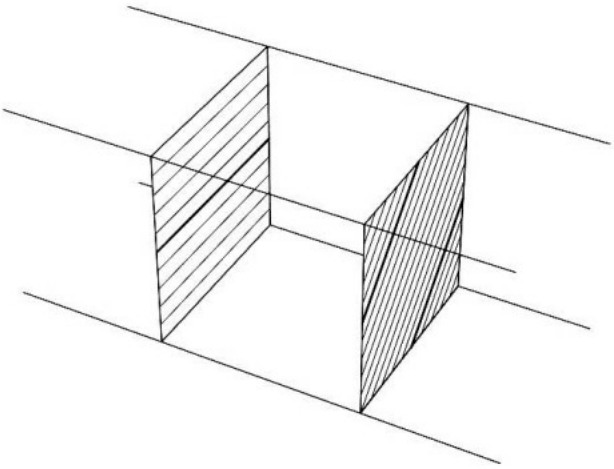

Figure 3.26. The quotient of $\mathbf{R}^3$ by the Heisenberg group. The quotient of $\mathbf{R}^3$ by H is also the quotient of $\mathbf{R} \times T^2$ by the cyclic group generated by the map $(x, y, z) \mapsto (x+1, y, z+y)$. The figure shows $\mathbf{R} \times T^2$ (opposite walls of the cylinder should be thought of as being identified); the shaded squares represent the toruses at $x = 0$ and $x = 1$. We get $\mathbf{R}^3/H$ by taking the region between the two toruses and identifying the toruses so the shadings match.

Two connected Lie groups have isomorphic Lie algebras if and only if they have isomorphic universal covers, so we start by looking at three-dimensional Lie algebras. We will think of a Lie group's Lie algebra sometimes as the tangent space at the identity, and sometimes as the set of left-invariant vector fields on the group.

Suppose G is a Lie group, and Y is a left-invariant vector field on G. Up to a factor, there is a unique volume form ω on G that is invariant under left multiplication. The flow of Y is given by *right* multiplication by a one-parameter subgroup of G, and does not, in general, preserve ω. As in the proof of 3.8.4(b), however, the assumption that there is a compact manifold modeled on (G, X) implies that Y must preserve volume (see Exercise 3.8.5).

Exercise 3.8.8 (adjoint representation). If G is a Lie group with Lie algebra $\mathfrak{g}$, the action of an element $g \in G$ by conjugation is a diffeomorphism of G fixing the identity, and therefore its derivative at the identity is a linear automorphism of $\mathfrak{g}$, which we denote by $\operatorname{ad} g$. The homomorphism $\operatorname{ad} : G \to \mathrm{GL}(\mathfrak{g})$ is called the *adjoint representation* of G. Since ad itself is a smooth map, we can consider its derivative at the identity, also called the *adjoint representation* of the Lie algebra $\mathfrak{g}$, and denoted by $\mathrm{ad} : G \to \mathrm{GL}(\mathfrak{g})$.

(a) Show that $(\mathrm{ad}\, v)(w) = [v, w]$ for elements $v, w \in \mathfrak{g}$.

(b) Show that the divergence (with respect to the invariant volume form on G) of the left-invariant vector field corresponding to v is constant over G, and equal to the trace of the linear map $\mathrm{ad}\, v : \mathfrak{g} \to \mathfrak{g}$. (Hint: the derivative at the identity of the determinant map $\det : \mathrm{GL}(V) \to \mathbf{R}$, for V a vector space, is the trace map.)

A Lie group where every left-invariant vector field preserves volume is called *unimodular*. From now on we assume that G is unimodular, so that $\operatorname{tr} \mathrm{ad}\, V = 0$ for all V in the Lie algebra $\mathfrak{g}$ of G.

Being skew-symmetric, the product (Lie bracket) on $\mathfrak{g}$ can be thought of as a map $\wedge^2\mathfrak{g} \to \mathfrak{g}$. For G three-dimensional, if we fix a positive definite quadratic form (dot product) and an orientation for $\mathfrak{g}$, we get an identification between $\wedge^2\mathfrak{g}$ and $\mathfrak{g}$, sending $V \wedge W$ to the cross product $V \times W$. Then the Lie bracket can be seen as a linear map $L : \mathfrak{g} \to \mathfrak{g}$, which turns out to be symmetric with respect to the quadratic form: $L(V) \cdot W = V \cdot L(W)$ for all $V, W \in \mathfrak{g}$.

To see this, fix an orthonormal, positively oriented basis for $\mathfrak{g}$, say $\{e_1, e_2, e_3\}$, and let l_{ij} be the entries of the matrix of L with respect to that basis. The unimodularity condition $\operatorname{tr} \mathrm{ad}\, V = 0$, applied to $V = e_1$, becomes $\sum_{i=1,2,3} [e_1, e_i] \cdot e_i = 0$, or

$$L(e_3) \cdot e_2 - L(e_2) \cdot e_3 = l_{23} - l_{32} = 0.$$

Repeating for the other basis vectors, we see that unimodularity is equivalent to the symmetry of L.

Every symmetric linear transformation has an orthonormal basis of eigenvectors. Changing $\{e_1, e_2, e_3\}$ to such a basis, the matrix of L becomes diagonal, with entries $c_i = l_{ii}$. In other words,

$$[e_i, e_{i+1}] = c_{i+2}e_{i+2},$$

where the subscripts are taken modulo 3. If we change the quadratic form so as to make the basis $\{a_1e_1, a_2e_2, a_3e_3\}$ orthonormal, where $a_1, a_2, a_3 > 0$, each c_i gets replaced by $c_i\,(a_{i+1}a_{i+2}/a_i)$. Therefore we can arrange for all the c_i's to be equal to ± 1 or 0. To normalize further, we can permute the basis elements, but if it is an odd permutation we must also change the orientation of the vector space, so the net effect is that the c_i's are permuted and change signs. To undo the sign changes, we can replace the basis elements by their negatives. Therefore, using these operations, we can arrange to have $c_1 \geq c_2 \geq c_3$, and to have at least as many positive c_i's as negative ones. Up to isomorphism, then, there are six possibilities for $\mathfrak{g}$, and therefore for the Lie group G. Only one gives rise to a new geometry:

- ○ $c_1 = c_2 = c_3 = 1$ gives $G = S^3$.
- ○ $c_1 = c_2 = 1$ and $c_3 = -1$ gives $G = \widetilde{\mathrm{SL}}(2, \mathbf{R})$.
- • $c_1 = c_2 = 1$ and $c_3 = 0$ gives rise to *solvegeometry*. The generators e_1 and e_2 commute, so the Lie group G contains a copy of $\mathbf{R}^2$. This is a normal subgroup, with quotient group $\mathbf{R}$. The Lie group is therefore a semidirect product of $\mathbf{R}^2$ with R, and determined by the action of the one-parameter group generated by e_3 on $\mathbf{R}^2$. The derivative of this action at the identity is $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$. By rotating e_1 and e_2 by 45° we can make the action of e_3 diagonal, with derivative at $t = 0$ equal to $\left(\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right)$, so the actual transformations in this basis are given by

  $$t \to \begin{pmatrix} e^t & 0 \\ 0 & e^{-t} \end{pmatrix}.$$

  Thus G is an extension $0 \to \mathbf{R}^2 \to G \to \mathbf{R} \to 1$, consisting of maps of the form

  $$(x, y, t) \to (e^{t_0}x + x_0, e^{-t_0}y + y_0, t + t_0),$$

  for arbitrary real x_0, y_0 and t_0.
- ○ $c_1 = 1$ and $c_2 = c_3 = 0$ gives the Heisenberg group.
- ○ $c_1 = c_2 = c_3 = 0$ gives $G = \mathbf{R}^3$.
- ○ $c_1 = 1$, $c_2 = 0$ and $c_3 = -1$ gives the universal cover of the group of isometries of $\mathbf{E}^2$, where e_1 and e_3 act as translations in the x and y directions, while e_2 rotates about the origin.

Example 3.8.9 gives an example of a compact three-manifold modeled on solvegeometry, so this is actually a model geometry.

We still have to compute the full group G of isometries of solvegeometry. There are independent reflections in the two eigenspaces in the $\mathbf{R}^2$ direction. One can also reflect in the $\mathbf{R}$ direction while at the same time interchanging the two eigenspaces. Thus, the index of G' in G is 8. $\boxed{\text{3.8.4(c)}}$

Example 3.8.9 (solvegeometry manifold). Examples of three-manifolds modeled on solvegeometry can be obtained by forming the mapping torus M_ϕ for a diffeomorphism ϕ of the torus to itself. For example, let $\phi : T^2 \to T^2$ come from the linear automorphism of $\mathbf{R}^2$ with matrix $\left(\begin{smallmatrix} 2 & 1 \\ 1 & 1 \end{smallmatrix}\right)$. Arrange the universal cover of the torus in $\mathbf{R}^2$ so that the two orthogonal eigenspaces of ϕ line up with the x- and y-axes. Since the eigenvalues of ϕ are reciprocal to each other, there is some t_0 such that the transformation

$$\psi : (x, y, t) \mapsto (e^{t_0}x, e^{-t_0}y, t + t_0)$$

of $\mathbf{R}^3$ induces the given automorphism ϕ between $\mathbf{R}^2 \times \{0\}$ and $\mathbf{R}^2 \times \{t_0\}$. Therefore M_ϕ is a solve-manifold: it is the quotient of $\mathbf{R}^3$ by the discrete group of automorphisms of solvegeometry generated by ψ together with unit translations along the x- and y-axes.

Exercise 3.8.10 (mapping tori of the torus). Generalize the example above to the case when ϕ comes from an arbitrary linear automorphism of $\mathbf{R}^2$ that preserves the lattice $\mathbf{Z}^2 \subset \mathbf{R}^2$. If λ_1 and λ_2 are the roots of the characteristic polynomial of ϕ, show that:

(a) If λ_1 and λ_2 are not real, they are roots of unity, and ϕ has finite order. T^2 has a Euclidean structure for which ϕ is an isometry, and M_ϕ has a Euclidean structure.

(b) If λ_1 and λ_2 are real and distinct, ϕ has two eigenspaces. The torus has a Euclidean metric for which these eigenspaces are orthogonal, and M_ϕ has a solvegeometry structure. Find two linear maps that have the same characteristic polynomials with real distinct roots, but give rise to mapping tori that are not homeomorphic.

(c) In the remaining case, $\lambda_1 = \lambda_2 = \pm 1$, either we have $\phi^2 = 1$ and M_ϕ has a Euclidean structure, or ϕ is conjugate to a map with matrix $\pm\left(\begin{smallmatrix} 1 & n \\ 0 & 1 \end{smallmatrix}\right)$, for $n \neq 0$, and M_ϕ has a nilgeometry structure.

In general, show that M_ϕ is a cocompact discrete subgroup of a three-dimensional Lie group. How does this statement generalize for linear maps of the n-torus?

It is a curious fact that each of the eight three-dimensional model geometries is isometric to a three-dimensional Lie group with a left-invariant metric. All the Lie groups except for $\mathbf{H}^3$ are unimodular. The Lie group for $\mathbf{H}^3$ is the group of homotheties of the plane, which acts simply transitively as a group of isometries of upper half space. In every case but $\mathbf{H}^3$, the group of automorphisms of the geometry is the semidirect product of the simply connected Lie group with its group of isometric automorphisms.

Exercise 3.8.11 (two-dimensional geometries from groups). Derive the classification of two-dimensional model geometries from the classification of three-dimensional unimodular Lie algebras, but without using Riemannian geometry.

3.9. Piecewise Linear Manifolds

Example 3.2.11 suggests that triangulated spaces, even when they are manifolds, can be difficult to deal with. If we want manifolds of somewhat better quality, we must impose some additional structure, such as differentiability (Example 3.1.3). In the context of gluings it is natural to consider *piecewise linear* structures, which we introduce now.

A map from a subset of an affine space into another affine space is called *piecewise linear* if it is the restriction of a simplicial map defined on the polyhedron of some simplicial complex. A *piecewise linear manifold* is a manifold based on PL, the pseudogroup generated by piecewise linear homeomorphisms between open subsets of $\mathbf{R}^n$.

Problem 3.9.1. (a) The reason a piecewise linear map is defined in terms of the restriction of a simplicial map is that this definition is clearly satisfied for simple maps, such as the identity. Show that, given a piecewise linear map on an open set, the domain itself can be triangulated so that the map is simplicial.

(b) Show that piecewise linear homeomorphisms between open subsets of $\mathbf{R}^n$ form a pseudogroup. In particular, the "generated by" in the definition of PL is superfluous.

The notion of a piecewise linear map can be immediately extended to maps from a subset of an affine space to a piecewise linear manifold, by looking at the expression of the map in charts.

Convention 3.9.2. When we talk of a triangulation of a piecewise linear manifold X, we will normally have in mind a *piecewise linear triangulation*, that is, one where the homeomorphism $|\Sigma| \to X$ is a piecewise linear map.

Problem 3.9.3 (triangulating piecewise linear manifolds). (a) Show that any piecewise linear manifold has a triangulation. (Hint: start from a finite atlas—see Convention 3.1.4. See also the proof of Theorem 3.10.2.)

Length and Plane Area

21.1 The Definition of Arc Length

Given an arc $\widehat{AB}$ of a circle C:

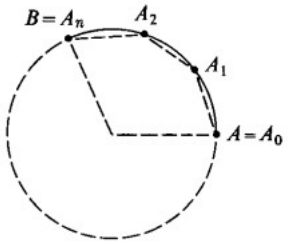

Figure 21.1

We take a sequence of points

$$A = A_0, A_1, A_2, \ldots, A_n = B\,,$$

in the order from A to B on the arc; and for each pair of successive points A_{i-1}, A_i we draw the segment $\overline{A_{i-1}A_i}$, as indicated in the figure. The union of these segments is called an *inscribed broken line;* and the sum of their lengths is denoted by p_n. Thus

$$\begin{aligned} p_n &= A_0A_1 + A_1A_2 + \cdots + A_{n-1}A_n \\ &= \sum_{i=1}^{n} A_{i-1}A_i\,. \end{aligned}$$

There are now various ways that we might define the length of the arc $\widehat{AB}$. If we merely want to *state* a definition, as a matter of form, without intending to use it, then our problem is simple. We agree to use equally spaced points $A_0, A_1, \ldots, A_n$. Then length p_n of our broken line is now determined by n, and we can define the length to be

$$p = \lim_{n\to\infty} p_n .$$

To justify this, we would need to explain what is meant by $\lim_{n\to\infty}$, and we would have to show that the indicated limit exists, for every circular arc.

The following definition, however, is more manageable. Let P be the set of all numbers p_n which are lengths of broken lines inscribed in $\widehat{AB}$. Thus

$$P = \left\{ p_n \,\middle|\, p_n = \sum A_{i-1}A_i \right\}.$$

Let

$$p = \sup P .$$

To justify this, we need to prove the following theorem.

■ *THEOREM 1.* P has an upper bound.

It will then follow that P has a *least* upper bound sup P. The proof is easy, on the basis of the following preliminary result. Let $\triangle PQR$ be an isosceles triangle, with $PQ = PR$.

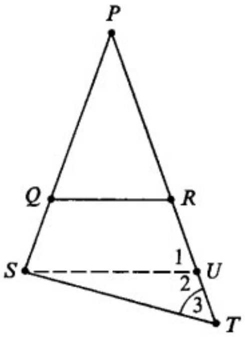

Figure 21.2

We assert that if P-Q-S and P-R-T, then

$$ST > QR .$$

Suppose (without loss of generality) that $PS < PT$, as in the figure, and take U between R and T so that $\overline{SU} \parallel \overline{QR}$. Then

$$\frac{SU}{QR} = \frac{PS}{PQ} > 1 .$$

Therefore

$$SU > QR.$$

We shall now show that $ST > SU$. Evidently $\angle 1$ is acute, because $\angle 1$ is a base angle of an isosceles triangle. Therefore $\angle 2$ is obtuse. Therefore $\angle 3$ is acute. Therefore $m\angle 3 < m\angle 2$. Therefore $ST > SU$. (Why?)
